Various vasoactive medications can decrease blood flow to the gastroesophageal varices and help to control hemorrhage. Although vasopressin is the most potent available splanchnic vasoconstrictor, its clinical utility is limited by systemic vasoconstrictive properties that can produce hypertension, myocardial ischemia and subsequent cardiac failure, arrhythmias, ischemic abdominal pain, and limb gangrene. Consequently, vasopressin should always be used in conjunction with the venodilator nitroglycerin to reverse the systemic hemodynamic effects of the former medication without compromising the reduction in portal pressure.

Octreotide, a somatostatin analog with a longer half-life than its native counterpart, is a splanchnic vasoconstrictor and inhibitor of glucagon and other vasodilatory peptides. Octreotide is the only somatostatin analog available in the United States and often is used as an adjunct to endoscopic therapy in the control of acute variceal bleeding. The current regimen at the authors' center combines continuous infusions of octreotide with pantoprazole to suppress gastric acid secretion.

ENDOSCOPIC DIAGNOSIS AND THERAPY

Emergent esophagogastroduodenoscopy (EGD) plays a critical role in the diagnosis and therapy for suspected acute variceal hemorrhage. EGD is used to identify the presence of varices and to exclude other sources of bleeding, such as portal hypertensive gastropathy, gastritis, or ulcers. Endoscopic interventions in the form of sclerotherapy or variceal band ligation are effective in controlling hemorrhage in nearly 90% of patients.

In endoscopic sclerotherapy, a small amount of sclerosant is injected into the varix or adjacent tissues, causing thrombosis and obliteration of the varix. Complications associated with sclerotherapy occur in 10% to 40% of cases and include adverse pulmonary and renal effects, esophageal ulceration, stricture, and perforation.

Variceal band ligation is a newer therapeutic modality that involves suctioning the varix into a plastic sheath attached to the tip of the endoscope and then deploying a tight band around the varix to interrupt its blood supply. Endoscopic variceal band ligation is at least as effective as sclerotherapy in controlling bleeding, but it has a lower complication rate and therefore has largely replaced sclerotherapy as the preferred mode of endoscopic management.

TABLE 1: Causes of portal hypertension by location

Location	Etiologies
Prehepatic	Portal vein thrombosis Splenic vein thrombosis Congenital thrombosis of portal vein Arteriovenous fistula, resulting in excessive inflow
Intrahepatic	Presinusoidal Primary biliary cirrhosis Sinusoidal Cirrhosis Infiltrative liver diseases Idiopathic portal hypertension Congenital hepatic fibrosis Nodular regenerative hyperplasia Polycystic liver disease Postsinusoidal Venoocclusive disease
Posthepatic	Budd-Chiari syndrome Inferior vena cava webs or thrombosis Congestive heart failure Constrictive pericarditis Tricuspid valve diseases

TABLE 2: Common sites of varices

Portal inflow	Systemic outflow	Collaterals
Left gastric vein, short gastric veins	Intercostal, diaphragmatic, and esophageal veins	Gastroesophageal varices
Superior hemorrhoidal vein	Middle and inferior hemorrhoidal veins	Hemorrhoids
Left portal vein via falciform ligament	Umbilicus and abdominal wall veins	Caput medusa
Liver via lienorenal ligament	Left renal vein	Retroperitoneal collaterals

LUMINAL TAMPONADE

When medical and endoscopic measures fail to control variceal hemorrhage, the use of luminal tamponade with Sengstaken-Blakemore or Minnesota tubes can be a life-saving maneuver. Both of these devices have a large round gastric balloon, which compresses the gastroesophageal junction and reduces blood flow to the esophageal varices when the tube is placed on traction, and a distal port to evacuate luminal contents of the stomach. If the use of traction alone is insufficient to control the hemorrhage, the more proximal esophageal balloon is inflated to provide direct tamponade to the varices. Minnesota tubes are more modern devices that also contain an opening proximal to the esophageal balloon to remove swallowed saliva, obviating the need for the placement of a second tube for this purpose.

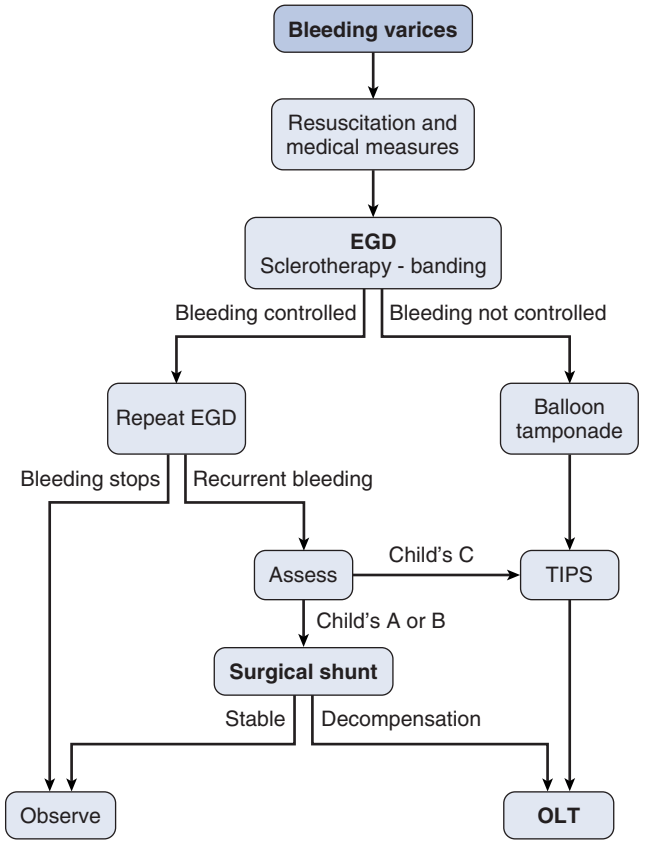

FIGURE 1 Management of acutely bleeding gastroesophageal varices. *EGD,* Esophagogastroduodenoscopy; *OLT,* orthotopic liver transplantation; *TIPS,* transjugular intrahepatic portosystemic shunt.

Aspiration pneumonia is the most common complication of luminal tamponade. Elective endotracheal intubation is often recommended to prevent aspiration, particularly in patients with encephalopathy. Other serious complications, such as airway obstruction or esophageal necrosis may occur, and therefore, the placement and maintenance of these tubes require experience and adherence to a strict protocol.

When properly applied, luminal tamponade can control bleeding in up to 90% of cases, but rebleeding occurs in 50% when the balloons are deflated. Moreover, the duration of balloon tamponade should not exceed 36 hours to avoid tissue necrosis. For these reasons, this treatment modality should only be considered a temporary bridge to more definitive measures of variceal hemorrhage control.

RADIOLOGIC INTERVENTIONS

Transjugular Intrahepatic Portacaval Shunt

Transjugular intrahepatic portacaval shunt (TIPS) is an interventional radiologic procedure by which a tract is created between the hepatic vein and portal vein and kept open with deployment of an expandable metallic stent covered with polytetrafluoroethylene (PTFE). This procedure creates a portacaval shunt within the liver, thereby reducing portal pressure. TIPS is an important modality for treatment of the complications of portal hypertension, such as variceal bleeding, portal gastropathy, ascites, or hepatic hydrothorax. The procedure has been shown to be highly successful in producing initial hemostasis in patients with acute variceal hemorrhage.

The most frequent complication after TIPS placement is worsening encephalopathy, which occurs in up to 30% of patients. A high rate of thrombosis also is seen and is attributed to intimal hyperplasia

along the intrahepatic course of the metallic stent. Stenosis or occlusion occurs in the majority of cases by 1 year after TIPS placement, with recurrent variceal hemorrhage in 18% to 32% of patients. Repeated interventions such as dilation or restenting are often needed to maintain TIPS patency.

Balloon-Occluded Retrograde Transvenous Obliteration

The balloon-occluded retrograde transvenous obliteration (BRTO) procedure, used commonly in Asia since the 1980s, is now gaining popularity in the United States for the specific management of bleeding gastric varices in patients with spontaneous gastrorenal, splenorenal, or gastrocaval shunts shown on contrast-enhanced cross-sectional imaging. With a transjugular or transfemoral approach, a balloon-occlusion catheter is directed through the left renal vein into the spontaneous shunt; a sclerosing agent is then infused to obliterate the gastric varices. BRTO effectively controls gastric variceal hemorrhage and has the added advantage of preserving portal flow to the liver, thus reducing the risk of hepatic encephalopathy relative to TIPS. The occlusion of spontaneous gastrorenal shunts, however, can further exacerbate portal hypertension, precipitate hemorrhage from esophageal varices, and aggravate ascites. Nevertheless, BRTO can be a useful adjunct to TIPS in the management of gastric variceal bleeding, particularly for patients with poor hepatic reserve or a history of hepatic encephalopathy.

REBLEEDING PROPHYLAXIS

After the initial episode of variceal hemorrhage, untreated patients are at significant risk for rebleeding. The median rebleeding risk is approximately 70% within 2 years of the index hemorrhage, with an associated mortality rate of 33%. Secondary prophylaxis should therefore begin once the acute bleeding is controlled. Pharmacologic prophylaxis includes the use of nonselective beta blockers such as nadolol and propranolol, which reduce the risk of rebleeding by 40% and improve overall survival rate by 20%. The addition of endoscopic variceal band ligation to pharmacologic therapy further reduces the rebleeding risk. In patients with refractory variceal hemorrhage despite maximal pharmacologic and endoscopic prevention, TIPS or surgical shunting is warranted.

SURGICAL SHUNTS

Although surgical shunts are still considered in patients with recurrent variceal bleeding and preserved liver function, their use is much less common with the advent of endoscopic therapy, TIPS, and liver transplantation over the past several decades. Surgical shunts are categorized as total, partial, and selective. All provide decompression of gastroesophageal varices but differ in the maintenance of portal flow to the liver. The choice of surgical shunt should depend on the surgeon's familiarity with the procedure and the patient's native portal venous anatomy.

Total Portosystemic Shunts

These are large-caliber connections between the portal and systemic circulations with an end-to-side or side-to-side portacaval shunt, or alternatively with a mesocaval shunt with an interposition graft (Figure 2). Total portosystemic shunts effectively prevent variceal bleeding and control ascites, with additional advantages of ease of construction and durability. However, these shunts allow portal

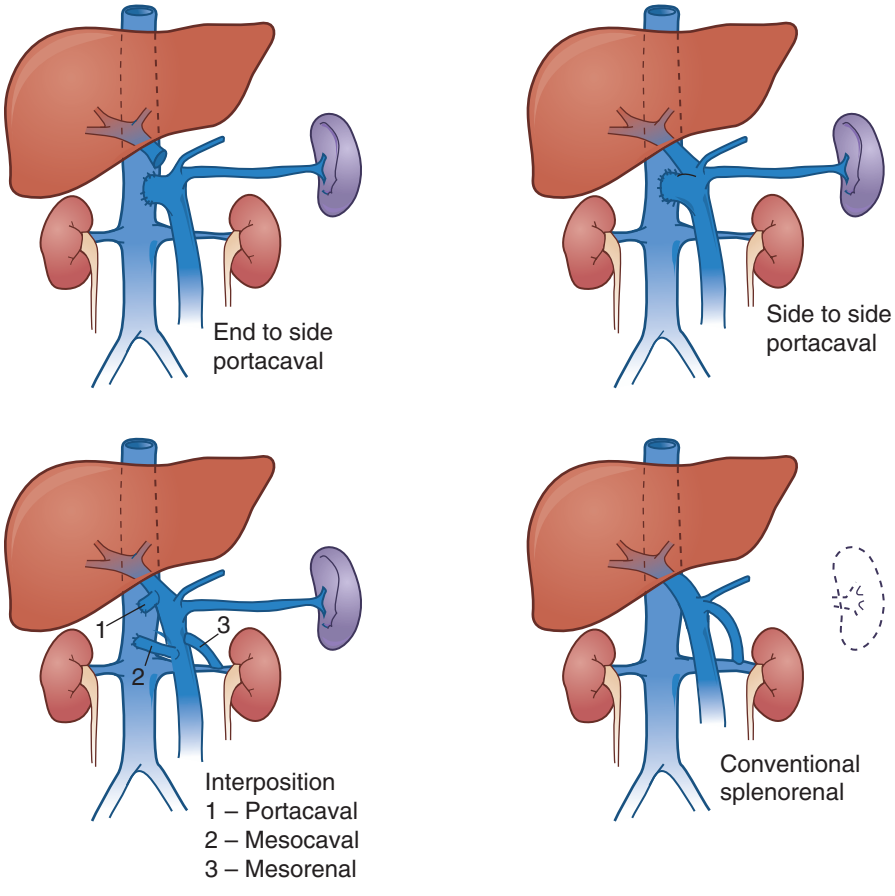

FIGURE 2 Total portosystemic shunts completely divert portal blood flow away from the liver. Various types of portosystemic shunts are illustrated, including the end-to-side or side-to-side portacaval shunts, interposition grafts, and the proximal splenorenal shunt. *(From Rikkers LF: Portal hypertension. In Moody FG, editor:* Surgical treatment of digestive disease, *Chicago, 1986, Year Book Medical, pp 409–424.)*

blood to bypass the metabolic actions of the liver, predisposing to development of hepatic encephalopathy and acute liver failure.

Portacaval shunting is discouraged in potential liver transplant candidates because scarring from previous dissection in the porta hepatis and the need for shunt dismantling significantly increases the technical complexity of the transplant operation. Portacaval shunts also have been associated with the development of a sclerotic portal vein, which is difficult to use for vascular anastomosis at the time of transplantation.

For these reasons, the mesocaval shunt has been advocated as a bridge to liver transplantation because it avoids dissection in the porta hepatis and is easily ligated during the transplant operation. The operative technique involves isolating the superior mesenteric vein at the root of the mesocolon; mobilizing the inferior vena cava below the third portion of the duodenum, which is reflected superiorly; and placing an interposition PTFE graft between these two vessels.

Partial Portosystemic Shunts

Partial, or small-diameter, portosystemic shunts have been advocated in place of total shunts to avoid the deleterious effects of portal blood flow deprivation on hepatic function. The operative strategy for a partial portosystemic shunt is similar to that for a complete shunt, with the exception that the shunt diameter is limited to 10 mm or less. In most instances, an 8-mm PTFE graft is placed between the inferior vena cava and the portal vein for portacaval shunts (Figure 3) or between the superior mesenteric vein and the inferior vena cava for mesocaval shunts. In comparison with complete portosystemic shunts, partial shunts have been reported to reduce the rate of encephalopathy, with maintenance of excellent long-term patency.

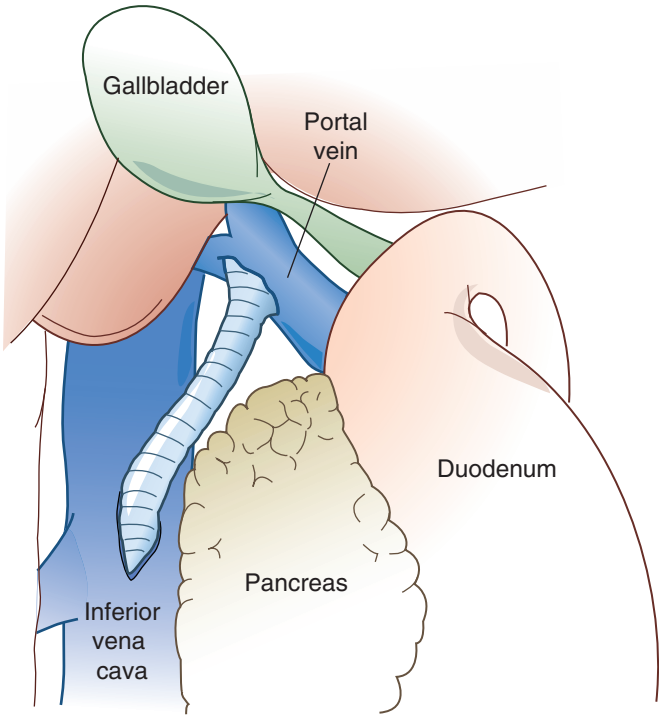

FIGURE 3 A small-diameter (8-mm or 10-mm) interposition portacaval shunt partially decompresses the portal venous system while preserving hepatic portal flow. *(From Sarfeh IJ, Rypins EB, Mason GR: A systematic appraisal of portacaval H-graft diameters: clinical and hemodynamic perspectives,* Ann Surg *204(4):356–363, 1986.)*

Selective Shunts

Selective shunts have excellent long-term patency and are effective at preventing recurrent variceal hemorrhage, while preserving portal blood flow, resulting in much reduced rates of encephalopathy and liver failure in comparison with total portosystemic shunts. First described by Warren in 1967, the distal splenorenal shunt (DSRS) is the most common type of selective shunt and serves to selectively decompress gastroesophageal varices while preserving blood flow to the liver.

The DSRS is constructed with mobilization of the splenic vein and the left renal vein, followed by ligation of the splenic vein near its junction with the superior mesenteric vein. The distal splenic vein is then anastomosed to the left renal vein, allowing gastroesophageal blood to decompress into the left renal vein and inferior vena cava. In addition, the coronary vein is ligated to complete the portal-azygous disconnection (Figure 4). Similar to the mesocaval shunt, the DSRS has the advantage of avoiding dissection of the porta hepatis in patients who may later become candidates for liver transplantation. The splenorenal shunt does not require inspection or ligation at the subsequent transplant operation.

One limitation of the DSRS is that new collateral venous channels may form with gradual reversal of flow, causing the shunt to lose its selectivity over time. Another potential drawback is the increase in splanchnic portal hypertension after complete portal-azygous disconnection, which may exacerbate existing ascites.

COMPARISON OF TRANSJUGULAR INTRAHEPATIC PORTACAVAL SHUNT WITH SHUNT SURGERY

A multicenter, prospective randomized controlled trial compared TIPS with the DSRS shunt in Child-Pugh class A and B cases with refractory variceal bleeding. The investigators found no significant differences in rebleeding, encephalopathy, or 2-year and 5-year survival rates between the two treatment modalities. The rates of thrombosis, stenosis, and reintervention were dramatically higher with TIPS (82%) than with DSRS (11%). Although this study illustrates that both procedures are effective in the control of refractory variceal

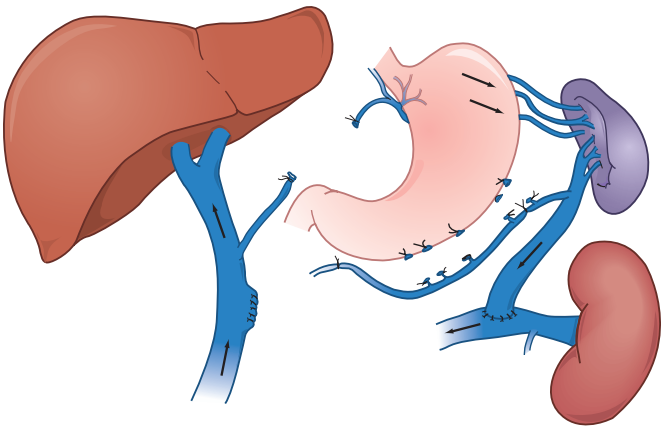

FIGURE 4 The distal splenorenal shunt allows selective variceal decompression into the left renal vein. Hepatic portal perfusion is maintained with complete portal-azygous disconnection, which is achieved by interruption of the coronary vein, gastroepiploic vein, and any other prominent venous collaterals. *(From Salam AA: Distal splenorenal shunts: hemodynamics of total versus selective shunting. In Baker RJ, Fischer JE, editors:* Mastery of surgery, *ed 4, Philadelphia, 2001, Lippincott Williams & Wilkins, pp 1357–1366.)*

bleeding in Child-Pugh class A or B cases, surgical therapy is preferred because of a less frequent need for reintervention, provided that the required expertise is available. Other patient factors, such as comorbidities, reliability to return for follow-up visits, and ongoing access to prompt medical care must also be considered when formulating a treatment plan for recurrent variceal bleeding.

SUMMARY

Bleeding from gastroesophageal varices causes significant morbidity and mortality in patients with portal hypertension. A multidisciplinary approach incorporating medical management, endoscopic interventions, and TIPS is the mainstay of therapy for control of variceal hemorrhage. Although now used rarely, surgical shunts can be safe and effective for recurrent, refractory bleeding in the carefully selected patient with preserved liver function.

The Role of Liver Transplantation in Portal Hypertension

Andrew Singer, MD, PhD, and
Susanna Nazarian, MD, PhD

The liver has a unique, dual circulation with roughly three quarters of flow supplied through the portal vein and the balance delivered via the hepatic artery. Portal inflow is itself derived from contributions from the splenic and superior mesenteric veins. Impedance to venous flow at any point along its path can result in increased portal venous pressures with morbid and potentially lethal consequences. Portal hypertension, a pathologic elevation of pressure within the portal venous system, is most commonly seen with cirrhotic, end-stage liver disease.

ETIOLOGIES OF PORTAL HYPERTENSION

Whereas in the United States chronic alcoholism and hepatitis C infection (HCV) are the most common causes of cirrhosis and portal hypertension, worldwide, hepatitis B infection (HBV) is the modal cause. Portal hypertension can, however, occur in the absence of cirrhosis. These noncirrhotic etiologies of portal hypertension can be divided into presinusoidal, sinusoidal, and postsinusoidal causes. That said, over time, all these processes may result in progression to cirrhosis. Prehepatic portal hypertension, seen with thrombosis of the portal vein, is often associated with hypercoagulable states or may occur in infants after umbilical vein cannulation. Schistosomiasis is an endemic parasite in some parts of the world, particularly in Asia, and can lead to both presinusoidal and sinusoidal portal hypertension. This fluke enters the skin and ultimately lodges in the superior or inferior mesenteric veins. Eggs from the adult worm flow into portal vein tributaries and elicit an immune response that leads to inflammation and eventual fibrosis. Portal hypertension in this setting is predominantly presinusoidal initially but eventually progresses to sinusoidal fibrosis. Noncirrhotic portal fibrosis, also known as idiopathic portal hypertension, is a sinusoidal variant of portal hypertension with dense portal fibrosis and dilated sinusoids in the absence of cirrhosis. Finally, postsinusoidal causes include hepatic vein thrombosis (Budd-Chiari syndrome), venous occlusive disease seen with allogeneic bone marrow transplant, and right heart failure.

PATHOPHYSIOLOGY OF PORTAL HYPERTENSION

Portal hypertension in the setting of cirrhosis is a result of both altered hepatic architecture and an imbalance of local vasodilators and vasoconstrictors. Hepatic fibrosis elevates intrahepatic resistance and increases portal pressures. Of the overexpressed vasoconstrictors, endothelin appears to play an especially critical role in the increased vascular tone seen with cirrhosis. Meanwhile, a relative deficiency in nitric oxide leads to contraction of septal fibroblasts and smooth muscle myocytes, further exacerbating the vascular tone imbalance. Portal hypertension is defined as a hepatovenous pressure gradient (pressure in the portal veins relative to the pressure in the vena cava) of at least 10 mm Hg. This pressure gradient can result in life-threatening morbidities, including the production of ascites, development of varices, and splenomegaly with associated thrombocytopenia from platelet sequestration and destruction.

With altered vascular tone, there is marked vasodilation of arterioles in the splanchnic organs and a decrease in the peripheral circulation resulting in relative hypotension and activation of the renin-angiotensin-aldosterone system. This causes salt and water retention, promulgating the production of ascites. Further, relative hypoperfusion of the kidneys and renal artery vasoconstriction may lead to hepatorenal syndrome and renal failure. Spontaneous bacterial peritonitis (SBP) complicating ascites, diagnosed with positive bacterial culture or an elevated polymorphonuclear white blood cell count in the peritoneal fluid, can be lethal, with a mortality rate that exceeds 30%. However, if SBP is recognized and treated early, best with a third-generation cephalosporin such as ceftriaxone, the mortality rate is less than 10%. Trials of antibiotic prophylaxis with either fluoroquinolones or co-trimoxazole in those with ascites have suggested a benefit in SBP reduction and overall patient survival.

The liver of a patient with portal hypertension is impaired in its ability to clear ammonia and other toxic metabolites, not only from its inherent parenchymal dysfunction but also from the shunting of blood around the liver. Hepatic encephalopathy ensues, which can range from mild fatigue, difficulty sleeping, and forgetfulness, to hepatic comas and even intracranial hypertension in acute liver failure. Treatment with lactulose or rifaximin can minimize hepatic

encephalopathy and has been shown to reduce frequency and duration of encephalopathy-related hospitalizations. The most lethal consequences of portal hypertension, however, are bleeding complications. Twenty-five percent to 40% of patients with cirrhosis have gastroesophageal variceal hemorrhage develop. Acute bleeds from varices carry a mortality rate of 20% to 30% with the first bleed and up to 75% with recurrent bleeds.

MEDICAL MANAGEMENT OF PORTAL HYPERTENSION

Medical management can temporize and ameliorate the consequences of portal hypertension but does not treat the underlying causes. Diuretics, usually a combination of furosemide and spironolactone, help limit the production of ascites. The administration of albumin complements diuretic therapy by increasing oncotic pressure. Fluid restriction and compliance to a low-salt diet is also essential in controlling ascites. Nonselective beta-blockers, such as nadolol or propranolol, reduce the hepatoportal gradient and lower hepatic blood flow, curbing the progression of varices and reducing the bleeding risk. Other agents used to reduce portal pressure via splanchnic vasoconstriction or impedance of the renin-angiotensin-aldosterone system include octreotide, somatostatin, and midodrine. Repetitive large-volume paracenteses can improve patient mobility, respiratory status, and overall comfort.

Acute variceal bleeding can be torrential and rapidly fatal unless arrested with timely intervention. In the setting of such uncontrolled bleeding, a Sengstaken-Blakemore tube can be life saving. This nasogastric tube features a gastric balloon that can be pulled up against the gastroesophageal junction and an esophageal balloon that can be inflated to further tamponade bleeding. Care must be taken to deflate the balloon after 90 minutes to avoid pressure necrosis. With these tubes, it is possible to temporize vigorous bleeding and allow time for resuscitation, transfusion, correction of coagulopathy, and eventually definitive endoscopic banding and sclerotherapy. These endoscopic techniques are also crucial to the prevention of rebleeds, and surveillance esophagogastroduodenoscopy (EGD) should be undertaken at regular intervals to check for variceal recurrence and progression.

SURGICAL AND RADIOLOGIC MANAGEMENT OF PORTAL HYPERTENSION

Shunts to bypass portohepatic flow, and hence to limit the consequences of portal hypertension, were first introduced in 1903 by Vidal. Portosystemic shunts deliver splanchnic blood to the systemic system, circumventing the high-pressure portohepatic system. As a result, ascites production and variceal propagation are curbed. Shunts can be roughly divided into two categories: (1) nonselective shunts that completely divert blood from the portal venous circulation; and (2) selective shunts that divert the esophagogastrosplenic venous flow to the systemic circulation while maintaining portal flow from the upper intestinal circuit. The latter serve to minimize left-sided portal hypertension and esophagogastric varices with less exacerbation of encephalopathy as compared with nonselective shunts.

Until the early 1970s, shunts were exclusively a surgical undertaking. However, the introduction of the transjugular intrahepatic portosystemic shunt (TIPS) has revolutionized the management of portal hypertension, and the creation of surgical shunts is now rarely indicated. TIPS, a nonselective shunt, can be performed electively or created emergently in the setting of acute variceal bleeding. This interventional radiologic technique begins with access of the hepatic vein, most commonly the right, via the right internal jugular vein. With fluoroscopy, needle access to the right portal system is attained, across hepatic parenchyma. The tract is then dilated, and a stent is introduced to connect the portal and systemic systems. The most feared complications related to TIPS are hepatic encephalopathy and frank liver failure. Although TIPS efficiently minimize ascites production and limit variceal bleeding, there is the risk of increased accumulation of toxic metabolites and in turn worsened encephalopathy as blood bypasses the hepatic parenchyma. In a similar fashion, the diversion of blood from the parenchyma may propel a compensated cirrhotic into acute liver failure.

Less catastrophically, TIPS are plagued with occlusion from endothelial proliferation, requiring repeated interventions. Stent patency, however, has markedly improved with the development of polytetrafluoroethylene (PTFE)–covered stents. When used judiciously, TIPS are highly effective at reducing the risk of bleeding from varices, with a rebleeding rate of 4% per year. Ascites is markedly decreased, with a reduced need for paracentesis and fewer episodes of spontaneous bacterial peritonitis. The incidence of hepatorenal syndrome is also lowered, and overall survival is increased. Absolute contraindications to TIPS include severely elevated right heart pressures, severe hepatic encephalopathy, and active infections. Relative contraindications include hepatic vein thrombosis, portal vein thrombosis, and poor hepatic reserve.

Although rare in the TIPS era, open surgical shunts are still performed when TIPS is not feasible or has failed. Examples of nonselective shunts include mesocaval shunts, which are fashioned by sewing a piece of prosthetic graft between the superior mesenteric vein and the vena cava, and the even more rarely performed total portosystemic shunt, which is created by side-to-side portocaval anastomosis. A splenorenal, or Warren shunt, is an example of a selective shunt. This shunt is created by disconnecting the splenic vein at its confluence with the superior mesenteric vein and anastomosing it to the left renal vein. In addition, the coronary vein and veins along the greater curvature of the stomach are ligated in an effort to minimize left-sided portal hypertension while maintaining some portal flow to the liver. Trials comparing surgical shunts and TIPS have shown roughly equivalent decrease in variceal bleeds and overall patient survival with similar impact on encephalopathy.

LIVER TRANSPLANTATION

Whereas medical treatments and shunting aim to temporize the sequelae of portal hypertension, with liver transplant, there is the promise of cure. This intervention, however, is limited by organ availability and the need for life-long immunosuppression after transplant. Accordingly, it is meted to those with advanced hepatic failure or to those who have primary hepatocellular carcinoma (HCC) in the setting of cirrhosis. The most common indications for adult liver transplantation in the United States are HCV and alcoholism. Others include nonalcoholic steatohepatitis (NASH), HBV, primary sclerosing cholangitis (PSC), autoimmune hepatitis, primary biliary cirrhosis (PBC), Wilson's disease, and hemochromatosis. In the pediatric population, biliary atresia is by far the leading indication for liver transplantation. Others include progressive fibrosing intrahepatic cholestasis (PFIC), acute hepatic failure from toxic exposures or viral infections, and rare inborn errors of metabolism.

The presence of portal hypertension complicates liver transplant and nontransplant surgeries. Disruption of varices within the esophagus, abdominal wall, peritoneal cavity, or retroperitoneum poses the threat of rapid and voluminous blood loss. The potential risk of esophageal and gastric variceal hemorrhage has limited the use of hemodynamic monitoring with transesophageal echocardiography (TEE) in patients with signs of portal hypertension undergoing liver transplantation. Splenic injury, given immense hypersplenism seen with portal hypertension, also brings the possibility of difficult-to-control bleeding. Likewise, the rapid removal of ascites during surgery may lead to hemodynamic instability. Despite correction of

portal hypertension through liver transplant, ascites may persist in a subset of patients postoperatively. Although this phenomenon is incompletely understood, it is most often seen in those who had suffered from massive ascites before transplant. Hypersplenism, too, may take years to resolve.

With 16,000 people on the waiting list for liver transplantation and only 6000 transplants occurring annually, much thought has been given regarding the system for allocation of this precious resource. The United Network of Organ Sharing (UNOS) oversees the allocation of organs. The nation is divided into 10 regions and then subdivided into 58 organ procurement organizations (OPOs) within these regions. Within blood groups, livers are offered first within the OPO based on a scoring system for assessing the severity of liver disease, the Model for End-Stage Liver Disease (MELD), which predicts 90-day risk of death without transplantation. The MELD score ranges between 6 and 40 and is calculated from 3 measured laboratory values: bilirubin, international normalized ratio (INR), and creatinine. Nationally, the median MELD at transplant is approximately 26, yet it varies by blood group and transplant region. Because liver transplant has been shown to be a powerful tool in the treatment of early primary liver cancers, those with appropriately sized HCC are given 22 exception points, with additional points awarded quarterly while they remain on the wait list to facilitate timely transplantation. It is important to note that the degree of portal hypertension and associated morbidities are not components of the MELD score. That said, the organ allocation algorithm is continually under review to ensure fairness and achieve its goal of minimizing patient death on the waitlist.

Ninety percent of liver transplants in the United States use whole, cadaveric grafts. Pediatric transplantation requires either an appropriately sized graft, from a child or small adult, or a segmental graft from either a live or deceased donor. For adults unable to obtain timely deceased donor transplantation, often those underserved by the MELD allocation system, live donor liver transplantation of a hemiliver, most commonly the right lobe, from adult to adult may sometimes be an appropriate option. Significant recipient portal hypertension, however, may be a relative contraindication for use of these reduced sized grafts because it may result in portal hyperperfusion and allograft dysfunction.

Efforts to expand the organ pool have led to the use of expanded-criteria grafts with success. The donor pool now includes livers from elderly donors and those with elevated body mass index (BMI), allografts with prolonged cold ischemia time, those from donors with cancer history, and those procured from donation after cardiac death. Currently, nationwide 1-year graft and patient survival rates are approximately 84% and 88%, respectively. Liver transplantation remains the most efficacious and durable intervention for the treatment of portal hypertension in the setting of end-stage liver disease resulting from a heterogeneous collection of causes. As graft and recipient selection, operative techniques, perioperative and postoperative management, and immunosuppression continue to improve in the coming years so too will the safety and efficacy of liver transplantation.

Endoscopic Therapy for Esophageal Variceal Hemorrhage

Justin A. Reynolds, MD, and
Francisco Antonio Durazo, MD, FACP

OVERVIEW

Gastroesophageal varices are the most important type of portosystemic collaterals that develop in the setting of portal hypertension. Variceal rupture is a well-known complication of portal hypertension and cirrhosis and is more common as the stage of liver disease progresses. Bleeding from esophageal varices can occur in up to 30% of patients with cirrhosis. Despite advances in medical and endoscopic therapy for variceal hemorrhage, the mortality rate associated with bleeding is as high as 20%.

All patients with suspicion of variceal bleeding should have adequate intravenous access established and undergo rapid resuscitation. Vasoactive medications such as octreotide are helpful in controlling bleeding and can be administered as a 50-μg bolus, followed by a 25-μg/h intravenous infusion. This should be continued for a minimum of 72 hours after definitive endoscopic therapy for a variceal bleed. Intravenous proton pump inhibitors (e.g., pantoprazole) are routinely given as well in case the source of bleeding is an ulcer rather than a varix. Blood products are often necessary for correction of thrombocytopenia and coagulopathy. Occasionally, the patient needs endotracheal intubation for airway protection or for lack of cooperation or encephalopathy.

Patients with cirrhosis who experience gastrointestinal (GI) bleeding are at greatly increased risk of infection-related complications such as bacteremia, pneumonia, and bacterial peritonitis from infected ascites fluid. These patients should receive empiric broad-spectrum antibiotics (e.g., ceftriaxone or norfloxacin) for at least 5 days.

Up to 25% of patients with known portal hypertension may present with upper GI hemorrhage that is not the result of esophageal varices. In these patients, common causes of bleeding include peptic ulcer disease, erosive esophagitis, Mallory-Weiss tears, portal hypertensive gastropathy, and gastric fundal varices. A careful diagnostic endoscopic evaluation should be performed in all such patients. In

patients with documented esophageal varices but no other potential sources of bleeding identified at endoscopy, a variceal source of hemorrhage should be presumed.

ENDOSCOPIC THERAPY

Endoscopic Band Ligation

Endoscopic band ligation is a well-established, safe, and effective means of hemostasis for esophageal varices. Although preceded by sclerotherapy, band ligation has largely replaced it as a result of improved safety and equal efficacy. All band ligation devices are affixed on the tip of an endoscope that then uses suction against a mound of target tissue while a small, circular elastic band made of rubber or latex is deployed around the base of the target tissue. This compression results in hemostasis with subsequent sloughing of the necrotic tissue.

Several components are common to all band ligation devices, including a transparent cylindrical cap that carries up to 10 bands. A tripwire runs from the cap to a control knob assembly that is inserted into the accessory channel of the endoscope. When secured in place, the bands may be fired individually with the turn of a knob. Most endoscopists use a multiband device with at least six bands available to be deployed with one insertion of the endoscope. Single-fire devices are rarely used but are best with an overtube that allows for easy insertion and withdrawal of the endoscope for reloading and multiple-band applications.

After a diagnostic endoscopy has been done and varices amenable to band ligation have been identified, the endoscope is removed and the band ligation device is attached. After reinsertion, the endoscope is advanced until the banding cylinder is in 360-degree contact with the varix. Continuous suction is applied and maintained until the varix is drawn into the cap, fully causing a *red-out* appearance that obscures vision. The firing mechanism is then activated, and an elastic band is deployed around the base of the varix. Suction may then be withheld, and the banded varix disengages from the cylinder. Some transient bleeding may be encountered during band ligation as a result of variceal rupture. This process is then repeated until all varices have been banded, and the endoscope is then removed.

The optimal technique for ligation of esophageal varices begins with the largest column of varices at the most distal point, usually at or just below the gastroesophageal junction. Starting distally allows for better visualization and avoids the risk of band dislodgement during advancement of the endoscope. Subsequent ligations are applied to all columns at the same level and then repeatedly as the endoscope is withdrawn more cephalad. In the case of active hemorrhage, the bleeding varix is often targeted first, with band placement caudal and cephalad to the rent or directly on the rent itself. Large columns of varices frequently require multiple bands along the length for adequate ligation. With good technique, varices should decompress more proximally, signifying adequate compression and hemostasis.

After band ligation treatment, the patient may experience mild temporary chest pain that is generally alleviated with viscous lidocaine, or opiates in severe cases. The authors' practice is to allow the patient clear liquids that day, followed by soft-consistency foods for the ensuing 3 days before a normal diet resumes. Nasogastric or feeding tubes should be avoided so as not to dislodge any elastic bands. Repeat band ligation treatments are typically performed at 10-day to 14-day intervals until the varices are eradicated. This usually requires three to four treatment sessions for completion.

Endoscopic Sclerotherapy

Endoscopic sclerotherapy is still commonly used worldwide, although in the United States, it has largely been replaced by band ligation and now is used most often as salvage or an adjunct therapy during acute hemorrhage. Sclerosants are irritants that cause endothelial damage and thrombosis and lead to vascular obliteration. These can be injected directly into the lumen of the varix (intravariceal) or adjacent to the varix (paravariceal) or a combination of both.

After the diagnostic endoscopy is complete, an injector needle is advanced through the instrument channel of the endoscope. Most endoscopists then inject 1 to 5 mL of sclerosant directly into each varix. Treatment is confined to the distal esophagus unless a source of bleeding is identified elsewhere. The most commonly used sclerosants include ethanolamine, sodium morrhuate, and sodium tetradecyl sulfate. The maximum amount of sclerosant that may be used depends on the agent selected but should never be more than 5 mL per varix or 20 mL per session.

Patients with active bleeding from a discretely identified site should have that varix treated first with injection of sclerosant below the site of active bleeding. After hemostasis is achieved, the most distal varices near the gastroesophageal junction should then be treated and the injections should proceed proximally until all varices have been treated.

Complications of sclerotherapy may occur in up to 25% of patients. Common problems include chest pain, mucosal ulcerations and bleeding, esophageal strictures, and bacteremia. Patients with immunocompromise, those with a history of endocarditis, and those who have prosthetic valves, shunts, or ascites should all be considered for antibiotic prophylaxis before sclerotherapy.

Other Endoscopic Methods

Several other techniques for treatment of esophageal varices have been described. Most of these techniques, however, have been used either for salvage therapy of an acute bleed or in experimental studies.

For persistent variceal bleeding despite endoscopic therapy, an urgent transjugular intrahepatic portosystemic shunt (TIPS) or other type of portocaval shunt is often indicated. As a temporizing measure, the endoscopist may place a Sengstaken-Blakemore tube into the esophagus. This tube has a gastric balloon that compresses the gastroesophageal junction as traction is applied. An esophageal balloon is also inflated to provide temporary hemostasis as a bridge to more definitive therapy aimed at portal decompression. The use of covered esophageal stents has also been reported in several series as a salvage therapy to achieve hemostasis.

Tissue adhesives and fibrin glues have been studied for hemostasis and the prevention of variceal bleeding. Endoscopic injection of rapidly setting polymers such as cyanoacrylate is well described but not yet available in the United States. In such cases, the polymer is mixed with radiopaque contrast to slow hardening and allow for fluoroscopic monitoring for determination of proper injection location. Care must be taken to avoid gluing the injector needle into the varix or the endoscope.

Hemostatic sprays or powders have widely been used for the control of hemorrhage in battlefields, and one such compound is currently under evaluation for endoscopic use. With a through-the-scope delivery catheter, the powder is delivered with a pressurized CO_2 canister and applied to the site of hemorrhage until hemostasis is achieved. The coagulum later sloughs off and is naturally eliminated. Although this spray has been evaluated in other countries, it has not yet been evaluated or approved in the United States.

RESULTS

Endoscopic band ligation and sclerotherapy are successful in controlling variceal hemorrhage in upwards of 95% of patients. Band ligation is the preferred treatment for acute bleeding because of its lower risk of treatment-induced complications and also because of its excellent efficacy. Band ligation also requires fewer treatment sessions

than sclerotherapy to eradicate varices and carries a lower incidence of recurrent bleeding.

Recurrent varices after initial eradication are common and occur more often in patients receiving band ligation than sclerotherapy. When encountered, one or two additional endoscopic treatment sessions are typically required. These patients frequently need routine endoscopic evaluations for surveillance. Nonselective beta-blockers such as propranolol or nadolol can also be used for prevention of variceal bleed if endoscopic therapy is not used. However, care should be exercised in beta-blockade for patients with advanced cirrhosis due to the potential risk of precipitating hepatorenal syndrome.

Complications

Endoscopic sclerotherapy is associated with a high risk of minor complications such as bacteremia, fever, pain, pulmonary infiltrates, and pleural effusions. These generally resolve spontaneously without intervention. Shallow mucosal ulcerations at the site of sclerosant injection are also common and occasionally result in recurrent bleeding or esophageal stricture formation (in up to 20% of patients). These strictures are typically responsive to balloon dilation or bougienage.

Endoscopic band ligation therapy has a lower overall risk of treatment-related complications. Shallow postbanding mucosal ulcers may form and result in recurrent bleeding in up to 5% of patients. However, most bleeding from ligation-induced ulceration is self limited. Temporary chest pain after banding is common and self limited. Esophageal strictures are very uncommon.

Prevention of First Variceal Hemorrhage

Endoscopic band ligation, nonselective beta-blockers, and a combination of both have all been shown to reduce the risk of hemorrhage from large esophageal varices in patients who have never bled before. However, prophylactic band ligation therapy is superior to beta-blockade medical therapy and also reduces the risk of a first variceal bleed by up to 70% compared with no treatment at all.

SUMMARY

Endoscopic treatment for variceal hemorrhage is safe and effective. Endoscopic band ligation is most commonly performed for acute variceal bleeding, although sclerotherapy may also be used as primary treatment or as salvage therapy. Other techniques for refractory hemorrhage are also available. Endoscopic band ligation compared with sclerotherapy is associated with more efficient eradication of esophageal varices and also fewer complications. However, recurrence of esophageal varices is more common after band ligation than after sclerotherapy. Prevention of a first variceal bleed is most effective with prophylactic band ligation, although nonselective beta-blockers may also be used.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Ezana M. Azene, MD, PhD, and Kelvin Hong, MD

OVERVIEW

The creation of a transjugular intrahepatic portosystemic shunt (TIPS) was put forth as a possible treatment for the symptoms of portal hypertension in the early 1970s. Over the ensuing 2 decades, the work of many pioneers—including Rosch, Uchida, Colapinto, Palmaz, and others, many of whom lent their names to relevant apparatus—culminated with the introduction of TIPS in mainstream clinical practice.

TIPS can be a life-saving procedure, as well as one that alleviates severe symptoms related to portal hypertension. TIPS is also a durable solution with a long-term efficacy of 90%. It is, however, a double-edged sword, demanding meticulous technique and stringent patient selection to keep what was once a high morbidity and mortality at a minimum.

INDICATIONS

The list of causes of portal hypertension is long and is summarized in Table 1. Whatever the causative pathophysiology, TIPS can reduce or normalize the portal pressure and ameliorate the associated symptoms. As the technique for placing a TIPS became more refined and safer, and the technology became more adapted to the specific physiology and anatomy of a portosystemic shunt, the indications for TIPS have gradually expanded. Table 2 shows the indications and contraindications for TIPS.

Variceal Bleeding

Portal hypertension can cause varices along the entire gastrointestinal tract, including the small bowel and colon (hemorrhoids). Varices are more apt to bleed through the mucosa of the gastroesophageal junction, where the coronary vein is particularly disposed to dilatation.

TABLE 1: Causes of portal hypertension

Presinusoidal	Perisinusoidal	Postsinusoidal
Portal, splenic, or superior mesenteric vein thrombosis	Cirrhosis	Budd-Chiari syndrome
Idiopathic portal hypertension	Congenital hepatic fibrosis	Venoocclusive disease (sinusoidal obstruction syndrome)
Mass effect (i.e., tumor)	Cystic liver disease	Chronic passive congestion (nutmeg liver)
Schistosomiasis	Sarcoidosis	Mass effect (i.e., tumor)
Precirrhotic stage, primary biliary cirrhosis		
Alcoholic central sclerosis		
Endotheliitis (liver rejection, radiation injury)		
Arterioportovenous fistula (traumatic or Osler-Weber-Rendu)		
Hyperdynamic splenomegaly (infectious or myelodysplastic)		
Nodular regenerative hyperplasia		
Congenital extrahepatic portal vein occlusion		

TABLE 2: Indications and contraindications for Transjugular Intrahepatic Portosystemic Shunt

Indications			Contraindications	
	EMERGING INDICATIONS			
Standard of Care	*Supported by Controlled Studies*	*Supported by Noncontrolled Studies and Case Series*	*Absolute*	*Relative*
Portal variceal hemorrhage refractory to medical/endoscopic management	"Cirrhotic" portal vein thrombosis caused by slow blood flow in the portal vein	Hepatorenal syndrome (more so type II than type I)	Severely elevated right heart pressure	Hepatic vein thrombosis
Ascites refractory to medical management	Childs-Pugh B and C with acute esophageal variceal bleeding (simultaneously treated with medical and/or endoscopic interventions)	Hepatopulmonary syndrome	Severe tricuspid regurgitation	"Noncirrhotic" portal vein thrombosis caused by hypercoagulability or tumor thrombus
Budd-Chiari syndrome not responsive to anticoagulation		Portal gastropathy refractory to β-blockers	Severe pulmonary hypertension	Poor liver function reserve
Hepatic hydrothorax refractory to diuretics and salt restriction		Hepatic venoocclusive disease	Severe congestive heart failure	Polycystic liver disease
			Severe encephalopathy	Central liver mass
			Uncorrectable bleeding diathesis	Gastric antral variceal ectasia
			Active systemic or hepatic bacterial infection	
			Unrelieved biliary obstruction	

The primary treatment of bleeding gastroesophageal varices is medical management and/or endoscopic management. Even though endoscopic management is often successful, because of the progressive nature of chronic liver disease, recurrent bleeding should be expected in more than 50% of patients. Unlike medical or endoscopic management, shunting procedures like TIPS address the underlying cause of variceal bleeding (portal hypertension). Portosystemic shunting is therefore the only definitive treatment for portal variceal bleeding. Meta-analysis of the literature has shown that TIPS has a lower rate of both variceal rebleeding and death due to rebleeding, with a strong trend toward increased survival (at the expense of increased hepatic encephalopathy). Most of the studies included in these meta-analyses predate the era of polytetrafluoroethylene (PTFE)-covered TIPS stent-grafts, which have improved long-term patency over bare-metal stents with a trend toward better overall survival. Head-to-head comparisons of TIPS created with stent-grafts to endoscopic and medical management is lacking.

Currently, the primary indication for TIPS is to control portal variceal bleeding refractory to medical and endoscopic management. However, there is evidence from one randomized controlled study supporting the early use of TIPS in selected patients with advanced cirrhosis (Childs-Pugh B and C) and acute esophageal variceal bleeding. Additional studies are needed to confirm this finding before TIPS can be accepted as a first-line therapy for bleeding esophageal varices in patients with advanced liver disease.

Ascites

Ascites is the most common complication of cirrhosis, and in addition to the severe limitations in lifestyle, it poses a risk for bacterial peritonitis and other infections, renal failure, and increased mortality. No single cause for cirrhosis-related ascites has been identified. However, it is likely that a combination of causes, including decreased plasma albumin levels, increased bowel permeability, and cirrhosis-related hemodynamic changes—such as increased cardiac output, vasodilatation, and increased plasma volume—factor together in the formation of ascites.

Initial management consists of sodium restriction and administration of loop diuretics and aldosterone antagonists. In advanced stages, ascites becomes refractory to medical management, and TIPS may be indicated. TIPS is very effective in eliminating ascites. Because the root causes are hemodynamic/hormone related, response to TIPS is not immediate. It may take 2 to 4 weeks after TIPS for ascites to resolve, during which time additional paracenteses may be necessary. Randomized controlled trials, meta-analyses, and systematic reviews of the literature have demonstrated that TIPS significantly improves transplant-free survival compared to repeated paracentesis.

Hepatic Hydrothorax

Hepatic hydrothorax is defined as the accumulation of at least 500 mL of pleural fluid in a patient with cirrhosis without cardiopulmonary disease. Even though this definition is not 100% specific to hepatic hydrothorax, additional signs, such as isolated right-sided hydrothorax and concurrent ascites, help confirm the diagnosis. It occurs in less than 10% of patients with cirrhosis, as peritoneal fluid permeates via small diaphragmatic communications. Again, initial management is sodium restriction and diuretics. In nonresponsive patients, TIPS will eliminate hydrothorax in most and decrease the frequency of thoracentesis in the rest.

Hepatorenal Syndrome

Hepatorenal syndrome portends a poor prognosis for the cirrhotic patient because it occurs during the late stages of the hemodynamic changes related to cirrhosis. Alterations in vasoactive hormones responding to these hemodynamic changes result in splanchnic vasodilation, renal arterial vasoconstriction, and the opening of small intrarenal arteriovenous communications. The end result is renal hypoperfusion and ensuing renal failure.

Two distinct forms of hepatorenal syndrome (HRS) have been identified: *type I HRS,* which is rapidly progressing, and *type II HRS,* which evolves slowly. Type I HRS is precipitated by an event that incites acute-on-chronic liver failure, an exaggerated systemic inflammatory response, and kidney dysfunction as part of a broader multiorgan failure. Targeting the precipitating event is the hallmark of treatment for Type I HRS. Type II HRS results in large part from a reduction in effective arterial blood volume created by a shift of fluid from the intravascular compartment to the extravascular compartment (i.e., ascites). Noncontrolled studies suggest that using TIPS to reduce the production of ascites may improve renal function in type II HRS. However, the use of TIPS in HRS should be undertaken after serious consideration because of the contrast load and acute hemodynamic changes it involves.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome is the presence of intrapulmonary vasodilatation and multiple small, right-to-left shunts that result in impaired gas exchange. Because of the lack of data, TIPS cannot be recommended as a standard treatment for hepatopulmonary syndrome. In selected cases, however, especially in severely compromised patients on the liver transplant list, TIPS may prove to be a life-saving bridge to surgery.

Budd-Chiari Syndrome

Budd-Chiari syndrome is caused by mechanical obstruction of the hepatic venous outflow and gradually results in cirrhosis and portal hypertension. Excluding the hepatic venous web, which can successfully be treated with simple balloon angioplasty, treatment for the fulminant form of Budd-Chiari syndrome is liver transplantation, although anticoagulation may help stave off disease progression. TIPS has proven to be a valuable tool to bridge such patients to transplantation.

In the nonfulminant form of Budd-Chiari syndrome, anticoagulation is first-line therapy. When anticoagulation fails, TIPS is a reasonable and accepted next step. The use of TIPS in this patient population was studied in a large retrospective study that showed 1-year and 10-year transplant-free survival that was much greater than expected. The American Association for the Study of Liver Diseases (AASLD) now recommends creation of a TIPS in patients with Budd-Chiari syndrome who fail to improve with anticoagulation.

Portal Gastropathy

Portal hypertensive gastropathy (to be distinguished from vascular ectasia) is the diffuse dilatation of gastric veins that, along with the inflamed and fragile mucosa of the stomach, predispose the patient to bleeding. TIPS, which normalizes the portal pressure, and mucosal protection (avoiding nonsteroidal antiinflammatory drugs, alcohol) combine to minimize this risk.

TECHNIQUE

Patient Preparation

Many of the complications related to the placement of TIPS can be avoided by proper patient workup. Review of pertinent cross-sectional imaging will confirm a patent (nonthrombosed) portal vein and reveal the relative orientation of the hepatic and portal veins. This minimizes the number of attempts to engage the portal vein and therefore minimizes the associated bleeding risk. Good hydration will minimize the risk of acute renal failure, and initiation of metronidazole (Flagyl) and/or lactulose mitigates the risk of encephalopathy. Type and cross of blood may prove lifesaving if a bleeding complication is encountered. Finally, all involved should be cognizant of related risks, especially the 30-day mortality, which ranges from less than 5% for elective procedures in well-compensated patients to 50% for emergent procedures in unstable patients with advanced liver disease.

Access

Access through the right internal jugular vein is preferred, although the left internal jugular vein can also be used. Access is maintained with a long, large vascular sheath parked in the intrahepatic inferior vena cava to allow multiple catheter-wire exchanges without recrossing the right atrium (Figure 1).

Diagnostic Assessment

Optimizing the TIPS outcomes requires not only anatomic assessment but also functional assessment of the patient's hemodynamic status. One of the contraindications to TIPS is elevated right heart pressure. Ensuring that the right atrial pressure is not severely elevated is mandatory prior to shunting the portal venous blood to an already overburdened right heart. Right atrial pressures below 15 mm Hg are generally safe, whereas pressures above 20 mm Hg predispose the patient to acute right heart failure. There are no specific guidelines, and sound clinical judgment is important. For example, a right atrial pressure of 16 mm Hg should not preclude creation of a TIPS in an unstable patient with ongoing variceal bleeding.

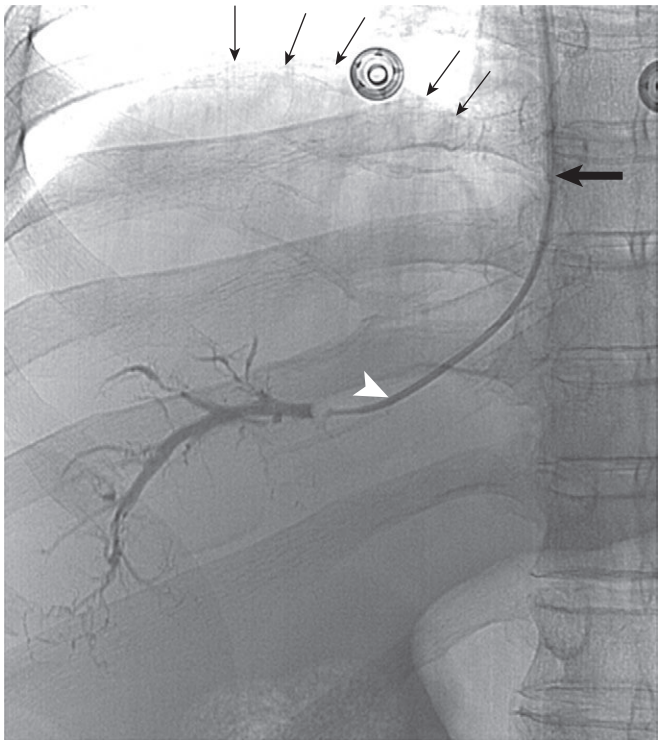

FIGURE 1 Right hepatic venogram performed via a selective catheter *(white arrowhead)*. The tip of the internal jugular sheath *(large black arrow)* is below the diaphragm *(black arrows)* to avoid catheter/wire manipulations in the right atrium. The steps of TIPS insertion outlined in Figures 1 to 9 are all from the same patient.

After selecting the right hepatic vein, free and wedged hepatic venous pressures are measured, which usually confirm portal hypertension. Normal corrected pressures should not necessarily terminate the procedure because these are not terribly accurate in general and are wholly inaccurate in cases of presinusoidal portal hypertension.

Delineation of the portal venous system is accomplished by injection of CO_2 via a catheter wedged into the hepatic vein. CO_2 is not nephrotoxic and can be given in virtually unlimited quantity. Frontal and lateral views show the anatomic relationships so the right portal vein can be targeted for access (Figure 2).

In the vast majority of patients, the TIPS is placed from the right hepatic vein into the right portal vein because this is the shortest and most direct path for shunt creation. However, a recent randomized controlled trial found that using the left portal vein resulted in a significant reduction in the incidence of encephalopathy and rehospitalization during two years of follow-up after TIPS creation. These data must be confirmed in additional studies before the standard approach of targeting the right portal vein is abandoned.

Shunt Placement

The next step is the cannulation of the right portal vein from the right hepatic vein. To accomplish this, a curved metallic sheath is advanced via the existing right internal jugular sheath in the right hepatic vein. The new catheter is rotated based on the anatomy revealed during CO_2 portography so it targets the right portal vein. When the operator judges the curved sheath to be directed toward the right portal vein, a long needle is advanced toward it. Aspiration of blood suggests intravascular location, and contrast injection confirms the tip to be in the portal vein (Figure 3).

Once it is confirmed that the tip of the needle is in the right portal vein, a wire is passed distally through the main portal vein into the superior mesenteric vein or splenic vein for security (Figure 4). The traversed liver parenchyma is fibrotic and difficult to cross unless predilated. A small-caliber (4 to 6 mm diameter) balloon is used to predilate the liver parenchyma between the right hepatic and right portal vein now crossed by the wire (Figure 5). A marking catheter is then passed over the wire into the portal venous system. This allows

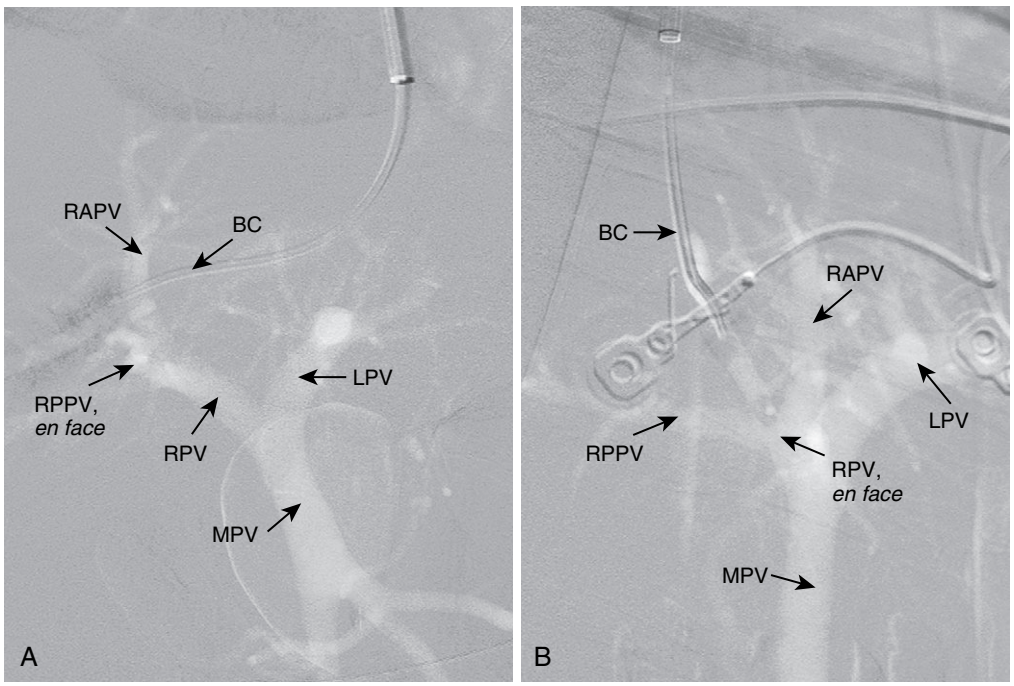

FIGURE 2 Frontal **(A)** and lateral **(B)** digital subtraction views of a CO_2 hepatic venogram. CO_2 is injected via a balloon occlusion catheter to force the CO_2 retrogradely into the portal system. The right portal vein and its first-order branches, the left portal vein, and the main portal vein are easily visualized. In the lateral projection, the right portal vein is seen nearly en face. The operator usually targets the right portal vein from the right hepatic vein with a long needle introduced via the right internal jugular sheath. *BC,* Balloon occlusion catheter; *LPV,* left portal vein; *MPV,* main portal vein; *RAPV,* right anterior portal vein; *RPPV,* right posterior portal vein; *RPV,* right portal vein.

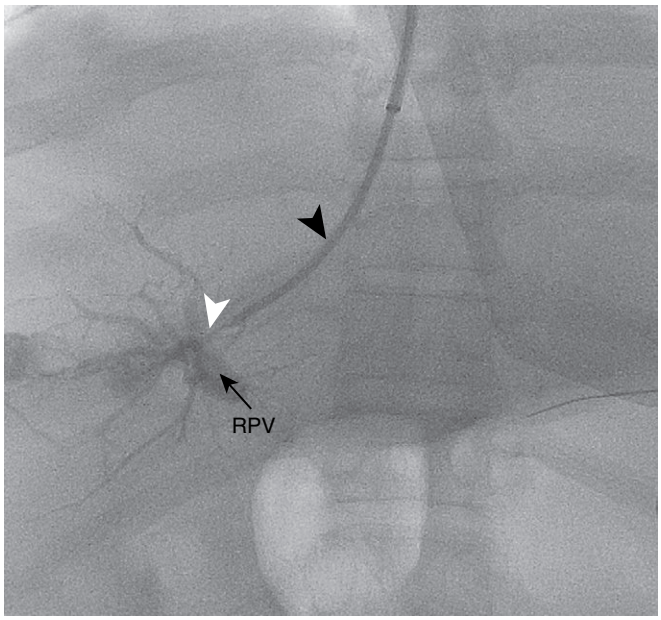

FIGURE 3 Frontal unsubtracted venogram via a needle *(white arrowhead)* after it was advanced from the right hepatic vein through a catheter *(black arrowhead)* toward the right portal vein (RPV). Contrast fills branches of the right portal vein with hepatopetal blood flow.

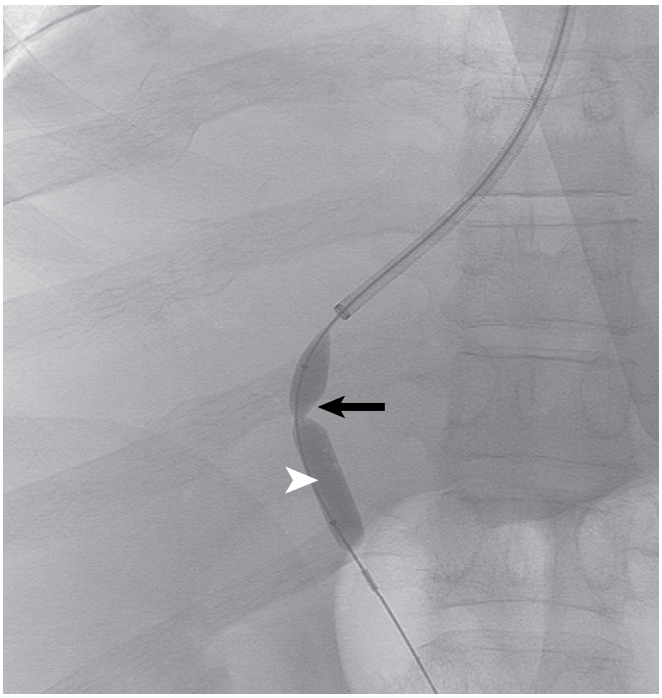

FIGURE 5 Because cirrhotic liver is difficult to cross, it is predilated with a small balloon *(white arrowhead)* to facilitate the necessary sheath exchanges. The "waist" *(black arrow)* in the middle of the balloon reveals just how hard the liver parenchyma can be.

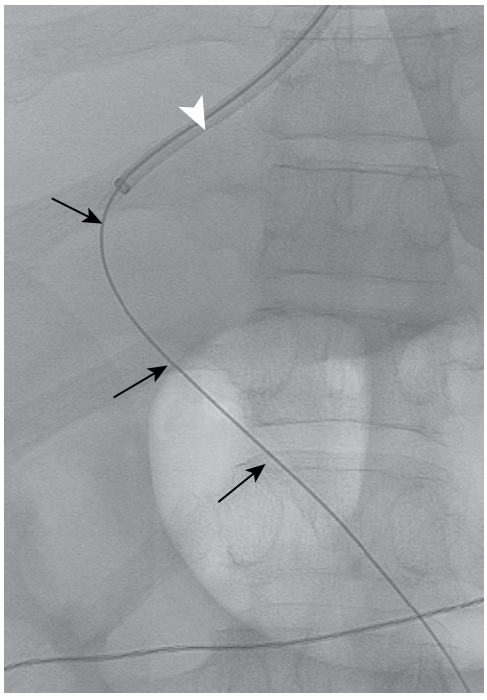

FIGURE 4 After the needle is confirmed to be in the targeted portal vein branch, a wire is advanced through it into the portal vein *(black arrows)*. Note the location of the right internal jugular sheath *(white arrowhead)*. The wire now crosses from the right hepatic vein, through a short segment of liver parenchyma, and into the right portal vein.

for direct portal pressure measurement and a portal venogram. The venogram will be used to select the appropriate length stent to be placed (Figure 6).

If the direct portal pressure is within normal limits, TIPS creation is abandoned irrespective of the clinical picture. If a TIPS is not possible or is contraindicated, the gastroesophageal varices can be embolized via a catheter to stop the hemorrhage without placing a TIPS. Though this is very effective, it is nevertheless temporary; the ongoing portal hypertension will likely cause new varices to form.

The stent is advanced through the larger sheath, which keeps it constrained and in position. The sheath is pulled back into the right atrium, uncovering the stent. The distal 2 cm of the stent is uncovered and flares out upon withdrawal of the sheath. The rest of the stent is "rip-corded" open once it is in the appropriate position (Figure 7).

Shunt Evaluation

Usually, a 10-mm–diameter stent is used and initially balloon-dilated up to 8 mm in diameter. The direct portal pressure is measured again, and if it is not satisfactory, a 10-mm balloon is used to open the stent to capacity (Figure 8). The smaller the stent diameter, the less the chance for encephalopathy post procedure. A final portal venogram is performed to document flow and lack of variceal filling (Figure 9).

Special Cases

Budd-Chiari Syndrome

The creation of a TIPS in a patient with Budd-Chiari syndrome is especially challenging because the hepatic veins are thrombosed. This

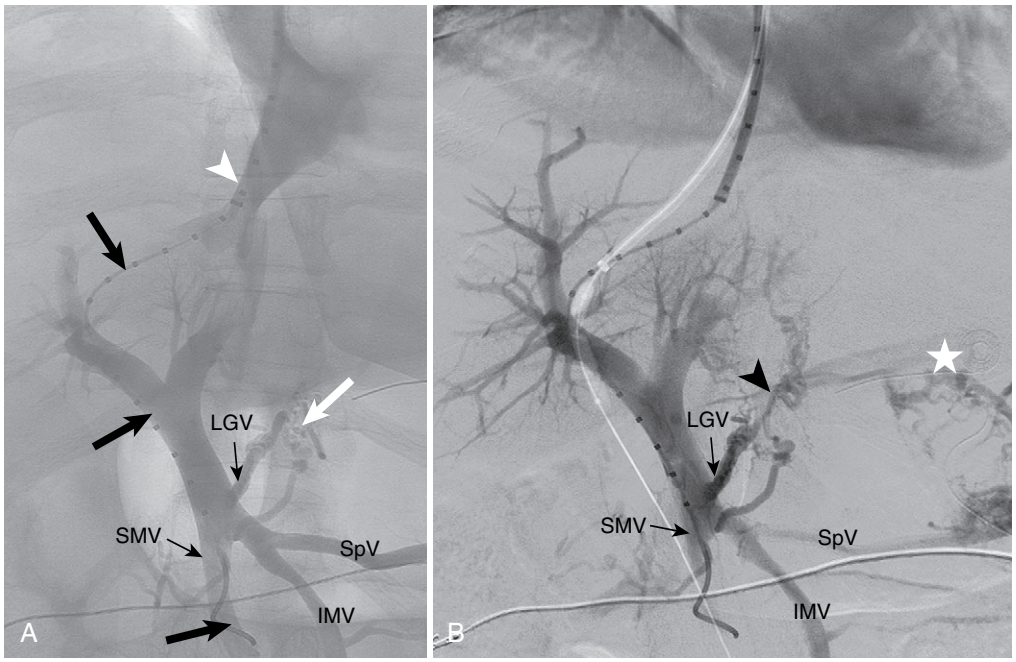

FIGURE 6 Frontal unsubtracted **(A)** and subtracted **(B)** venograms. Simultaneous contrast injection **(A)** via the right internal jugular sheath *(white arrowhead)* and marker catheter *(black arrows)* in the portal vein allows for calculation of the required length of the stent. Note the esophageal varices *(white arrow)* arising from the left gastric vein. A wider field of view with digital subtraction **(B)** shows to greater effect the ominous esophageal *(black arrowhead)* and gastric *(asterisk)* varices. *IMV,* Inferior mesenteric vein; *LGV,* left gastric vein; *SMV,* superior mesenteric vein; *SpV,* splenic vein.

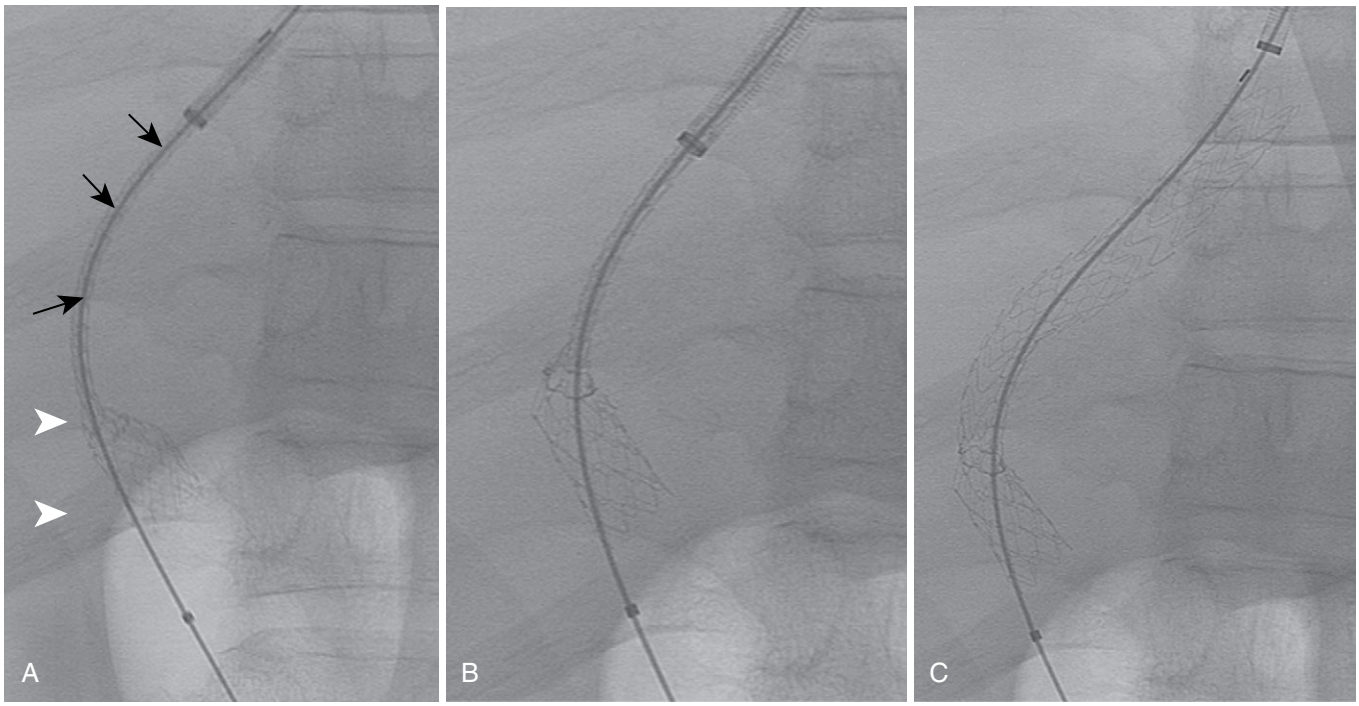

FIGURE 7 Frontal views of the deployment sequence of a TIPS stent. The stent is first advanced via a sheath through the right hepatic vein, across the liver parenchyma, and into the portal vein. **A,** The stent's distal 2 cm *(arrowheads)* are constrained only by the sheath, and once the sheath is pulled back, it springs open. The remainder of the stent *(black arrows)* remains undeployed. The entire system is then gently withdrawn until the proximal end of the distal 2 cm hits the parenchymal tract **(B)**. Once the operator judges the stent to be in proper position the remainder of the stent is opened by pulling on the rip cord **(C)**.

FIGURE 8 After TIPS placement, a balloon is used to open the stent to the desired diameter. The objective is to open the stent to the minimum diameter required to reduce the portal pressure to the desired level.

shows as the classic spider vein appearance on a hepatic venogram (Figure 10). Though it is best if the TIPS is placed from hepatic vein to portal vein, the lack of patent hepatic veins may necessitate an inferior vena cava (IVC) to portal vein TIPS through the caudate lobe, a so-called direct intrahepatic portocaval shunt (DIPS).

Parallel TIPS

Rarely, despite a previous TIPS, the patient's symptoms may not be completely alleviated. If portal hypertension and variceal bleeding are a persistent problem despite a TIPS, or if the first TIPS thromboses, a second TIPS may be placed utilizing the other hepatic and portal veins (Figure 11).

Transumbilical or Direct Portal Access

When access into the portal vein is challenging due to anatomy, the operator has two other options. First, access into the umbilical vein, which is usually dilated, provides a conduit into the left portal vein. A catheter there allows opacification of the portal venous system, which provides a better target for TIPS (Figure 12). Second, access through a naturally occurring portosystemic shunt, such as a splenorenal shunt, can sometimes be used to gain access to the portal circulation. When the umbilical vein is not accessible and a natural portosystemic shunt does not exist, direct percutaneous access into the right or left portal vein can allow for contrast opacification and targeting (Figure 13).

TIPS Reversal/Revision

Occasionally a TIPS reversal or revision is necessary. Limited liver reserve and/or overzealous shunting may result in liver failure or intractable encephalopathy. In such cases the interventionalist has the option to decrease the shunting or shut down the TIPS altogether. Several maneuvers exists to reduce shunting, including placing a stent

FIGURE 9 Frontal view of a portal venogram via a catheter *(arrow)* after TIPS placement *(arrowheads)*. Note the antegrade flow of contrast into the right atrium and no contrast filling the varices. Compare to Figure 6.

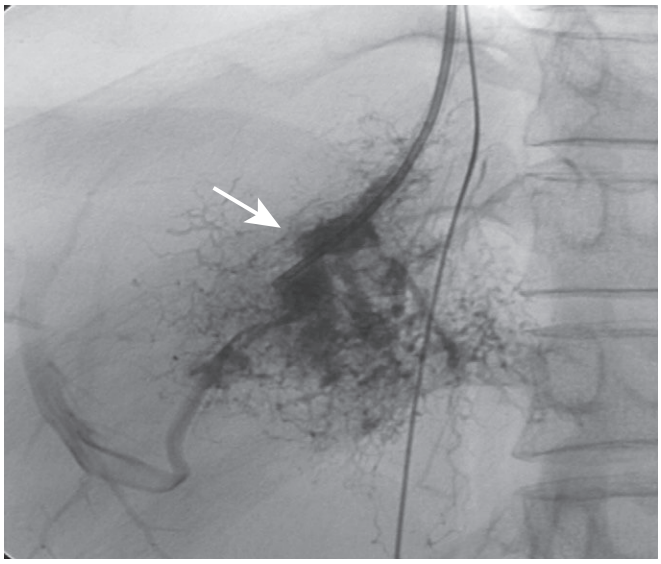

FIGURE 10 Frontal subtracted hepatic venogram in a patient with Budd-Chiari. Hepatic venogram shows the "spider-like" appearance *(arrow)* of multiple small collateral draining veins.

FIGURE 11 Frontal subtracted portal venogram **(A)** via a catheter placed through the middle hepatic vein shows the previously placed right hepatic to right portal vein TIPS *(arrowhead)* to be occluded. Because of this, the patient had recurrent bleeding from gastric varices *(asterisk)*. Repeat portal venogram **(B)** after placement of a parallel TIPS *(arrow)* shows antegrade flow into the right atrium and decompression of the varices. The occluded right hepatic to right portal vein TIPS *(arrowhead)* is medial to the new parallel TIPS *(arrow)*.

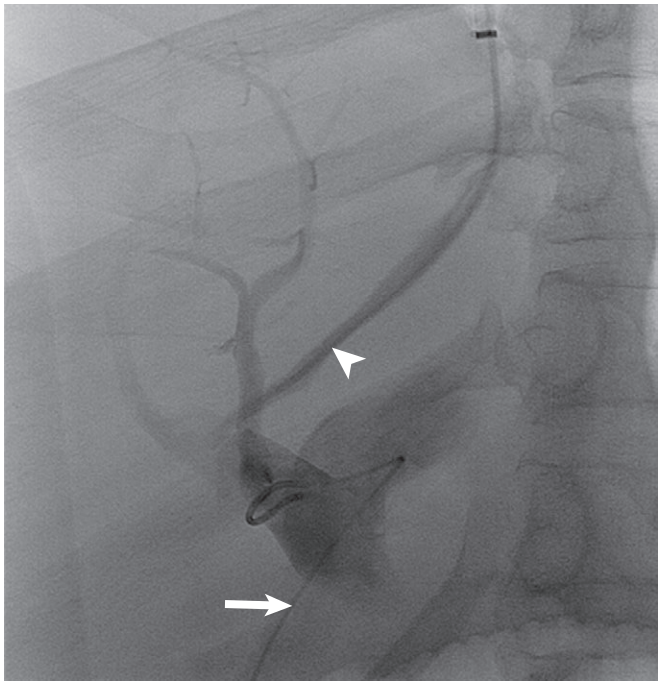

FIGURE 12 Superficially accessible portosystemic collateral vessels can be used to access and opacify the portal venous system for targeting prior to needle advancement. Here, a percutaneously placed transumbilical vein *(arrow)* opacifies the portal branches. A catheter *(arrowhead)* is seen traversing the parenchymal tract between the right hepatic vein and right portal vein.

within the TIPS, or two stents side by side, or even a "waisted" (hourglass-like) stent. If these interventions are not possible or are inadequate, then the entire TIPS can be shut down. TIPS shutdown is a rarely performed and is an advanced procedure beyond the scope of this text.

CLINICAL OUTCOMES

Clinical Response to TIPS

TIPS is the most effective option for treating gastroesophageal variceal bleeding. The rebleeding rate after TIPS placement is 4% per year—the lowest among all treatment options, including endoscopic management. TIPS is reserved after failure of endoscopic management only because of the greater risks associated with it, particularly encephalopathy. Cessation of bleeding is evident almost immediately after TIPS creation.

TIPS has also been shown to be very effective in treating ascites, and it reduces the risk of ascites by 50% to 80% over the life of the patient. Additionally, TIPS has been shown to improve survival and transplant-free survival compared to other treatment options. Resolution of ascites may take up to 4 weeks after TIPS placement.

In patients with hepatorenal syndrome, TIPS improves renal function in 62% of patients. However, it is occasionally difficult to distinguish non–cirrhotic-related chronic renal insufficiency from hepatorenal syndrome.

Complications and Management

The complications related to TIPS are shown in Table 3. The most feared complication is liver failure, which usually results from excessive portohepatic venous shunting in a liver with limited baseline reserve. If patients with no liver reserve are appropriately excluded, the risk of liver failure is 2% to 4%.

Encephalopathy can be seen in up to 12% of patients with compensated liver disease and in up to 50% of patients with noncompensated liver disease. Flagyl and/or lactulose provide significant relief for such patients, but a small percentage (~4%) will not respond and may require TIPS reversal.

Death from sepsis is rare (~4%) but very difficult to treat. Bacteremia results in TIPS stent seeding ("endotipsitis"), which can be very challenging or impossible to treat. Broad-spectrum antibiotics may

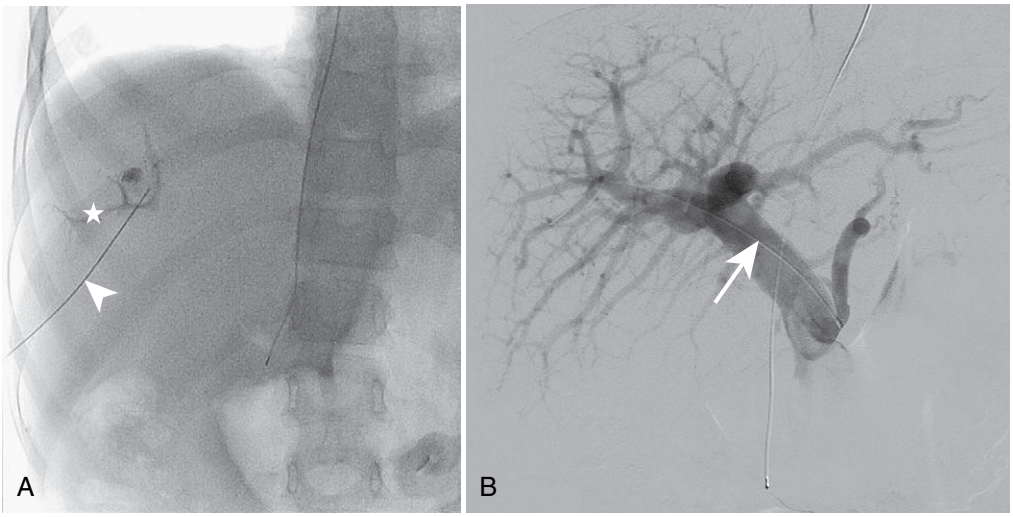

FIGURE 13 In cases where no other option is available, direct percutaneous portal vein access **(A)** can be useful. A needle *(arrowhead)* is placed under ultrasound guidance into the portal venous system, which is then opacified with contrast *(asterisk)*. **B,** A catheter *(arrow)* is advanced into the main portal vein, where a portal venogram is performed and targeted for TIPS creation from the right hepatic vein.

TABLE 3: Complications related to TIPS

Complication	Frequency	Predisposing factors	Mitigating factors
TIPS dysfunction	Occlusion/stenosis: 18%-78% Thrombosis: 10%-15%	Uncovered stents Smaller-diameter stents Stent-migration/suboptimal placement	Choice of stent Precise deployment Venoplasty and/or restenting
Encephalopathy	In compensated liver disease: up to 12% In uncompensated liver disease: up to 50% Requiring TIPS reversal: 4%	History of encephalopathy High ammonia levels Limited reserve Increased age	Reduce or close the TIPS Metronidazole or lactulose
Bleeding	Hemobilia: <5% Intraperitoneal bleeding: 1%-2%	Difficult anatomy Abnormal coagulation profile	Correct coagulation profile
Sepsis	2%-10%	Active infection	Treat infection prior to TIPS
Renal failure	Highly variable	Elevated creatinine Dehydration Diabetes High contrast load	Hydrate Use carbon dioxide contrast
Liver failure/hepatic infarction	2%-4%	Limited reserve High bilirubin Overshunting	Reduce or close the TIPS

TIPS, Transjugular intrahepatic portosystemic shunt.

clear the bacteremia, but in some cases it recurs after cessation of treatment because the seeded stent elutes more bacteria. Active infection is an absolute contraindication to TIPS, and any infection must be cleared prior to intervention.

The overall post-TIPS 30-day mortality ranges from less than 10% to up to 40%. The higher mortality rate is seen in patients with poorly compensated liver disease who are having a TIPS created on an emergent basis, usually for life-threatening variceal bleeding. For patients with compensated liver disease who are having a TIPS created on an elective basis, mortality is less than 5%. It is therefore important to carefully select patients and refer for TIPS placement before it manifests into an emergency.

The Model for End-Stage Liver Disease (MELD) score, routinely used to predict survival in patients with end-stage liver disease and to allocate liver transplants, was initially developed to predict poor survival in patients after creation of a TIPS. The cutoff score for high-risk short-term mortality (expected survival less than 3 months after TIPS creation) in the initial MELD study was 18. The MELDNa

score, which incorporates serum sodium with the serum INR, bilirubin, and creatinine of MELD, has been shown to be a more accurate predictor of risk post-TIPS (MELDNa ≥15). Both versions of the MELD score are more accurate predictors of risk after TIPS than the Child-Pugh score.

Follow-up

TIPS follow-up is mostly based on clinical signs and symptoms. Ultrasound surveillance can be useful. However, false-positive reports (of occluded stent) can result if ultrasound is performed too soon after TIPS creation. The newly placed TIPS has air trapped within it, which limits ultrasound penetration and can simulate the sonographic appearance of an occluded TIPS. Waiting at least 2 weeks after TIPS for the air to be absorbed is generally adequate to avoid this problem. Recurrent variceal bleeding or ascites are a very specific indicator of TIPS restenosis or occlusion and should prompt a diagnostic venogram and/or intervention. There is a 10% rate of reintervention for stenosed or occluded TIPS. The 1-year primary unassisted patency rate for ePTFE covered stents is 80% to 85%. There is no role for the use of uncovered bare metal stents because their restenosis rate after TIPS creation is unjustifiably high.

SUMMARY

The most important determinant of clinical outcomes after TIPS placement is proper patient selection and preparation. Cirrhotic patients with portal hypertension should be under surveillance and should be referred for TIPS after conservative management fails but before the complications of portal hypertension manifest into an emergency. This, along with optimal patient preparation, can help reduce the morbidity and mortality related to TIPS to the lowest possible levels. Additionally, the introduction of expanded polytetrafluoroethylene stents has improved the efficacy and patency rate of TIPS, and many patients survive with a TIPS for many years. The benefits of a TIPS include reduced drop-off risk from the transplant list, improved lifestyle quality (i.e., resolution of ascites), as well as reduction in the many portal hypertension–related complications. But most importantly, TIPS often is a life-saving procedure for those with variceal hemorrhage.

The Management of Refractory Ascites

Nyan L. Latt, MD, and Ahmet Gurakar, MD

INTRODUCTION

Ascites is defined as an abnormal accumulation of fluid in the peritoneal cavity due to portal hypertension, renal function, plasma hydrostatic-oncotic pressure imbalance, and endogenous vasoactive substances. Although cirrhosis of the liver is the primary etiology for more than 80% of patients with ascites, a small portion of ascites can be caused by other conditions such as malignancies (e.g., peritoneal carcinomatosis), infectious causes (e.g., abdominal tuberculosis), congestive heart failure, nephrotic syndrome, hepatic vein obstruction, pancreatic diseases, and miscellaneous disorders of the peritoneum. It is vital to diagnose the cause of ascites initially because the management can be very different, depending on the etiology. For a practicing surgeon, the presence of ascites is particularly important for preoperative risk assessment because most patients with ascites develop severe hepatic dysfunction, poor nutritional status, and electrolyte imbalances, which increase overall perioperative risks.

This chapter provides various pharmacologic and surgical treatment options and the rationale behind them in the management of refractory ascites. The pathophysiology of ascites and diagnostic modalities are briefly discussed to provide a better understanding of the different therapeutic approaches.

PATHOPHYSIOLOGY

The first hypothesis of ascites formation was the "backward theory" in early 1960s, in which portal hypertension and hypoalbuminemia lead to excessive splanchnic lymph formation, which causes the thoracic duct to flow backward to the heart and then extravasate into the peritoneal space. The backward flow theory was discredited later when it was found that systemic vasodilatation, caused by decreased systemic vascular resistance secondary to increased plasma volume and cardiac output. The "overflow theory," again, was dismissed later when studies showed that angiotensin-II blockade induced a significant reduction of the wedged hepatic venous pressure without any change in the hepatic blood flow. This finding suggests that arterial vasodilation is not systemic but rather confined to the regional splanchnic circulation.

The currently accepted hypothesis for the mechanism of ascites in cirrhosis is the "peripheral arterial vasodilation" theory. The primary causative effect is sinusoidal portal hypertension secondary to progressive hepatic fibrosis. Portal hypertension induces the release of nitric oxide and vasodilator peptides, which causes the splanchnic arterial vasodilation. The arterial vasodilation in the splanchnic circuit leads to reduced effective arterial blood volume, which activates vasoconstrictors and sodium-retaining systems, resulting in renal sodium retention. Therefore, high sodium concentration increases splanchnic capillary permeability and causes ascites formation.

Refractory Ascites

Ascites that are not responsive to sodium restriction and maximal diuretic therapy are called refractory ascites. The responsiveness to therapy is determined by weight loss and the negative balance of sodium. Ascites of patients who develop complications such as hepatic encephalopathy, renal insufficiency, and hyponatremia after diuretics therapy are also considered refractory. Refractory ascites represent less than 10% of all ascites.

Diagnosis of Ascites

All patients with new-onset ascites or all patients with known ascites on admission should get diagnostic paracentesis because 10% to 25% of these patients can present with spontaneous bacterial peritonitis (SBP) without overt clinical signs and symptoms.

Analysis of ascitic fluid can help determine the etiology of the underlying conditions as well as detect causative microorganisms in infectious processes. Cell counts, gram stains, cultures, albumin, total protein, glucose, and LDH from ascitic fluid should be sent to the laboratory for analysis. Triglyceride levels should be added in suspected cases of chylous ascites. Cytology should be sent in suspected malignancies. Serum albumin, total protein, and LDH should be sent at the same time to compare serum-ascitic gradients. Testing serum for CA-125 is not necessary to make a diagnosis of ascites. Its use is not recommended in patients with ascites of any type.

To determine the etiology of ascites, the current recommendation is to calculate the serum-ascites albumin gradient (SAAG) rather than differentiate transudates from exudates. SAAG is based on the plasma oncotic-hydrostatic pressure balance and is directly related to portal pressure.

$$\text{SAAG} = \text{Serum albumin} - \text{Ascitic albumin}$$

The etiologies of ascites, according to SAAG, are shown in Table 1.

Paracentesis

Although most cirrhotic patients have prolonged prothrombin time and thrombocytopenia, there is no evidence supporting significant bleeding from paracentesis in this population. Routine transfusion of platelets or fresh frozen plasma is not recommended to perform paracentesis. The major contraindication for paracentesis is disseminated vascular coagulopathy (DIC).

The preferred site for needle entry is 3 cm medial and 3 cm superior to the anterior superior iliac spine on the left lower quadrant of the abdomen. The midline approach is not preferable because many patients are obese. The right lower quadrant also is not desirable because cecum can become distended in patients who take lactulose. The distended cecum has a higher risk of perforation. The needle should not be inserted in areas with cutaneous infection, abdominal wall hematoma, scars, or visibly engorged subcutaneous veins. Bedside ultrasound, if available, is useful, especially in ascites accumulated in compartments.

The paracentesis needle can be inserted by using either the angular technique or the Z-track technique. In the angular technique, the needle is inserted obliquely from the cutaneous site into the peritoneum. In Z-track, cutaneous tissues are pulled down, and the needle is inserted straight into the peritoneum. The purpose of these techniques is to ensure that cutaneous and peritoneal sites do not directly overlap each other, thereby minimizing ascetic fluid leakage (Figure 1).

Treatments of Ascites

The pathophysiology of ascites formation from cirrhosis is due to renal retention of sodium and water. Therefore, the goal of the treatment is to mobilize the ascitic fluid by creating a net negative balance

TABLE 1: Etiologies of ascites with or without portal hypertension

SAAG ≥1.1 g/dL: portal hypertension	SAAG <1.1 g/dL: no portal hypertension
• Cirrhosis • Alcoholic hepatitis • Vascular obstructions (Budd-Chiari syndrome or portal vein thrombosis) • Congestive heart failure • Metastasis to liver • Fatty liver disease of pregnancy • Myxedema	• Peritoneal carcinomatosis • Nephrotic syndrome • Pancreatitis • Peritoneal tuberculosis • Serositis

of sodium. Net negative sodium balance can be achieved with decreasing sodium intake and increasing sodium secretion. Urinary sodium excretion in cirrhosis plays a role as a prognostic factor. While spot Ur Na^{++} less than 10 mg/dL represents only 20% in 2-year survival, Ur Na^{++} over 10 mg/dL represents 60% in 2-year survival among cirrhotic patients. The treatment of low-SAAG ascites should concentrate on underlying causes.

Nonpharmacologic Therapies

Dietary Sodium Restriction

Restriction of dietary sodium intake is one of the most important nonpharmacologic treatments of ascites because renal sodium retention is the key contributing factor of ascites formation. When sodium intake surpasses urinary and insensible losses of sodium, net positive sodium balance retains extra fluid, causing ascites and peripheral edema. The goal is to create a negative net balance of sodium, thereby contracting extracellular fluid volume. Fluid restriction is not necessary in patients with cirrhosis who are on diuretic therapy and sodium restriction.

A typical American diet usually contains 4 to 6 g of sodium per day. About one third of this sodium comes from salt, another one third comes from processed foods, and the rest is from water and other foods (meat, vegetables, etc.). Daily sodium restriction of 1.5 to 2 g is recommended. One teaspoon of table salt contains 2300 mg of sodium, which is more than the recommended daily sodium intake. It is very important for patients not to add any salt to their food at all. Staying away from all processed foods is also essential because processed foods contain a lot of sodium for preservation. Patients should be instructed to replace processed meats and vegetables with fresh or frozen and also to avoid eating at fast-food restaurants because processed food is their main ingredient.

Patients should keep a record of what they eat, including portion size and sodium content. Patients should weigh themselves and record their weight every day as well. Compliance is the most important part of this treatment because most patients fail to stick to a low-sodium diet. The progress of treatment can simply be monitored with daily weight, but there are objective measures to prove noncompliance in patients. Although the most accurate measurement is 24-hour urinary sodium, it is not practical to obtain, especially in outpatient settings. On the other hand, a spot urinary sample can easily be collected. It has been shown that a spot urinary Na^+/K^+ ratio of greater than 1 represents 24-hour sodium intake of greater than 2 g, indicating noncompliance. In such patients, nutrition counseling with a registered dietitian referral might be helpful.

In cirrhosis, only 15% to 20% of patients can achieve negative sodium balance by restricting dietary sodium intake, without diuretics. Therefore, diuretic therapy should be started on these patients, along with sodium restriction from the beginning of treatment.

Fluid Restriction

Restriction of daily fluid intake to 1 to 1.5 L per day is usually not necessary in patients with ascites because an adequate negative sodium balance can help eliminate excess free water. The only benefit of fluid restriction can be observed in patients with profound hyponatremia—that is, serum Na^+ less than 125 mg/dL.

Pharmacologic Therapies

Diuretics

Most patients with cirrhosis need to take diuretic agents to control their ascites in addition to dietary sodium restriction. Diuretics increase renal sodium excretion, thereby achieving net negative sodium balance and eliminating excess fluid accumulated in extracellular spaces. The most commonly used diuretics are potassium-sparing aldosterone antagonists (e.g., spironolactone or amiloride) and loop diuretics (e.g., furosemide).

There are two strategies of treating ascites with diuretic agents. The first regimen begins with an aldosterone antagonist alone. The dose of spironolactone is increased every week to its maximal dose until the clinical response is achieved. If there is no response after maximal dose of spironolactone, furosemide should be added, and its dose should be increased every week. In the second approach, both spironolactone and furosemide are started as a combination from the beginning of treatment, and the doses are increased weekly with regard to clinical response and measurement of urinary sodium excretion. Studies have shown that there is no significant difference in terms of efficacy and incidence of complications between these two regimens.

The doses of diuretics are generally higher than doses started for hypertension or heart failure. The starting doses of spironolactone and furosemide are 100 mg and 40 mg per day, and the maximal doses are 400 mg and 160 mg per day, respectively. The therapeutic response can simply be monitored with daily weight. The goal of effective diuresis is losing 2 pounds per day in patients with peripheral edema and 1 pound per day without edema because the highest absorptive capacity of the peritoneal cavity is approximately 0.5 L per day. Overdiuresis can induce severe electrolyte imbalances and renal failure. A spot urinary Na^+/K^+ ratio of greater than 1 has a 90%

sensitivity in predicting a negative balance (>78 mmol/day sodium excretion).

The advantages of using aldosterone antagonists and loop diuretics together are counterregulatory effect on potassium reabsorption, greater natriuretic potency, and earlier onset of diuresis. Thiazide diuretics are not recommended, in general, despite their synergistic effect in blocking sodium reabsorption in distal tubules when used together with loop diuretics. Thiazides plus loop diuretics can cause significant hypokalemia and hyperammonemia via various mechanisms. In cirrhosis, hyperammonemia can result in hepatic encephalopathy. In individuals who develop gynecomastia due to spironolactone use, amiloride can be substituted. Other loop diuretic agents, such as torsemide and bumetanide, can also be used safely and effectively in cirrhotic patients with ascites. Diuretic agents should be discontinued when there are diuretic-induced complications, such as severe hyponatremia (serum Na^+ <120 mg/dL), renal failure, or hepatic encephalopathy.

Albumin

Hypoalbuminemia is a common complication of liver failure in cirrhosis because albumin is mainly synthesized in the liver. Albumin is a plasma volume expander, and it plays a crucial role in maintaining plasma oncotic pressure. On the other hand, as mentioned above, the pathogenesis of ascites is due to increased splanchnic arterial vasodilation, causing decreased effective plasma volume. In addition, intravenous albumin has a short half-life, and it is not cost-effective. Therefore, albumin should not be used routinely in the management of ascites. On the other hand, albumin infusions are very effective in preventing renal dysfunction associated with spontaneous bacterial peritonitis. Recently, concomitant use of albumin and vasoconstrictors has been shown to improve circulatory hemodynamics, renal function, and control of ascites.

Vasoconstrictors

Vasoconstrictors have been used in the management of hepatorenal syndrome and the prevention of hemodynamic instability after large volume paracentesis (LVP), along with albumin. Recent studies have shown that the use of vasoconstrictors in cirrhotic patients with preserved renal function improves sodium excretion, circulatory function, and ascites control. Various vasopressors have been studied for this purpose. Octreotide, a somatostatin analogue, can cause splanchnic vasoconstriction and improve renal perfusion. Midodrine, an α_1-receptor agonist, can also be used along with octreotide and albumin. A randomized pilot study showed that midodrine plus standard medical therapy (sodium restriction, diuretics, and large volume paracentesis [LVP]) is superior to standard medical therapy alone for the control of ascites without any renal or hepatic dysfunction. Terlipressin, a vasopressin derivative, also induces splanchnic vasoconstriction and can be used to control ascites. Although terlipressin is not available in the United States, it has been widely used for hepatorenal syndrome in Europe and other parts of the world. A recent study showed that terlipressin plus diuretics and albumin might improve the outcomes of refractory ascites by increasing urinary sodium excretion and decreasing the need for LVP (Table 2).

Interventional Therapies

Patients with ascites, which are refractory to nonpharmacologic treatment options, often require additional interventional approaches to control their ascites. Interventional therapies include serial LVP, a transjugular intrahepatic portosystemic shunt (TIPS), a peritoneovenous shunt, and, ultimately, liver transplantation.

Large Volume Paracentesis

LVP, or therapeutic paracentesis, has been used in the management of cirrhosis patients with ascites for centuries, long before the discovery of diuretic agents. In LVP, 4 to 5 liters of ascitic fluid are removed. Randomized controlled trials have demonstrated that LVP can be performed safely and effectively every 2 weeks, even in patients with minimal urine sodium excretion. It can be performed either in an outpatient clinic or in a hospital setting. One controversy that has erupted over LVP is postparacentesis albumin infusion. Many studies have failed to reveal that albumin infusion after LVP has mortality or morbidity benefits, while significant improvements have been observed in electrolyte imbalances, plasma rennin, and creatinine levels. Since albumin is very expensive, it is not cost-effective to use routinely after LVP of 4 to 5 liters. In cases of larger amounts of ascitic fluid removal (i.e., 6 to 8 liters), however, albumin infusion should be considered to maintain homeostatic fluid balance.

Transjugular Intrahepatic Portosystemic Shunts

Although TIPS was pioneered by Dr. Josef Rosch in 1969, it was not in clinical practice until the late 1990s due to technical difficulties. Later, TIPS was used to decrease portal hypertension in the management of refractory variceal hemorrhage. However, it was found that

TABLE 2: Summary of medical therapy for refractory ascites

Category and action	Drugs	Dose	Remarks
Diuretics			
Aldosterone antagonist	Spironolactone	100 mg to 400 mg PO daily	Monotherapy or combination with furosemide
Epithelial sodium channel blocker	Amiloride	10 mg to 40 mg PO daily	Substitute for spironolactone in cases with gynecomastia
Loop diuretics (torsemide and bumetanide can be used)	Furosemide	40 mg to 160 mg PO daily	Combination with spironolactone
Vasoconstrictors			
Somatostatin analogue	Octreotide	300 mcg twice daily SQ	Can be used in combination with midodrine
α_1-receptor agonist	Midodrine	7.5 mg three times daily PO	Can be used in combination with octreotide and albumin infusion

PO, By mouth; *SQ,* subcutaneous.

TIPS might benefit in eliminating refractory ascites by means of increasing natriuretic effects. The TIPS procedure is essentially done by interventional radiologists in the United States, while some hepatologists perform TIPS in Europe. During the TIPS procedure, a shunt is created between the hepatic vein and the portal vein from a percutaneous jugular venous approach. A stent is then deployed across the shunt to maintain its patency. The major indications for TIPS placement are refractory ascites requiring LVP more frequently than every month, refractory variceal bleeding, and as a bridge to liver transplantation. The absolute contraindication for TIPS placement is worsening hepatic encephalopathy (Figure 2).

Recently, new synthetic fluoropolymer-covered stents have been used in TIPS procedures. A randomized trial showed that polytetrafluoroethylene-coated stents yielded more than twice the duration of patency of metal stents in 1 year. Meta-analyses have established that TIPS can provide better control of ascites and possible improvement in survival, although there are higher rates of hepatic encephalopathy. Reinitiating and titrating up the doses of diuretic agents in post-TIPS patients are reasonable because better natriuresis can be achieved after portal hypertension has been reduced.

Because favorable outcomes have been shown in recent studies, it is recommended that TIPS be performed earlier as a first-line treatment for acute and recurrent variceal bleeding in patients who have hepatic venous pressure gradients higher than 20 mm Hg. Additional benefits of TIPS are potential improvements in nutrition, body mass index, and quality of life in severely malnourished patients with end-stage liver disease.

Peritoneovenous Shunts

A peritoneovenous shunt (PVS) is a shunt that drains ascitic fluid from the peritoneal cavity to the systemic veins such as the internal jugular vein or the superior vena cava. It lies underneath the skin and runs from the abdomen to the upper part of the body. PVSs (also known as LeVeen shunts and Denver shunts) were introduced in the 1970s and were widely used until the late 1980s. Currently, PVSs are not used in clinical practice due to higher rates of complications and the development of newer and safer techniques such as TIPS. The complications associated with a PVS are obstructions (40% of shunt failure in first year) due to kinking/clogging of the shunts and thrombosis, serious infections such as peritonitis and bacteremia,

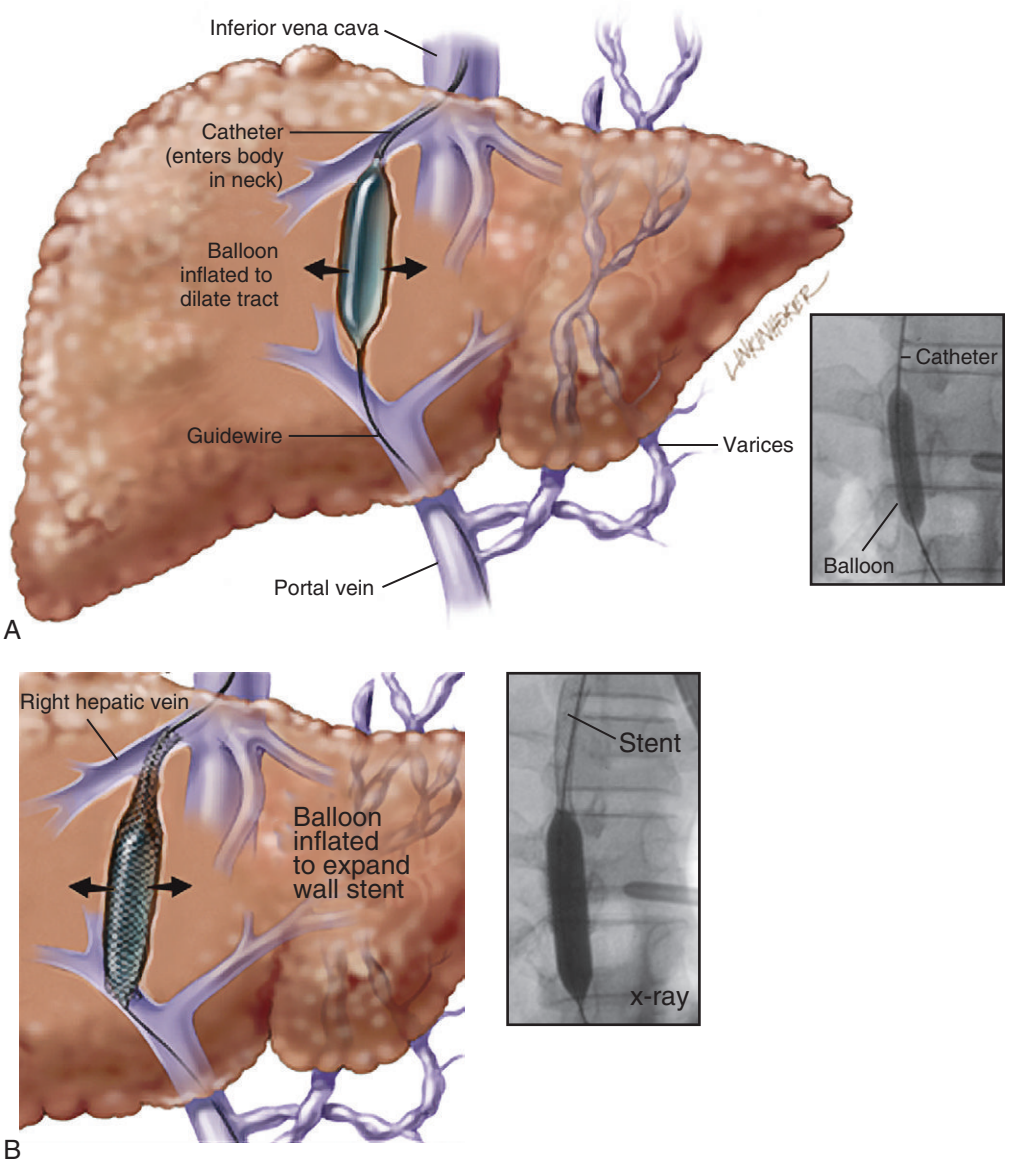

FIGURE 2 Transjugular intrahepatic portosystemic shunt placement. *(From Johns Hopkins Medical Institutions, used with permission.)*

postshunt coagulopathy leading to DIC, pulmonary edema, and increased risk of variceal bleeding secondary to increased venous return and hepatic encephalopathy.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is an infection of the peritoneum that spontaneously occurs without any overt source that can be remedied surgically. It is a common complication in patients with portal hypertension and ascites. Approximately 30% of cirrhotic patients with ascites develop SBP, and it is associated with a 20% mortality rate. All hospitalized patients with ascites must have paracentesis for ascitic fluid analysis because clinical signs and symptoms are not sufficient to diagnose SBP. Patients with a previous normal ascitic fluid analysis who later develop abdominal pain, fever, encephalopathy, leukocytosis, or renal failure should have repeat paracentesis. Treating SBP only with empiric antibiotics, without a definitive bacterial culture, is not recommended because it can lead to inadequate therapeutic response and increased resistance of microorganisms.

Treatment of SBP

Ascitic fluid with absolute neutrophil counts more than 250 cells/mm^3 is diagnostic for SBP. Empiric antibiotics need to be initiated as soon as possible before the result of bacterial culture is available. Most ascitic fluid culture will grow specific microorganisms, and the antibacterial therapy should be narrowed down. Patients who have negative culture results but have suspicious clinical symptoms of SBP should also be empirically treated with antibiotics. The recommended antibiotic therapies are summarized in Table 3.

Studies have shown that a decrease in mortality was observed in some patients with SBP who received intravenous albumin infusion along with empiric antibiotics. Current guidelines support giving 1.5 g/kg of albumin infusion within 6 hours of SBP diagnosis and 1.0 g/kg of albumin infusion on day 3 in patients with SBP who also have blood urea nitrogen less than 30 mg/dL, serum creatinine over 1 mg/dL, or total bilirubin less than 4 mg/dL.

Patients with ascites may also develop secondary peritonitis involving bowel perforation or intra-abdominal abscess. Clinical signs and symptoms are not helpful in distinguishing secondary peritonitis from SBP, although SBP infection can sometimes present with mild symptoms. It is recommended to perform ascitic fluid analysis for total protein, LDH, and glucose to assist in determination of secondary peritonitis. Elevated ascitic fluid absolute neutrophil counts (in thousands), multiple organisms on gram stains and cultures (including fungi and enterococcus), ascitic fluid total protein over 1 g/dL, ascitic fluid LDH more than half of the upper limit of the serum, and ascitic fluid glucose less than 50 mg/dL are suggestive of secondary peritonitis with 100% sensitivity and 43% specificity. These patients should be evaluated immediately with emergent abdominal x-rays and computed tomographic scanning to look for signs of intra-abdominal perforations or abscesses.

SBP Prophylaxis

Secondary prophylaxis with daily norfloxacin or trimethoprim-sulfamethoxazole is recommended in patients with ascites after the first episode of SBP. Primary prophylaxis for SBP in patients with cirrhosis and ascites is still controversial. Current guidelines support giving primary prophylaxis with oral norfloxacin to patients with ascitic fluid protein less than 1.5 g/dL and at least one of the following: serum creatinine over 1.2 mg/dL, blood urea nitrogen over 25 mg/dL, serum sodium below 130 mEq/L, or Child-Pugh over 9 with serum total bilirubin over 3 mg/dL. In patients with prior SBP who develop acute upper gastrointestinal bleeding, intravenous ceftriaxone therapy for 7 days is recommended. The antibiotic therapy for SBP prophylaxis is summarized in Table 3.

TABLE 3: Summary of treatment and prophylaxis in spontaneous bacterial peritonitis

Antibiotics	Route and dosages
Empiric Antibiotics	
First-Line Therapies	
Cefotaxime	2 g IV every 8 hours (or)
Ofloxacin (patients with mild infection with no shock, vomiting)	400 mg PO every 12 hours
Second-Line Therapies	
Ceftriaxone	1 g IV every 12 hours (or)
Ciprofloxacin	400 mg IV every 12 hours (or)
Piperacillin-tazobactam	3.375 g IV every 6 hours (or)
Ertapenem	1 g IV every day for resistant pathogens (or)
Cefepime	1-2 g IV every 8 hours for resistant pathogens (or)
Prophylactic Antibiotics	
First-Line Therapy for Patients with GI Bleeding	
Ceftriaxone	1 g IV every day for 7 days
Secondary-Line Therapy for Patients with GI Bleeding	
Norfloxacin	400 mg PO every 12 hours for 7 days
Daily Primary Prophylaxis	
Norfloxacin	400 mg PO every 12 hours (or)
Trimethoprim-sulfamethoxazole	1 double-strength tablet PO every day

Hepatic Hydrothorax

Hepatic hydrothorax is a development of pleural effusion in a cirrhotic patient with portal hypertension, without any underlying cardiopulmonary diseases. It commonly presents on the right side, but left-sided and bilateral involvements can also be seen. The likely mechanisms for pathogenesis of hepatic hydrothorax are hypoalbuminemia, which reduces plasma osmotic pressure, azygos veins hypertension, transdiaphragmatic migration of ascitic fluid via lymphatic systems, and ascitic fluid leakage via diaphragmatic defects. Hepatic hydrothorax may occur in the absence of ascites. As in ascites, all patients who present with hepatic hydrothorax or pleural effusion with unclear etiology should have a diagnostic thoracentesis. Hepatic hydrothorax typically presents with transudative pleural effusions.

However, as in ascites and SBP, hepatic hydrothorax can become infected spontaneously, called spontaneous bacterial empyema (SBEM). In this case, the pleural fluid analysis becomes exudative. The diagnostic criteria for SBEM are serum-pleural albumin gradient over 1.1 g/dL, pleural fluid neutrophil counts over 500/mm^3, with the

absence of pneumonia or contiguous infectious process on chest radiography. SBEM occurs as a result of a direct microbial spread from the pleural cavity in the presence of portal hypertension. Rarely, SBEM can develop without clinically significant ascites. All patients with hepatic hydrothorax who develop fever, chest pain, dyspnea, and encephalopathy should have repeat thoracentesis to evaluate pleural fluid analysis.

The management of hepatic hydrothorax is basically the same as with refractory ascites. The conservative management includes sodium restriction and diuretic therapy. In refractory cases, therapeutic thoracentesis, TIPS, and peritoneovenous shunting can be performed. Tube thoracostomy with injection of a sclerosing agent can be a long-term management, but the evidence for its efficacy is not validated. In patients with documented SBEM, third-generation cephalosporins such as ceftriaxone (1 g intravenously daily for 10 days) can be given empirically. An antibacterial regimen should be narrowed down as soon as the results of bacterial cultures are obtained.

Hepatic hydrothorax is a late and serious complication of cirrhosis. Patients with hepatic hydrothorax generally have end-stage liver disease, and these individuals should be evaluated for liver transplantation.

The Management of Hepatic Encephalopathy

David Victor, MD, and Ayman A. Koteish, MD

OVERVIEW

Hepatic encephalopathy (HE) is a complex, potentially reversible, neuropsychiatric syndrome observed in patients with cirrhosis or acute liver failure. Patients with HE may have symptoms ranging from subtle abnormalities, detectable only through specialized psychological testing, to frank coma. Generally accepted stages for the broad spectrum of clinical manifestations of encephalopathy are based on level of consciousness, cognitive function, behavioral disturbances, and neuromuscular features (Table 1). In milder cases, the encephalopathic patient may be unaware of any deficits, and symptoms such as sleep pattern reversal, mild confusion, irritability, or personality changes may be apparent only to close contacts. Consequently, it is often helpful to obtain a history from a cirrhotic patient in the presence of family members.

HE remains largely a clinical diagnosis; no specific signs, symptoms, or laboratory test results are diagnostic of this disorder. The symptoms commonly associated with HE also occur in other conditions, such as hypoglycemia, head trauma, and intoxication. Asterixis, a flapping tremor of the outstretched hands, is a common feature of HE but also occurs in other metabolic encephalopathies. Elevated plasma levels of ammonia are common but not universal in HE, and the level of blood ammonia concentration is not always correlated with the severity of encephalopathy. Electroencephalography testing results are always abnormal in overt HE, but observed changes, such as triphasic waves, are not specific. Focal neurologic deficits such as hemiplegia or hemiparesis are observed in fewer than 20% of patients with HE, and seizures are rarely observed. Consequently, other causes of altered mental status must be ruled out before the diagnosis of HE is confirmed, and any focal neurologic deficiency should prompt central nervous system (CNS) imaging to rule out structural lesions.

PATHOPHYSIOLOGY

The pathogenesis of HE is multifactorial, and despite extensive research in both humans and animals, it remains unclear. The basic tenet of most hypotheses is that the brain is exposed to toxic substances produced in the gut by the actions of bacteria on nitrogenous compounds, which are incompletely cleared from the blood by the compromised liver. Ammonia was the first such substance described and has been the most extensively studied. There is compelling evidence that ammonia is an important pathogenetic factor in HE. Most patients with overt HE exhibit elevated plasma levels of ammonia, and children with urea cycle enzyme deficits and otherwise normally functioning livers develop profound hyperammonemia and symptoms indistinguishable from those of HE.

Ammonia can affect CNS function through several mechanisms. After crossing the blood–brain barrier, ammonia enters CNS astrocytes and combines with the neurotransmitter glutamate to form glutamine through the action of glutamine synthetase. Astrocytic glutamine enters mitochondria, in which it is converted back to ammonia and glutamate. Mitochondrial ammonia contributes to the production of reactive oxygen species and upregulates aquaporin 4. This results in astrocytic swelling that causes histologic changes known as *Alzheimer type II astrocytosis.* Adverse effects of ammonia on cerebral perfusion and glucose metabolism additionally contribute to CNS impairment. There is evidence that γ-aminobutyric acid (GABA), the primary inhibitory neurotransmitter in the CNS, may also play an important role in the pathogenesis of HE. Increased GABA levels have been associated with liver injury and hyperammonemia. Increased production of endogenous benzodiazepine ligands by gut bacteria can result in increased GABAergic transmission and altered CNS function. This explains why some patients with HE respond to the benzodiazepine antagonist flumazenil even in the absence of exposure to exogenous benzodiazepines.

Other substances, such as mercaptans and neurosteroids, and manganese toxicity may also contribute to neuronal and astrocytic

TABLE 1: Clinical manifestations and severity of hepatic encephalopathy

Encephalopathy stage	Level of consciousness	Cognitive function	Behavioral disturbance	Neuromuscular feature
I (mild)	Abnormal sleep pattern	Shortened attention span, mildly impaired computations	Euphoria, depression, irritability	Tremor, muscular incoordination, impaired handwriting
II (moderate)	Lethargy, mild disorientation	Amnesia, grossly impaired computations	Overt change in personality, inappropriate behavior	Slurred speech, asterixis (flapping), hypoactive reflexes, ataxia
III (severe)	Somnolence, semistupor	Inability to compute	Paranoia, bizarre behavior	Hyperactive reflexes, nystagmus, Babinski sign, clonus, rigidity
IV (coma)	Stupor, unconsciousness	None	None	Dilated pupils, opisthotonus, coma

Modified from Conn H, Lieberthal M: The hepatic coma syndromes and lactulose, *Baltimore, 1979, Williams & Wilkins.*

injury in HE. In all likelihood, these factors have varying influences in individual patients, depending on the cause, acuity, and severity of the liver disease and hence the variable manifestations of HE.

BOX 1: Precipitating factors in hepatic encephalopathy

Gastrointestinal bleeding
Sedatives or analgesics
Dehydration
Renal failure
Hypokalemia
Metabolic alkalosis
Infection (spontaneous bacterial peritonitis, pneumonia, urinary tract infection)
Excessive dietary protein
Constipation

CLASSIFICATION AND MANAGEMENTOF HEPATIC ENCEPHALOPATHY

HE can be classified according to the underlying disorder that leads to it. It is associated with cirrhosis and portal hypertension, the presence of shunts, and, more ominously, acute liver failure. In practice, HE is classified as overt encephalopathy, minimal HE, and encephalopathy associated with acute liver failure.

Overt Encephalopathy

HE is a common complication of cirrhosis and can be episodic, developing over a short period of time with fluctuations in severity, or it can be persistent, with continuous overt neurologic or behavioral abnormalities. In most patients with episodic encephalopathy, a precipitating factor other than liver disease can be identified (Box 1).

Gastrointestinal bleeding is a very common precipitant of HE. This occurs through a combination of decreasing hepatic and renal perfusion and a large protein load to the gut, which results in increased production of nitrogenous byproducts. Evaluation of gastrointestinal blood loss and control of active bleeding must be performed in all patients with episodic HE. Infection is also a common precipitating factor for HE. The clinician must search for a source of infection. Cirrhosis can make the signs of infection less apparent. The baseline neutropenia and impaired response to infection can obscure the source of infection. The authors recommend a basic workup for infectious disease and that patients with overt HE and ascites undergo a diagnostic paracentesis to rule out spontaneous bacterial peritonitis. If there is a high index of suspicion for infection, empiric antibiotic therapy should be started after culture samples have been obtained. Many cirrhotic patients take diuretics; intravascular volume depletion from vigorous diuresis can reduce renal perfusion and result in azotemia and increased ammonia production. A hypokalemic alkalosis can enhance renal ammonia production, thereby precipitating HE. Reestablishing intravascular volume and correcting electrolyte imbalances often reverses encephalopathy. Exposure to sedatives and analgesics, especially benzodiazepines, can potentiate the effects of putative neurotoxins in HE and should be avoided. In postoperative or critical care settings, HE is often blamed for the prolonged effects of sedation in patients with cirrhosis. In such patients, use of sedatives should be minimized as much as possible, and clinicians must be aware that these drugs may have prolonged effects.

Treatment for overt HE is designed to treat the inciting factors. If this is insufficient, then modulating the gut bacteria with medication is the mainstay of treatment. The medications used reduce the gut production of ammonia through a variety of mechanisms. Despite maximal medical therapy, HE is refractory in some patients. The medications used for treatment of overt HE are used for all types of HE but are best understood in the context of overt HE.

Oral Disaccharides

For many years, the nonabsorbable disaccharides lactulose and lactitol have been the mainstay of therapy for HE. Theoretically, lactulose increases ammonia clearance through its cathartic action and decreases ammonia absorption by increasing the stool pH. Many affected patients have an improvement in symptoms of HE within hours of lactulose administration. These agents improve symptoms of encephalopathy, but they do not reduce the mortality rate. Despite the limitations, these treatments are the "gold standard" of therapy for HE. Lactulose is typically administered orally and in multiple doses each day. The dosing schedule should be individualized for the patient to achieve three to five bowel movements per day. Excess bowel movements as a result of these agents can actually precipitate episodes of HE, probably through dehydration and electrolyte

abnormalities. The side effects of these agents (bloating, nausea, flatus, diarrhea, abdominal pain) dramatically limit their use in many patients. In view of the transient changes in the gut from these medications, noncompliance with the therapy results in return of HE symptoms. When these drugs are used, patient education and monitoring are paramount in trying to ensure compliance.

In a patient with acute or worsened overt HE, administration of these agents should be carefully monitored because excessive administration can lead to significant bloating if the patient is not having bowel moments. This results from the consumption of the compound by the gut bacteria, which leads to bloating and further stasis of the gut. For patients unable to take lactulose orally, it can be administered per rectum as a retention enema (300 mL of lactulose with 700 mL of water).

Dietary Protein Restriction

The potential association between dietary protein intake and encephalopathy was first described decades ago. In theory, reducing dietary protein intake should reduce nitrogenous toxin production. Although improvement may occur in individual encephalopathic patients with dietary protein restriction, this benefit has been difficult to demonstrate in controlled trials. In fact, in several studies of severe acute alcoholic hepatitis, the administration of high-protein/high-calorie diets improved rather than exacerbated encephalopathy. In addition, protein restriction to less than 40 g/day can accelerate catabolism and contribute to malnutrition. In practice, monitoring for changes in HE is best in patients on a regular-protein diet.

Low-Absorbable Antibiotics

Suppression of toxin production by gut bacteria is the basis for the use of poorly absorbed antibiotics. In numerous clinical trials, researchers have assessed the efficacy of various antibiotics in patients with different classes of encephalopathy. Neomycin and metronidazole were classically used to treat HE; however, the side effects of these medications have limited their use. Limited effectiveness is noted with oral vancomycin.

Rifaximin, a derivate of rifamycin, was originally developed to treat traveler's diarrhea and has broad-spectrum activity against gram-negative rods and gram-positive cocci. Several studies show that rifaximin is equal to if not better than oral disaccharides in patients with both overt and minimal encephalopathy. Concerns about possible bacterial overgrowth or fungal colonization are unfounded. Rifaximin has been shown effective in long-term treatment of HE with minimal side effects. There is a theoretical risk of bacterial overgrowth and associated infections with long-term use of rifaximin, but this has not been confirmed in studies. In patients with intolerance to oral disaccharides, it is the medication of choice, and for some patients, its lower side effect profile makes it the primary medication for treatment of HE. The U.S. Food and Drug Administration approved the use of rifaximin for the reduction in the risk of the recurrence of overt HE in patients with advanced liver disease. The recommended dosage is 550 mg by mouth twice per day. The medication is effective in treating acute HE and maintaining a response to prevent overt HE. Rifaximin remains expensive, however, and patients are often unable to afford the medication in the long term. In practice, the combination of lactulose and rifaximin is known to be additive in its effect in some patients.

Other Therapies

Sodium benzoate combines with ammonia to produce hippurate, which is renally excreted. In limited trials, it compares favorably with lactulose. L-ornithine L-aspartate increases hepatic conversion of ammonia and is better than placebo at lowering plasma ammonia levels and improving encephalopathy grade. Flumazenil, a benzodiazepine antagonist, showed improvement in encephalopathy grade but is not approved for this indication by the U.S. Food and Drug Administration. Zinc lowers plasma ammonia by increasing ornithine transcarbamylase activity, but its benefits in HE have been inconsistent. Branched-chain amino acids in several different formulations improve symptoms but not length of survival, and they are relatively expensive. Trials of probiotics, which are live organisms that confer a benefit on health, have yielded mixed results for benefit in treating encephalopathy. A meta-analysis suggested that probiotics might be beneficial in the treatment of HE. The evidence remains limited as to their effectiveness.

Hepatic Encephalopathy Associated With Acute Liver Failure

HE is a prominent and ominous component of acute liver failure, but it differs from that observed in cirrhosis and portal hypertension. Although marked hyperammonemia can occur in both disorders, cerebral edema with intracranial hypertension is common in acute liver failure but rarely occurs in chronic liver disease. The risk of cerebral edema is correlated with the encephalopathic grade in acute liver failure. It is very low in grades 1 and 2 HE but progresses to 35% in grade 3 HE and 75% in grade 4 HE. The reason for this association with acute liver failure is not entirely clear, because the consequences of hyperammonemia on cerebral function should be similar in acute and chronic liver disease. Some authorities have proposed that markers of systemic inflammation commonly observed in acute liver failure may be a contributing factor. Excess free water with hyponatremia may exacerbate ammonia-induced cerebral edema.

Accurately assessing intracranial pressure (ICP) on clinical grounds is difficult. Physical findings such as papillary changes, abnormalities in the oculovestibular reflex, and decerebrate posturing are indicators of intracranial hypertension but often are apparent only at an irreversible stage. Consequently, some medical centers advocate the use of invasive monitoring devices, which accurately measure ICP. However, there is significant risk in monitoring in patients with acute liver failure and related coagulopathy. Patients with acute liver failure who develop grade 2 HE should be admitted to an intensive care unit with integrated monitoring and multiorgan support. Patients with grade 3 encephalopathy should be ventilated for airway protection, and the head should be elevated to 30 degrees. Intravenous hypotonic solutions should be avoided because of the risk of hyponatremia-induced cerebral edema. Bolus infusions of mannitol (0.5 to 1 g/kg) or hypertonic saline should be given to patients with objective evidence of increased ICP. Temporary hyperventilation, with a goal $Paco_2$ of 25 mm Hg, may be helpful if the ICP cannot be adequately lowered with mannitol. Most patients require renal replacement therapy to lower ammonia levels because lactulose is ineffective in acute liver failure. Intracranial hypertension refractory to medical management should prompt consideration for liver transplantation. More detailed instructions for the management of patients with acute liver failure can be found in recommendations published by the U.S. Acute Liver Failure Study Group and by the American Association for the Study of Liver Diseases practice guidelines.

Minimal Hepatic Encephalopathy

Minimal HE is a milder form of HE in which impairment in cognitive function is detectable only through neuropsychological testing. It affects 20% to 70% of patients with cirrhosis. The number-connection test and block-design test have reasonable specificities for minimal HE and are easy to administer. The deficits in minimal HE are primarily related to visuospatial orientation, attention problems, and impaired short-term memory. Oral and written skills show little impairment. Neuroimaging studies have shown a correlation between minimal HE and changes in cerebral blood flow and abnormalities

on neuropsychological testing. Although patients with minimal HE have no overt symptoms of encephalopathy, their capacity to work or drive may be diminished. When tested on a driving simulator, patients with minimal HE both overestimate their abilities to drive and show impaired performance. Other studies have shown that patients with minimal HE have more collisions and have difficulty with traffic rules and road signs. At present, there is no consensus as to whether driving restrictions should be mandated. Treatment with both lactulose and rifaximin improve neuropsychological testing and quality of life in patients with minimal HE. These therapies also show some benefit in driving performance as well.

The Management of Budd-Chiari Syndrome

Jennifer C. Price, MD, and James P. Hamilton, MD

OVERVIEW

Budd-Chiari syndrome (BCS) refers to any pathophysiologic process that results in hepatic venous outflow tract obstruction, but it most commonly refers to thrombosis of the hepatic veins or the intrahepatic or suprahepatic inferior vena cava (IVC). The vast majority of patients with BCS have an underlying risk factor for thrombosis, although usually this is unrecognized at the time of presentation. Myeloproliferative disorders are the most common underlying thrombotic risk factor for BCS; others include factor V Leiden mutation; G20210A prothrombin mutation; antiphospholipid syndrome; deficiencies of protein C, S, or antithrombin; paroxysmal nocturnal hemoglobinuria; Behçet's syndrome; hyperhomocystinemia; MTHFR mutation; ulcerative colitis; hypereosinophilic syndrome; granulomatous venulitis; recent pregnancy; and recent oral contraceptive use. For decades, the optimal treatment of BCS involved the creation of a surgical shunt or liver transplant to relieve the portal hypertension. However, improvements in outcomes with less invasive procedures (i.e., transjugular intrahepatic portosystemic shunt [TIPS]) have changed the management of this life-threatening condition.

PRESENTATION AND DIAGNOSIS

The presentation of BCS ranges from asymptomatic in 20% of cases to acute liver failure. Rapid recognition and diagnosis of BCS is critical for initiation of organ-saving and life-saving medical and interventional treatment strategies. Patients afflicted with this potentially devastating disorder are typically young (ages 20 to 40 years) and most often female. The female predominance (3:1) is thought to be related to the concomitant use of prothrombotic, estrogen-containing oral contraceptives in the setting of previously undiagnosed hypercoagulable state. The classic clinical presentation includes hepatomegaly, right upper quadrant pain, and ascites, followed by jaundice. These clinical findings are the direct consequence of the underlying pathophysiology: hepatic outflow obstruction. Lower extremity edema, portal hypertension-related gastrointestinal bleeding, and hepatic encephalopathy may occur. In acute and subacute presentations of BCS, ascitic fluid analysis typically reveals a serum-ascites albumin gradient of 1.1 g/dL or more with a total protein of more than 3.0 g/dL. This pattern of laboratory values is indicative of hepatic congestion; thus, diagnostic transthoracic echocardiogram is required to help distinguish between BCS and right-sided heart failure. Ascitic fluid analysis in chronic BCS also reveals a serum-ascites albumin gradient of more than 1.1 g/dL, but the total protein value is usually lower than 2.5 g/dL. Serum laboratory abnormalities are often nonspecific. In acute presentations, serum transaminase values may be elevated up to 100 times the upper limit of normal. Alkaline phosphatase and bilirubin levels may also be elevated and gradually worsen with disease progression. Coagulation studies may be abnormal, with prolonged prothrombin time, indicating hepatic synthetic dysfunction, and elevated activated partial thromboplastin time (aPTT), signifying an underlying disorder of coagulation. Interpretation of the complete blood count often requires recognition of the overall disease process. In cases in which the hepatic vein thrombosis is caused by a myeloproliferative syndrome (i.e., essential thrombocytosis or polycythemia vera), the portal hypertension and associated splenomegaly/splenic sequestration may cause blood counts to fall into the normal range. Finally, a battery of laboratory tests is typically sent to diagnose a hypercoagulable state, with results specifying a diagnosis in approximately 50% of cases.

Doppler ultrasound scan is the initial study of choice in many centers to evaluate hepatic venous patency. Findings are highly correlated with venography, and it is relatively inexpensive and readily available. Other noninvasive imaging modalities for BCS include computed tomographic (CT) scan and magnetic resonance imaging (MRI), which in addition to characterizing hepatic outflow may also show parenchymal abnormalities, the degree of ascites, and the presence of caudate lobe hypertrophy. High-quality imaging can be diagnostic and used to help plan therapeutic intervention. For the best visualization of the hepatic vessels, it is critical that these cross-sectional imaging modalities are performed with intravenous contrast and with dedicated arterial, venous, and washout phases. A classic feature is caudate hypertrophy because the caudate lobe drains into the IVC and is spared from the outflow obstruction in BCS (Figure 1). Typical parenchymal perfusion patterns seen on CT scan or MRI in BCS are early central contrast enhancement with delayed patchy peripheral enhancement and prolonged peripheral retention of contrast. Ascites and splenomegaly may be seen; in addition, concomitant, extrahepatic portal vein thrombosis is present in approximately 15% of patients with BCS.

Hepatic venography remains the gold standard for diagnosis of BCS. In addition to diagnosis of difficult cases, venography can characterize the obstructive lesion and provides the opportunity to measure portal-caval pressures and perform a liver biopsy. Characteristic features of venography in BCS are occlusion of the hepatic veins and a "spider web" morphology of the small intrahepatic venules, which are thought to represent collateralization (Figure 2). Histologic findings of typical of BCS are centrilobular (zone 3) congestion, necrosis, fibrosis, and in some cases, cirrhosis. Intrahepatic

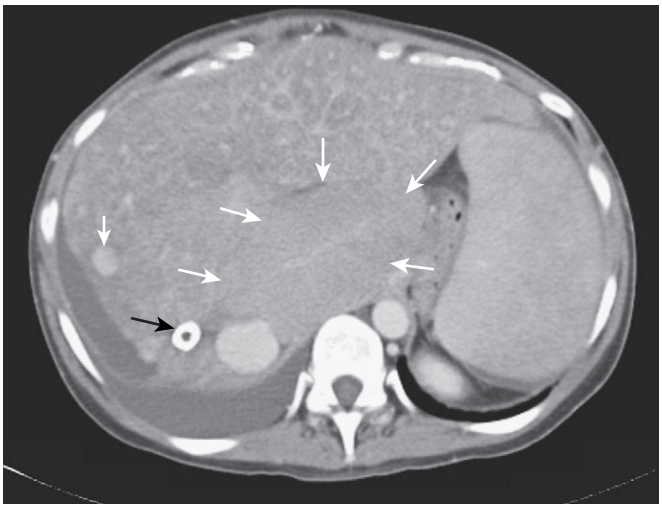

FIGURE 1 Typical computed tomographic scan of a patient with chronic Budd-Chiari syndrome. Note the heterogeneous appearance of the liver parenchyma, regenerative nodules *(small white arrow),* and caudate lobe hypertrophy *(white arrows).* The *black arrow* points to an occluded transjugular intrahepatic portacaval shunt.

FIGURE 2 "Spider web" morphology of small portal venules in Budd-Chiari syndrome as seen on venography. A catheter is seen transcending the liver *(arrow).*

portal vein thrombosis can occur and lead to portovenous and portoportal bridging fibrosis. Regenerative nodules are commonly seen in chronic BCS and may resemble focal nodular hyperplasia on histology and imaging. Hepatocellular carcinoma can develop in the setting of long-standing BCS and may be difficult to distinguish from regenerative nodules on imaging.

TREATMENT

The goals of treatment for BCS are to prevent clot propagation, restore vascular patency, decompress hepatic congestion, and treat complications of portal hypertension. The choice of therapy depends on a variety of factors, including the experience of the center, the availability of interventional radiology, and the patient's clinical presentation (Figure 3). The patency of the portal vein is often a critical factor because it may render TIPS or portal-caval shunt technically impossible.

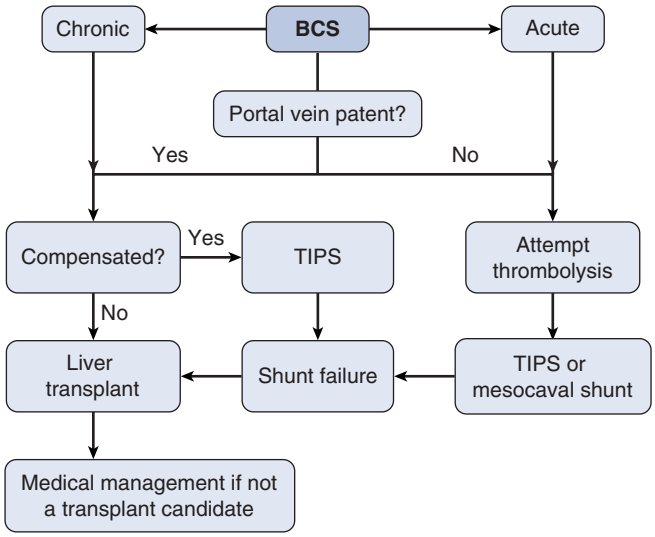

FIGURE 3 Treatment algorithm for patients with Budd-Chiari syndrome *(BCS). TIPS,* Transjugular intrahepatic portacaval shunt.

MEDICAL THERAPY

Immediately after diagnostic imaging is performed, anticoagulation therapy with fractionated heparin should begin. The underlying cause of BCS should be thoroughly investigated and treated. The V617F point mutation in the tyrosine kinase Janus kinase 2 (JAK2) gene in myeloid cells is highly specific for myeloproliferative disorders and should be tested in all patients with BCS. Most patients with a predisposing thrombotic disorder require indefinite anticoagulation therapy, although hydroxyurea and aspirin may be as effective as anticoagulation at preventing thrombosis in some patients with myeloproliferative disorders. Medical treatment for portal hypertension, including sodium restriction and diuretic therapy, should also be initiated. Renal function should be monitored carefully because the acute portal hypertension caused by BCS may precipitate hepatorenal syndrome. A subset of patients may demonstrate steady clinical improvement and may avoid invasive treatment. However, anticoagulation therapy alone is unlikely to result in adequate venous recanalization, and patients receiving medical therapy only must be closely monitored for disease progression.

Systemic and in situ thrombolytic agents have been used to treat BCS, although this has been poorly studied in controlled trials. Some evidence shows that directed thrombolysis is effective, and it can be considered in acute forms of BCS for patients without contraindications. In acute presentation, tissue plasminogen antagonist (TPA) may be delivered directly into the hepatic vascular system through cannulation of the portal vein. This strategy is often used over a period of 12 to 24 hours, with careful monitoring for hemorrhagic complications in an intensive care unit. Thrombolytic agents should not be used in chronic BCS given the low chance of venous recanalization and increased risk of bleeding complications in the setting of portal hypertension.

Interventional Radiology

Most patients with BCS do not have improvement with medical treatment alone. The role of interventional radiology in managing these patients has become increasingly important. Balloon angioplasty can be used in cases of focal occlusions, such as IVC webs or short-length hepatic vein stenoses. Vascular reocclusion occurs commonly, and therefore, stent placement is recommended if feasible. However, careful consideration must be made before stent placement

because it may interfere with vascular anastomosis if the patient eventually requires orthotropic liver transplantation (OLT). Successful stent placement leads to hepatic decompression, and clinical improvement can be sustained even despite reobstruction. Complications appear to be lower with the transluminal approach compared with the transhepatic approach.

Transjugular intrahepatic portosystemic shunt placement is now the standard of care for the treatment of BCS that has not responded to medical therapy. The rationale for TIPS is to create a intrahepatic shunt from the portal venous system to the proximal hepatic vein or IVC to bypass the obstructed hepatic veins (Figure 4). Historically, TIPS was not considered a durable therapy for BCS because of very high rates of stent occlusion (up to 75% at 1 year). At that time, TIPS was considered a bridge to definitive surgical therapies, such as liver transplant or creation of a surgical shunt. However, TIPS has been shown to be effective even in patients with severe BCS who have failed medical management. In 2008, Garcia-Pagan and colleagues showed an overall 84% 5-year survival rate after TIPS for BCS. This same series showed 88% and 78% 1-year and 5-year liver transplant-free survival rates. TIPS stents are now covered with polytetrafluoroethylene (PTFE). TIPS dysfunction from stent occlusion is less than 25% annually with these newer stents. TIPS can also be performed in the setting of BCS and portal vein thrombosis, although the success rate is lower in this setting, and the procedure may require an attempt of thrombolysis to the portal vein beforehand. TIPS remain a sophisticated procedure and is best performed by skilled interventional radiologists with much experience. Proper patient selection helps to increase the likelihood of success after TIPS. A right-sided echocardiogram should be performed, and TIPS should be avoided in patients with right heart failure. Patients with decompensated liver disease (e.g., Model for End-Stage Liver Disease [MELD] score of >17) often do very poorly after TIPS, and these patients should be considered for liver transplantation. The major complication after TIPS is the development of hepatic encephalopathy. This can be managed with nonabsorbable antibiotics and synthetic sugars to induce catharsis. Hepatic encephalopathy is typically not a problem in cases of acute BCS.

SURGICAL THERAPY

Portosystemic Shunting

Blakemore first described the portal-caval shunt in the late 1940s (Figure 5). Since then, multiple surgical variants have been developed, including splenorenal, mesocaval, and mesoatrial shunts. The choice of technique depends on individual patient factors such as patency of the IVC and extent of caudate lobe enlargement. Several studies show excellent short-term outcomes. However, among four multicenter retrospective analyses of patients with BCS who underwent portosystemic shunt, only one showed a survival advantage with portosystemic shunting after adjusting for Child-Pugh score. In 2012, Orloff and colleagues published results of their prospective cohort of 77 patients with BCS treated with surgical portosystemic shunt. Long-term survival rate was 95% among patients with isolated hepatic vein occlusion treated with side-to-side portacaval shunt after a mean follow-up period of 15 years. Mesoatrial shunt for IVC occlusion was associated with a high failure rate and thus discontinued in their series after 1990, but combined side-to-side portal-caval shunt with caval-atrial shunt in this population yielded a 100% survival rate at a mean follow-up period of 12 years.

Not surprisingly, shunt patency is essential to long-term success with portosystemic shunting. This was shown by Bachet and colleagues, who followed 39 patients a median of 100 months. Shunt dysfunction occurred in 20 patients and was associated with a significantly higher mortality (55% vs 16%). Shunt revision was successful for 7 of the 20 patients with shunt dysfunction, and none of these patients had refractory ascites develop or died during follow-up. Because of the increasing availability and success of TIPS for BCS, surgical portosystemic shunting has become less commonly performed at some centers. Nevertheless, surgical portosystemic

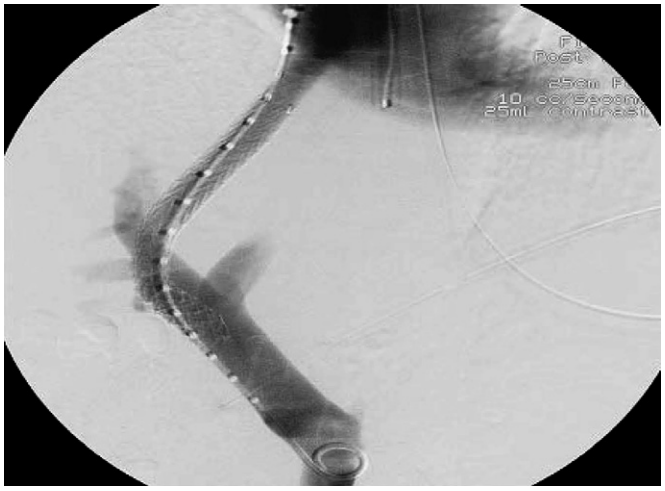

FIGURE 4 Transjugular intrahepatic portacaval shunt extending from right portal vein into the right atrium.

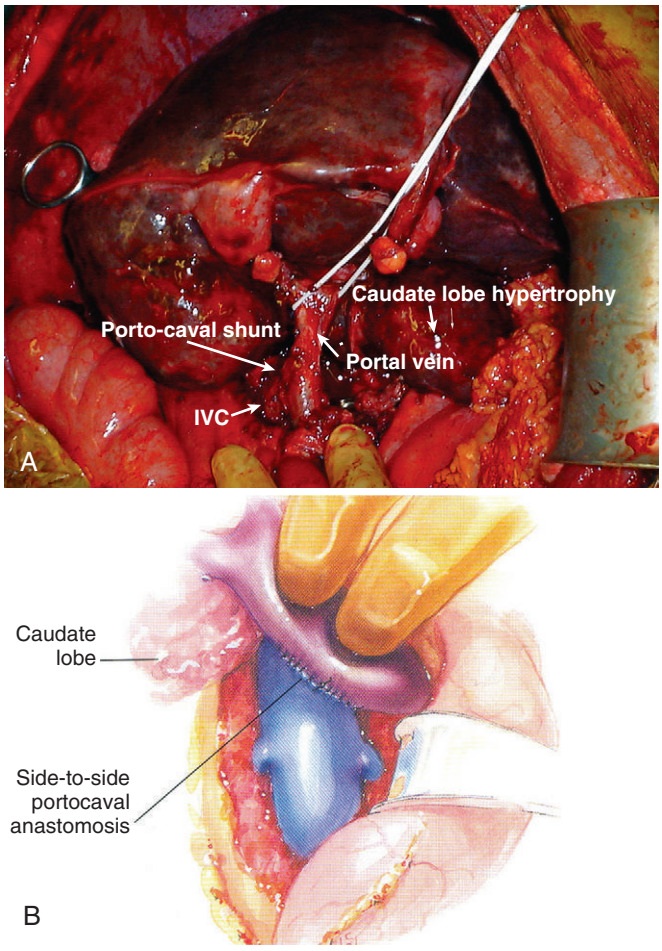

FIGURE 5 Budd-Chiari syndrome with previous portosystemic shunt procedure at the time of orthotropic liver transplantation. **A,** Caudate lobe hypertrophy. **B,** Side-to-side portal-caval shunt. *IVC,* Inferior vena cava.

shunting can be associated with excellent long-term outcomes if performed early in the course of the disease before the development of irreversible liver damage. Referral to an experienced surgeon is essential, and a liver transplant team should be consulted before a surgical shunt is performed.

Liver Transplantation

In patients with decompensated cirrhosis from BCS, OLT is the only curative option. In 1976, Putnam and Starzl reported the first case of OLT in a 22-year-old woman with acute hepatic venous occlusion, noting excellent results in 16-month follow-up. Since then, experience with OLT in the setting of BCS has undergone a dramatic evolution. Early experience with OLT for BCS yielded inferior outcomes, with 3-year survival rates as low as 45%. In general, two factors have modified the approach and positively influenced outcomes: (1) aggressive initiation of medical and interventional therapy; and (2) anticoagulation therapy. In the modern era of transplantation for BCS, survival has significantly improved. Mentha and colleagues evaluated 248 patients in the European Liver Transplantation Registry who underwent OLT for BCS and found 76%, 71%, and 68% 1-year, 5-year, and 10-year survival rates, respectively. Twenty-seven patients had venous thrombosis develop despite anticoagulation therapy, including six with recurrent venous outflow obstruction. Segev and colleagues examined 510 patients transplanted for BCS and found 81% graft and 85% patient survival rates at 3 years after OLT among those transplanted in the MELD era.

Liver transplantation in the setting of BCS poses several technical challenges. With acute or chronic disease, the liver may be markedly swollen and difficult to manipulate. Secondly, hyperplasia of the caudate lobe makes access to and dissection of the IVC a difficult endeavor. Concomitant stenosis of the IVC makes suprahepatic and infrahepatic control equally difficult. Although a prior TIPS procedure does not preclude OLT, distal migration of the stent may complicate the portal vein anastomosis. Substantial migration may require transection of the stent with the anastomosis performed directly to the portal vein remnant with the stent in situ. Noted by many institutional experiences, isolation of the hepatic veins for a piggyback anastomosis can be difficult with active outflow occlusion.

As mentioned in previous editions of this textbook, portal vein thrombosis can be a difficult problem, and it requires a strategic plan before transplant. At present, the authors find that the portal vein can routinely undergo thrombectomy and reasonable flow can be established, if the superior mesenteric vein (SMV) is patent. If this is not possible, a vein graft with donor iliac vein can be constructed between the donor portal vein and the SMV.

In the setting of complete mesenteric occlusion, two possibilities exist. First, many times, these recipients have an extremely large and patent coronary vein because of severe portal hypertension; this vein can be used for portal inflow. Second, anastomosis of the donor portal vein to the recipient's IVC (caval hemitransposition) with partial or total occlusion of the superior IVC superior is an option. Unfortunately, this approach can have extremely high morbidity and mortality.

Because of the aforementioned caudate lobe hyperplasia and caval stenosis, the recipient IVC may not be usable for live donor liver transplant (LDLT). In 2006, Yan and colleagues reported the first case of an adult-to-adult LDLT for BCS with a cryopreserved iliac vein graft. The authors highlight several important technical issues. In this case, it was necessary to incise the diaphragm and expose the pericardium to the level of the right atrium secondary to hepatic venous outflow occlusion. The iliac graft was then sewn to the suprahepatic and infrahepatic vena cavae. The right hepatic vein of the right hepatic lobe allograft was then sewn to the iliac graft in end-to-side fashion.

Alternatively, a large series from Japan reports the long-term outcome in eight patients with BCS who underwent LDLT. Of these, five patients underwent cavoplasty with a replacement vein graft after extensive resection of the thrombosed anterior IVC wall. Although the combined experience with LDLT for BCS is small, the current data suggest living donation as an emerging treatment option for this patient population.

Recurrence of hepatic venous outflow obstruction has been observed in up to 10% of patients, ranging from months to years after transplant. Consequently, lifelong anticoagulation therapy is currently recommended. Early experience with recurrent BCS after OLT carried an extremely high mortality rate. However, interventional techniques have provided some alternatives to retransplantation or death. In our experience, recurrent BCS can be approached in two ways. Primarily, retransplantation is an option in patients with mild to moderate thrombus burden in the hepatic veins and IVC refractory to an interventional approach. However, the anatomic features of the recurrent thrombus must be carefully delineated; recipients with a completed occluded IVC and portal vein are unlikely to be candidates for retransplant. In severe cases, TIPS can be used to reestablish flow in one or more hepatic vein in the setting of preserved liver function.

Finally, no evidence is found to suggest that OLT increases the risk of malignant transformation of underlying myeloproliferative disease in patients with BCS.

SUMMARY

The Budd-Chiari syndrome is a life-threatening condition that can be treated successfully when a timely diagnosis is made and the proper therapy applied. Initial treatment with anticoagulation therapy followed by placement of TIPS is the standard of care for patients with well-compensated liver function. Long-term follow-up studies of patients who undergo TIPS have shown excellent transplant-free survival rates, and stent failure is now uncommon. Although select centers have a robust experience with surgical portosystemic shunt procedures, the majority of institutions initially use interventional radiologic procedures for those with acute or subacute onset of disease.

Although long considered the most viable long-term treatment option for patients with all forms of BCS, liver transplant is typically reserved for patients with decompensated liver disease or recurrent stent/shunt failure.

Gallbladder and Biliary Tree

The Management of Asymptomatic (Silent) Gallstones

Victor Zaydfudim, MD, MPH, Kengo Asai, MD, PhD, and Michael G. Sarr, MD

OVERVIEW

Gallstones and their sequelae are one of the most common problems managed and treated by the general surgeon. In the United States, between 30 and 45 million residents have gallstones, with an approximate prevalence rate of 1 in 10, depending on patient age. Approximately 80% remain asymptomatic throughout the patient's lifetime. Unfortunately, with modern and frequently overutilized cross-sectional imaging, these asymptomatic, previously unrecognized, and unsuspected gallstones are identified incidentally. Once discovered, the asymptomatic gallstones become a matter of discussion, more frequently from the patient's point of view than that of the surgeon. A recent Cochrane Hepato-Biliary Group review failed to identify any randomized clinical trials comparing cholecystectomy versus no cholecystectomy among patients (or any subset of patients) with asymptomatic cholelithiasis. Progression from asymptomatic cholelithiasis to symptomatic gallstone disease obviously occurs but seems rare, and prophylactic or incidental cholecystectomy in patients with asymptomatic gallstones is usually unnecessary and should not be performed in most patients. This chapter addresses existing evidence and exceptional cases in which cholecystectomy for asymptomatic cholelithiasis could be considered.

EPIDEMIOLOGY AND NATURAL HISTORY

Gallstone disease is the leading cause for hospital admissions and clinic visits for gastrointestinal symptoms in the United States, with more than 750,000 cholecystectomies performed annually. The burden of disease has increased by an estimated 20% since the 1980s, and currently, 10% to 15% of the adult population in the United States harbors gallstones. Most these gallstones are asymptomatic, and the majority of patients do not know that they have gallstones. Less than 20% of patients with gallstones have biliary colic or symptomatic cholelithiasis develop during their lifetime; even fewer patients develop the more severe cholecystitis or biliary pancreatitis. Only about 4% of patients with asymptomatic cholelithiasis have secondary sequelae of gallstone disease (e.g., cholecystitis, obstructive jaundice, or pancreatitis). Annual progression has been estimated at 0.3% for acute cholecystitis, 0.2% for obstructive jaundice, and 0.1% to 1.5% for biliary pancreatitis. In longitudinal cohort studies, biliary colic typically precedes other complications and, as such, is a harbinger of further symptoms of cholelithiasis. A series of landmark studies by Gracie and Ransohoff in the 1980s established the safety of expectant management among male patients with asymptomatic cholelithiasis, confronting historical medical and surgical beliefs that the presence of gallstones requires cholecystectomy.

Asymptomatic cholelithiasis, per se, can be a difficult diagnosis to suspect and establish, and the distinction between symptomatic and asymptomatic gallstones can on occasion be elusive. Abdominal imaging for diagnosis of abdominal pain, discomfort, or mass is, by definition, not performed in an asymptomatic patient. Incidentally discovered gallstones are those that are: (1) found during imaging for reports not related to gallstones (e.g., vague nonspecific complaints, staging for lymphoma or other neoplasms, screening for abdominal aortic aneurysm, etc.); or (2) discovered incidentally during abdominal exploration for an unrelated operation (e.g., colon resection for cancer or operation for morbid obesity). The truly asymptomatic patient should have no subjective symptoms related to gallstones. Although symptoms can be vague and varied, classic symptoms of gallstone disease that are relieved with cholecystectomy are biliary colic and epigastric crescendo/decrescendo abdominal pain in patients with cholelithiasis. When present, these symptoms improve in more than 90% and 70% of the patients, respectively. As both ultrasound and cross-sectional abdominal imaging become a more routine part of patient evaluation and as the dramatic and frightening incidence of overweight and obesity continues to surge, the recognized prevalence and the overall incidence of cholelithiasis will also increase.

Population-based risk factors for gallstone formation and gallstone disease have been studied widely. Native American populations in both North and South Americas have a significantly greater prevalence of cholelithiasis. Increasing age, female gender, obesity, and metabolic syndrome have all been associated with an increased risk of cholesterol gallstones. In addition, rapid weight loss, particularly after operations for morbid obesity, predisposes markedly to cholesterol stone formation. Pigment stones are common in patients with hemolysis, such as those with hemoglobinopathies (sickle cell disease, hereditary spherocytosis, thalassemia), and in patients with cirrhosis, cystic fibrosis, Crohn's disease, and recurrent infection or inflammation of the biliary tree. When gallstone disease is symptomatic, operative management is recommended in all patients. Management of asymptomatic cholelithiasis in specific populations is addressed further in this chapter.

PROPHYLACTIC CHOLECYSTECTOMY

A number of investigations have focused on size of gallstones and the association with progression from asymptomatic to symptomatic cholelithiasis. These studies attempted to establish a role for prophylactic cholecystectomy for patients with stones that are either "too small" (typically defined as less than 5 mm) or "too big" (typically defined as larger than 3 cm). Among patients with small stones, investigators tested the associations between small stones and biliary pancreatitis. For patients with large stones, investigators tested the associations between large stones and cholecystitis (from presumed impaction in the neck of the gallbladder or Hartmann's pouch) or as a possible contributing factor in development of adenocarcinoma of the gallbladder. Although both of these associations can be seen among patients with the diagnosis of disease (e.g., pancreatitis, cholecystitis, gallbladder cancer), causation has not been shown in cohort studies for any pathology among patients with either small or large stones.

The relationship between gallbladder cancer and the presence of large gallstones remains highly controversial. Published studies vary from a nearly tenfold increase in the relative risk of gallbladder cancer among patients with stones greater than 3 cm to no significant difference at all. The role of prophylactic cholecystectomy for patients with large gallstones remains undefined; however, cholecystectomy in an asymptomatic patient with either epidemiologic risk factors or patient anxiety and gallstones larger than 3 cm could at least be considered. Studies supporting expectant management of large gallstones recommend ultrasound surveillance with cholecystectomy in patients with development of symptoms or changing characteristics on imaging. Predictive models with simulation decision analysis provide inconclusive evidence to support prophylactic operations in an asymptomatic patient with either small or large stones. Size alone is not a criterion for cholecystectomy, and patients with incidentally discovered, asymptomatic gallstones do not require cholecystectomy. Patients with small or large stones who have symptoms develop, however, should be treated with cholecystectomy.

The prevalence of gallstones increases with age, but the risk of progression from asymptomatic to symptomatic gallstone disease, although low, seems to increase with the duration of gallstone presence. A 30-year-old patient with asymptomatic gallstones has a greater lifetime risk for development of symptomatic gallbladder disease than does an octogenarian with asymptomatic gallstones. Although routine prophylactic cholecystectomy in a patient with known asymptomatic gallstones and long life expectancy cannot be supported, an incidental cholecystectomy during an intraabdominal operation for unrelated pathology could be considered. Two caveats are: (1) the age cut-off is not well defined; and (2) the exact definition of a "younger" patient with "increased" life-time risk compared with the general population has not been identified. In addition, the risk-benefit analysis of a concomitant cholecystectomy in an asymptomatic patient varies with other patient-specific covariates. As such, the decision for a concomitant/incidental cholecystectomy should be individualized. Incidental cholecystectomy is addressed further in the chapter.

Minimally invasive techniques have markedly decreased postoperative pain, duration of hospital stay, and time to return to work among patients undergoing uncomplicated cholecystectomy. In addition, patient acceptance and physician willingness to offer cholecystectomy has also changed with the minimal access approach; after all, it is "just a lap chole." But, these operations are not risk-free. Access injuries (bowel or vascular) during trocar placement, albeit infrequent, are likely underreported and, when present, can be disastrous. Nonbiliary complications, such as risks of postoperative bleeding requiring reoperation or intraabdominal abscess requiring intervention, are low but nevertheless present. Biliary injury and postinjury complications have been studied extensively and are not trivial. Frequency of bile duct transection or obstruction requiring hepaticojejunostomy is approximately 1 in 500 cases; more patients are treated by interventional endoscopists and radiologists for less severe biliary injuries. Justification of such risk, albeit low, is more difficult to an asymptomatic patient.

INCIDENTAL CHOLECYSTECTOMY

Although prophylactic operation implies cholecystectomy to prevent future complications of gallstones in an asymptomatic patient, incidental cholecystectomy performed during an operation for an otherwise unrelated diagnosis is more common. The most accepted indication for incidental cholecystectomy among patients with asymptomatic cholelithiasis is the presence of other gallbladder pathology that mandates cholecystectomy. The most common gallbladder pathology not directly related to gallstones is a gallbladder polyp. The natural history and clinical diagnosis of gallbladder polyps have been scrutinized extensively. Patients with polyps greater than 10 mm, sessile rather than pedunculated polyps, adenomatous polyps with vascularity, and polyps that show rapid growth are considered at greater risk for development of gallbladder malignancy and should be referred for a cholecystectomy. Extensive literature and surgical dogma cover a rarer group of patients with porcelain gallbladder. A recent systematic review estimated a prevalence rate of gallbladder cancer of 0.2% in patients with a porcelain gallbladder. Indeed, with the exception of a single study from Argentina published in 1967, the incidence rate of gallbladder cancer among patients with calcified gallbladder is almost 0. Confusion between a true porcelain gallbladder (i.e., complete/diffuse intramural calcification seen immediately on abdominal imaging) and selective mucosal calcifications within the gallbladder wall (i.e., focal mucosal calcium deposition) should be addressed. The former (porcelain gallbladder) is likely not an independent risk factor for gallbladder cancer, and the latter (selective mucosal calcification) has been associated with an increased risk of gallbladder malignancy. Despite this lack of evidence, many surgeons continue to recommend cholecystectomy for patients with incidentally discovered porcelain gallbladder. In both groups of patients, those with gallbladder polyps and those with porcelain gallbladder, gallstones (if present) are removed during cholecystectomy. Unlike prophylactic cholecystectomy, incidental cholecystectomy for patients with stones that are large (>3 cm) or small (<5 mm) is more commonly accepted. In addition, incidental cholecystectomy during reoperative surgery, with the exception of revision abdominal hernia repairs with prosthetic mesh implantation, have also been accepted anecdotally but without significant evidence of benefit.

Incidental cholecystectomy during hepatic metastasectomy has also been advocated. Colorectal and neuroendocrine neoplasms constitute the most frequent metastases to the liver. Therapy depends largely on burden of disease; however, when feasible, hepatic resection can be the primary treatment modality. Incidental cholecystectomy, regardless of the presence of gallstones or extent of metastasectomy, is prudent for two reasons. First, recurrent, isolated metastases to hepatic segments IVB/V can be treated thereafter with ablation, without concern for the heat-sink effect or gallbladder wall injury. Second, systemic transcatheter therapy, such as transarterial chemoembolization or selective internal radiation therapy, poses a risk for cholecystitis, which can be avoided with a preemptive, incidental cholecystectomy during the initial metastasectomy.

Historically, clinical and physiologic studies suggested an increased rate of gallstone formation among patients undergoing an upper gastrointestinal operation involving vagotomy: esophagectomy, gastrectomy, or vagotomy for peptic ulcer disease. In addition, most studies that evaluated the utility of incidental cholecystectomy during major general alimentary tract, gynecologic, and vascular operations were performed among patients undergoing laparotomy. The results have been divergent. Some authors described a safe and potentially prophylactic operation, and others have shown a slight increase in

risk without a clear benefit. A few considerations should be discussed. First, a number of these investigations were performed before routine use of therapeutic endoscopic retrograde cholangiography, and many patients in the control groups who needed postlaparotomy common bile duct explorations were treated currently with therapeutic endoscopy. Second, a number of patients in the control groups needed reexploration for an open cholecystectomy; currently, most of these patients would be candidates for minimally invasive cholecystectomy, alleviating much of the morbidity associated with relaparotomy. Third, abdominal access has evolved dramatically, and many operations are performed currently with laparoscopic or endovascular techniques.

The classic study by Ochsner, Cooley, and DeBakey published in 1960 pioneered the safety of concomitant incidental general surgery procedures for potential prophylaxis during abdominal aortic aneurysmectomy. Multiple subsequent studies showed the safety of cholecystectomy during open repair of abdominal aortic aneurysm, provided the retroperitoneum was closed over the prosthetic graft. Currently, however, more than 75% of aortic aneurysms are repaired endovascularly. No systematic studies have explored the need for, or the safety of, a concomitant cholecystectomy among patients with asymptomatic cholelithiasis undergoing endovascular aneurysm repair. Interestingly, one study evaluated development of gallbladder disease among 486 patients after endovascular abdominal aortic aneurysm repair (64 patients had known stones at the time of operation). Only three patients needed later intervention: one needed common bile duct exploration for an impacted stone 8 days after endovascular repair, another needed laparoscopic cholecystectomy for acalculous cholecystitis, and the third needed laparoscopic cholecystectomy for calculous cholecystitis 16 months after aneurysmorrhaphy. Data supporting any justification for a concomitant incidental cholecystectomy during endovascular operations are lacking, and currently the topic is moot.

Similarly, data to support concomitant incidental cholecystectomy among patients with asymptomatic cholelithiasis who are undergoing laparoscopic (or robotic) operations involving the gut, retroperitoneum, or pelvis are lacking. Has there been a shift in philosophy? One possibility is that trocar placement and triangulation, which are critical to a successful minimally invasive approach, limit the work area within the abdominal cavity. No studies have examined whether additional trocars and time during a laparoscopic colectomy or hysterectomy deter from "therapeutic" incidental cholecystectomy for asymptomatic gallstones. Second, the increasing subspecialization within general surgery creates the possibility that the surgeon performing colectomy or esophagectomy (not to mention hysterectomy) might be different than the one who usually performs a cholecystectomy. Third, the ability to perform a laparoscopic cholecystectomy later rather than the need for an open cholecystectomy has deflated the enthusiasm for a concomitant incidental cholecystectomy. As such, incidental cholecystectomy has lost favor largely by many surgeons among patients undergoing an intra-abdominal operation. The morbid obesity population is an exception and is discussed separately.

SPECIAL POPULATIONS

The following section discusses populations in whom an incidental or prophylactic cholecystectomy for asymptomatic cholelithiasis has been considered. In most circumstances, the recommendation currently directs expectant management.

Diabetes

Historically, recommendations for prophylactic cholecystectomy in patients with diabetes with asymptomatic gallstones stemmed from clinical data that suggested two observations: (1) that these patients were more likely to become symptomatic; and (2) that patients with diabetes have more complicated initial presentations of symptomatic cholelithiasis, in particular, acute cholecystitis. The clinical rationale argued for masked signs and symptoms of gallstone disease among patients with diabetic autonomic neuropathy, thereby leading to delayed diagnosis and worse outcomes. Historic reports described increased rates of severe cholecystitis (perforation, gangrene, and emphysematous cholecystitis) among patients with diabetes presenting with cholecystitis.

Subsequent studies from as early as 30 years ago failed to confirm that diabetes is an independent risk factor for adverse outcomes. Rather, the coexisting vascular, cardiac, and renal disease; obesity; and advanced age appear to play a greater role in outcomes than diabetes alone. Recent evidence including a 5-year prospective study of patients with non–insulin-dependent diabetics showed that only 15% of patients became symptomatic, congruent with the rate among the general population, and few presented with secondary sequelae of complicated gallstone disease. In addition, decision analysis models showed the superiority of expectant management over prophylactic cholecystectomy in most realistic modeling scenarios among patients with diabetes, with noninferiority and even possible improvements in life expectancy and quality of life. Thus, prophylactic cholecystectomy for asymptomatic cholelithiasis is not recommended in patients with diabetes. In the case of a patient with diabetes with asymptomatic gallstones discovered incidentally at the time of celiotomy for an unrelated condition (colon cancer, etc.), many surgeons would support a concomitant cholecystectomy.

Hemoglobinopathy

Hemoglobinopathies, including sickle cell disease, thalassemia, and hereditary spherocytosis, cause hemolysis and formation of pigment stones. Gallstones are most evident among patients with sickle cell disease. More than 55% of patients with sickle cell disease have gallstones by the age of 22 years, and up to 75% of these patients develop symptomatic cholelithiasis. In addition, more than 60% of patients with sickle cell disease have episodes of vasoocclusive, sickle cell crises. Symptom differentiation between biliary colic and cholecystitis and sickle cell crises can be difficult. As such, prophylactic cholecystectomy is recommended frequently in this population. Previous studies have suggested increased risks of vasoocclusive crises during the era of open cholecystectomy; however, laparoscopic approaches and improved perioperative management of patients at risk for crises (including hemoglobin optimization, hydration, pain control, and oxygenation) have improved markedly the safety of prophylactic cholecystectomy.

Patients with hereditary spherocytosis and thalassemia are also at increased risk of development of pigment gallstones. Fewer studies have examined the role of prophylactic cholecystectomy for asymptomatic cholelithiasis in these two patient populations. Current clinical evidence in patients with hereditary spherocytosis supports prophylactic cholecystectomy at the time of laparoscopic splenectomy. Asymptomatic patients should be screened for the presence of gallstones before splenectomy. Once the spleen is removed, no new stones should develop in this population. Patients with β-thalassemia pose a different challenge. Hepatomegaly is a frequent sequela of thalassemia major with hemosiderosis and secondary cirrhosis. Up to two thirds of patients with thalassemia major have pigment stones develop by the age of 15 years. Similar to patients with spherocytosis, concomitant prophylactic cholecystectomy can be performed safely during laparoscopic splenectomy. Laparoscopic cholecystectomy can also be performed safely in patients with thalassemia and symptomatic cholelithiasis. The role of prophylactic cholecystectomy for asymptomatic cholelithiasis as a stand-alone operation among patients with hereditary spherocytosis or thalassemia, however, has not been investigated adequately and is not recommended currently.

Transplant

Management of asymptomatic cholelithiasis among solid organ transplant recipients has been controversial. Chronic, posttransplant immunosuppression is associated with an increased risk of infection and a delay in the diagnosis of surgical pathology. In addition, the cholelithogenic effect of immunosuppressive calcineurin inhibitors (cyclosporine and tacrolimus) and early reports of substantial morbidity and mortality of cholecystectomy in symptomatic patients historically led to recommendations for prophylactic cholecystectomy in transplant candidates before transplant and for transplant recipients diagnosed with cholelithiasis after transplant. Subsequent studies, however, particularly in patients with kidney and pancreas transplant have shown the safety and efficacy of expectant management after introduction of laparoscopic cholecystectomy. Most patients with asymptomatic cholelithiasis after kidney or pancreas transplant remain asymptomatic; those few patients (~1%/y) in whom symptoms develop can and should be treated promptly with laparoscopic cholecystectomy. Treatment delays among symptomatic patients with immunosuppression can increase the risk of infectious complications. A decision analysis study by Kao, Flowers, and Flum provided convincing data to support the expectant management of asymptomatic cholelithiasis in patients with kidney or pancreas transplant. The mortality rate of expectant management was 2 deaths per 1000 patients compared with 5 deaths per 1000 prophylactic cholecystectomies. Expectant management was also favored in a wide range of adjustments considered during sensitivity analyses.

Risks and disease progression among patients with heart and lung transplants, however, appear different. Symptom progression among patients with known asymptomatic cholelithiasis before heart transplant has been documented in as many as 58% of heart recipients after transplant. Morbidity and mortality rates in this population can approach 40%, particularly in patients with secondary complications of gallstone disease. The decision analysis study by Kao and colleagues reported 5 deaths per 1000 patients who underwent prophylactic cholecystectomy after heart transplant compared with 44 deaths per 1000 patients modeled for expectant management. Thus, although expectant management is becoming the dominant strategy for patients with kidney and pancreas transplant, most patients with asymptomatic cholelithiasis after heart or lung transplant are managed currently with prophylactic cholecystectomy.

Gallbladder Cancer

Numerous risk factors for development of cholangiocarcinoma, including gallbladder adenocarcinoma, have been described. Some well-supported associations include ethnicity, including genetic and environmental predisposition (particularly American Indians, Native South Americans, and certain regions in North India), and the presence of concomitant pathology, such as choledochal cysts, gallbladder polyps (particularly larger vascular polyps), and selective mucosal calcifications in the wall of the gallbladder. As discussed, associations between large gallstones or porcelain gallbladder and development of malignant disease, although proposed in the past, are not supported by evidence. A number of studies evaluating "carcinogenesis" of gallstones have failed to control for other potential covariates such as ethnic predisposition. Presence of gallstones as the only potential risk factor for gallbladder adenocarcinoma in the non–Native American U.S. population does not merit cholecystectomy. There is no question that virtually all patients with gallbladder cancer have concomitant gallstones and the stones have some contribution to the pathogenesis of the gallbladder cancer, but the overall risk of development of gallbladder cancer when gallstones are present is negligible; therefore, other factors require consideration. Asymptomatic gallstones in conjunction with any other potential risk factor, such as ethnic or nongallstone pathologic predisposition, merit consideration for prophylactic cholecystectomy.

Spinal Cord Injury

Risk of gallstone formation is approximately two to three times greater among patients with spinal cord injury than in the general population. Multiple studies have evaluated the relationship between asymptomatic gallstones, symptomatic cholelithiasis, and secondary biliary complications in this patient population. Although the risk of cholelithiasis is greater, the risk of symptomatic progression is the same as in the general population. Regardless of level of injury, symptoms of biliary colic are not obscured typically among patients with spinal cord injury. Expectant management of asymptomatic gallstones should be advocated in this population, and cholecystectomy should be performed only in patients with symptomatic cholelithiasis.

Total Parenteral Nutrition

Two major factors predispose patients receiving prolonged total parenteral nutrition to an increased risk of gallstone formation. First is the decrease in overall gallbladder contractility. Although the gallbladder continues to undergo its cyclic pattern of contractions during fasting, the lack of postprandial contraction leads to biliary sludge and gallstone formation. Second is the altered composition of bile salts, particularly among patients with ileal pathology (either ileal Crohn's disease or resection) with a resultant disruption of the enterohepatic circulation.

Current evidence does not support prophylactic cholecystectomy among parenterally fed patients with asymptomatic gallstones. Reports from the early era of parenteral nutrition among chronically ill patients, almost half of whom needed an emergency open cholecystectomy, suggested routine ultrasound scan surveillance and consideration for early prophylactic cholecystectomy. In retrospect, the high rate of morbidity in that population was likely the result of a delay in diagnosis for a relatively new, pathophysiologic diagnosis. Modern understanding of hepatobiliary complications from parenteral nutrition precludes cholecystectomy in the asymptomatic patient. Patients with symptomatic cholelithiasis and those with acalculous cholecystitis (another well-known complication of parenteral nutrition) should undergo a prompt cholecystectomy.

Morbid Obesity

Obese patients have a greater incidence of gallstones than does the general population. In addition, rapid loss of excess body weight, common after operations for morbid obesity, has been linked to increased rates of gallstone formation. The reported prevalence rate of cholelithiasis after Roux-en-Y gastric bypass ranges from 28% to 71%, depending on how carefully patients were screened before surgery. In addition, altered anatomy after a Roux-en-Y gastric bypass or a duodenal switch/biliopancreatic diversion creates therapeutic challenges for the management of potential choledocholithiasis. Although preoperative prevalence and postoperative incidence of gallstones are clearly greater in this population, no consensus presently exists for management of patients with asymptomatic cholelithiasis. As such, current practice patterns vary, with a number of recommendations having been proposed, including: (1) routine prophylactic cholecystectomy in all patients at the time of bariatric surgery; (2) preoperative ultrasound screening followed by concomitant cholecystectomy at the time of bariatric operation if gallstones are identified; (3) postoperative use of oral ursodeoxycholic acid therapy for 6 months (the time of major weight loss and gallstone formation) among patients without gallstones; and (4) expectant management for all patients with asymptomatic gallstones.

Proponents of prophylactic cholecystectomy at the time of bariatric operation for all bariatric patients (whether gallstones are present or not) cite numerous advantages for routine

cholecystectomy for all bariatric surgery patients: the high incidence of stone formation, the challenge of preoperative imaging in obese patients, the frequency of gallbladder pathology identified after cholecystectomy (e.g., chronic cholecystitis), and the difficulty of managing biliary complications, especially choledocholithiasis or cholangitis with the altered postoperative anatomy. Short additional operative time, less than 20 minutes in some reports, and the low incidence of morbidity and mortality associated with concurrent cholecystectomy favor prophylactic cholecystectomy. Most of these arguments were more prevalent and attractive in the era of open bariatric surgery, but they may remain pertinent currently in the rare patient who needs an open bariatric operation.

Others have adopted a more selective approach that includes preoperative ultrasound scan or intraoperative evaluation, with concurrent cholecystectomy if gallstones (or other biliary pathology) are identified. In a retrospective analysis of 1713 consecutive patients undergoing Roux-en-Y gastric bypass, the authors used selective cholecystectomy based on the presence of gallbladder pathology. In patients with normal preoperative ultrasound scan results, 8% needed subsequent postbypass cholecystectomy for symptomatic disease that developed during an average follow up of 31 months. Of the patients who had stones identified but did not undergo cholecystectomy because of surgeon or patient preference or because of technical factors, 18% subsequently needed cholecystectomy. These data are consistent with reports that describe rates up to 27% of symptomatic cholelithiasis after gastric bypass requiring cholecystectomy. Such data seem to support a more selective approach to concurrent cholecystectomy (limited to patients with known gallstones) at the time of gastric bypass.

Expectant management in bariatric surgery patients with or without asymptomatic gallstones is also safe. Another recent study reported 1050 "at-risk" patients after laparoscopic Roux-en-Y gastric bypass followed for a median of 32 months. Subsequent cholecystectomy was performed eventually in only 5% of patients for symptomatic cholelithiasis. There were no secondary biliary sequelae or complications. Post–gastric bypass choledocholithiasis is not a frequent complication and can be managed either with double balloon enteroscopy to reach the duodenum (provided the Roux limb is not too long) or with laparoscopic gastrotomy for insertion of the endoscope into the gastric remnant. Of 15 patients managed with this latter procedure at a quaternary interventional gastroenterology practice over a 7-year period, only 4 had choledocholithiasis (9 had unexplained biliary dilation with abdominal pain, 1 had type I sphincter of Oddi dysfunction, and 1 had recurrent acute pancreatitis).

The increased risk of stone formation related to rapid weight loss is thought to be greatest in the early postoperative period. Numerous studies have advocated the use of ursodeoxycholic acid (600 mg daily for 6 months after surgery). A recent meta-analysis of randomized control trials of 521 patients reported a decrease in the development of gallstones from 27% to 9% with the use of postoperative ursodeoxycholic acid. Cost and medication side effects, however, limit patient compliance with oral ursodeoxycholate, potentially inflating its true efficacy.

As such, the management of asymptomatic gallstones in the obese patient remains controversial. Multiple management approaches are safe. Prophylactic cholecystectomy can be performed safely for patients with asymptomatic gallstones at the time of initial bariatric operation but may require more trocars and can be challenging in patients with a large liver or marked visceral obesity. Expectant management with subsequent (laparoscopic) cholecystectomy in patients in whom symptoms develop is also safe.

Acute Cholecystitis

James K. Elsey, MD, FACS, and David R. Schmidt, MD, FACS

OVERVIEW

Acute cholecystitis is a complication of biliary tract disease, which can be differentiated from chronic cholecystitis in its presentation. Patients with acute cholecystitis commonly have a sudden onset of symptoms that persists greater than 4 hours and causes them to seek consultation in the emergency room, urgent care center, or their physician's office. Symptoms develop from the presence of acute inflammation in the mucosa and wall of the gallbladder, leading to distention of the wall and eventual ischemia. The inflammatory response begins as sterile but can lead to secondary bacterial infection. Rarely, untreated acute cholecystitis can lead to perforation with abscess formation and peritonitis.

Gallstones are most commonly associated with biliary tract disease and can lead to the development of acute cholecystitis when the gallstones become lodged in the cystic duct, causing obstruction of the gallbladder's release of its bile into the common bile duct. Symptoms can improve if the stones become dislodged back into the gallbladder, but more serious illness can occur if the stones pass into the common bile duct, which can result in jaundice and pancreatitis. Acute acalculous cholecystitis can occur where the cystic duct is obstructed in the absence of gallstones and is less common in the general population but more often associated with critically ill patients in the intensive care unit (ICU) and in patients receiving total parental nutrition. Cholelithiasis is estimated to be present in 10% of the population, and one third has development of symptoms. The risk of asymptomatic stones becoming symptomatic is reported to be 1% to 2% per year. Once symptoms of acute cholecystitis develop, these symptoms should be treated immediately to prevent the risk of development of a more serious medical illness.

CLINICAL PRESENTATION AND EVALUATION

Patients with acute cholecystitis should be differentiated from patients with symptomatic biliary colic because they need immediate evaluation, workup, and treatment to prevent the deleterious progression of the disease. The classic right upper quadrant pain is accompanied by signs of the inflammatory response, which include fever, nausea, and vomiting and signs of peritoneal inflammation, causing pain radiating to the back and right scapulae regions. In contrast, patients with biliary colic often have intermittent pain that lasts less than a few hours and do not classically have fevers. The distinction is important because acute cholecystitis requires immediate treatment and biliary colic can be treated with cholecystectomy on a nonemergent elective basis.

Patients with acute cholecystitis commonly present with fever, tachycardia, and right upper quadrant tenderness on the physical examination. A positive Murphy's sign occurs when the pain in the right upper quadrant causes a sudden inspiratory arrest during deep palpation. Local peritoneal signs may also occur in acute disease, but diffuse peritonitis suggests a more advanced stage of disease and possible perforation. A palpable tender mass is indicative of a possible phlegmon, which can be a sign of advanced local inflammation indicating a more difficult surgical approach to cholecystectomy. If jaundice is noted on examination, this suggests common bile duct obstruction by choledocholithiasis or possibly Mirizzi's syndrome caused by a large cystic duct stone with inflammation compressing the common bile duct.

After a thorough history and physical examination, the next step in a workup includes laboratory evaluation. A complete blood count typically reveals an elevated white blood cell count (WBC). Although a complete metabolic profile typically reveals normal liver function, mild elevation of transaminase may occur from local inflammation to the liver and mild hyperbilirubinemia can be seen in severe infections. Markedly elevated transaminase values may be the result of hepatitis, whereas hyperbilirubinemia may be indicative of common bile duct obstruction and choledocholithiasis. Amylase and lipase levels should be tested to rule out the development of acute pancreatitis in any patient with abdominal pain.

A right upper quadrant ultrasound scan is the radiographic study of choice for its specific findings, easy availability, and inexpensive costs. Gallstones are commonly seen along with other findings highly suggestive of acute cholecystitis, including a lodged stone in the neck of the gallbladder, gallbladder wall thickening of 4 mm or greater, and pericholecystic fluid. In the unusual case in which ultrasound scan is not helpful or is inconclusive, a hepatobiliary iminodiacetic acid (HIDA) scan can determine whether cystic duct obstruction is present. A HIDA scan that shows nonvisualization of the gallbladder is consistent with acute cholecystitis from cystic duct obstruction, although false-positive studies can occur in fasting patients. Abdominal computed tomographic (CT) scan can also illustrate changes in patients with acute cholecystitis but is less sensitive in milder disease of the gallbladder and should not be used as the initial study in uncomplicated acute cholecystitis. The CT scan may show gallstones, a thickened gallbladder wall, or pericholecystic fluid as seen on ultrasound scan, but it is most beneficial to rule out other intraabdominal pathology if the diagnosis of acute cholecystitis is unclear. A magnetic resonance cholangiopancreatogram (MRCP) can also show signs of acute cholecystitis but is used in the authors' institution in the evaluation of hyperbilirubinemia to rule out choledocholithiasis or malignancy.

DIFFERENTIAL DIAGNOSIS

Acute cholecystitis is most often associated with gallstones or cystic duct obstruction in calculus disease. The differential diagnosis in patients with acute right upper quadrant pain includes gastric, colonic, renal, pancreatic, liver, lung, cardiac, and appendiceal disease processes. These include peptic ulcer disease, gastritis, gastroenteritis, colitis, right or transverse colon diverticulitis, nephrolithiasis, renal infarction or infection, pancreatitis, hepatitis, liver abscess, pneumonia, myocardial ischemia, and appendicitis. A common consult occurs in patients who are admitted to rule out cardiac disease and who after a negative cardiac workup are found to have acute biliary tract disease.

MANAGEMENT

Once the diagnosis of acute cholecystitis is determined, the patient's condition is stabilized, comorbid risk factors are managed, and broad-spectrum antibiotics are given. More than 50% of patients with acute cholecystitis have positive bile cultures, with *Escherichia coli, Klebsiella, Enterobacter,* and Bacteroides species the predominant isolates, and antibiotic coverage should be broad enough to cover these organisms. Except in the instance of the patient with sepsis or immunocompromise, antibiotics are discontinued in the early perioperative period.

The debate over the timing of surgery in the patient with acute cholecystitis is one of mainly historic interest; it is now widely accepted that cholecystectomy should be performed within the first 72 hours of diagnosis. In the nonseptic, high operative risk case with reversible or improvable comorbid risk factors, it is often prudent to manage with supportive care, optimizing the clinical situation as best as possible and performing an elective cholecystectomy in 6 to 12 weeks.

Multiple studies have clearly shown the safety and the advantage of early cholecystotomy in the management of this process. No demonstrable difference is found in mortality rate, major bile duct injury, postoperative pain, or other significant complications in patients treated with early or delayed cholecystectomy. Early cholecystectomy halts the progressive inflammatory response and coincident tissue fibrosis that complicates tissue dissection and vital structure identification, allowing for the increased opportunity for a safe laparoscopic procedure and reducing the chances of open conversion. In addition, early cholecystectomy in patients with cholecystitis and systemic toxicity, emphysematous cholecystitis, and acute acalculous cholecystitis reduces the known tendency towards gangrene and perforation in this subset of patients.

LAPAROSCOPIC CHOLECYSTECTOMY

Laparoscopic cholecystectomy is now considered the procedure of choice in the operative management of acute cholecystitis. Multiple studies have confirmed that the overall morbidity rate, length of hospital stay, cost, and time to return to function are lower in the patient treated laparoscopically when compared with the standard open technique. That said, the variable and often severe inflammatory response seen in the patient with acute cholecystitis adds special technical challenges to the laparoscopic technique, potentially leading to devastating and lethal vascular and ductal injuries. Severe inflammation limiting the safe conduct of the laparoscopic procedure requires open conversion in up to 20% of these patients. Dramatic and ongoing improvements in optics, instrumentation, and laparoscopic skills have reduced the absolute contraindications of the technique to patients with adhesive hostile abdomens and those who cannot tolerate abdominal insufflation.

The primary guiding principle of laparoscopic cholecystectomy in the patient with acute cholecystitis is the safe removal of the gallbladder without vital biliary structure injury. Inherent challenges in this subset of patients include a lack of tactile sensation, a two-dimensional view of a three-dimensional field, lateral retraction techniques that distort the normal alignment of critical biliary tract

structures, periodic difficulties in maintaining a dry field, and abnormal dissecting angles created by atypical and challenging body habitus. These limitations, combined with an often robust inflammatory response and the known frequent anatomic anomalies of the biliary structures, result in an inherently dangerous procedure of varying proportion. It is therefore essential to follow, without deviation, the time-honored proven techniques of laparoscopic cholecystectomy to avoid complications in these patients. Good visualization provided with a clear laparoscope with adequate illumination often aided by a 30-degree or directed device is essential. As in all operations, good exposure through adequate retraction is a fundamental requirement for success. The standard four-port approach is usually adequate; however, in more challenging cases, never hesitate to add more trocars and retractors to optimize exposure. Superolateral retraction on the dome of the gallbladder combined with inferolateral retraction of the infundibulum usually provides an adequate field to begin the dissecting process. In situations where the gallbladder is tensely distended, the retraction process can be greatly aided with needle drainage. Dissection is begun high on the gallbladder infundibulum with a goal of safely exposing and identifying the infundibular-cystic duct junction. The surgeon should avoid initial dissection efforts low on the gallbladder because it is very easy to become confused and lost in this area, creating a higher chance of vital structure injury. In cases of severe inflammation, it is often helpful to divide the inflamed or fibrotic gallbladder rind along the superior and inferior margins of the infundibulum before dissection, allowing for better mobilization and retraction of the infundibulum and, hence, safer dissection of the infundibular-cystic area. The top-down dissection should cautiously continue until the critical infundibular-cystic duct junction view is obtained. Dissection is only considered satisfactory when a complete and unobstructed 360-degree view of the infundibular-cystic junction is obtained, a clear space between the superior distal margin of the gallbladder and liver is seen, and the surgeon is absolutely certain that only two definite structures (cystic duct, cystic artery) are left entering the gallbladder. In no circumstance are any structures in this critical area to be clipped, cauterized, or divided until the surgeon has achieved this critical and certain level of dissection and exposure. In the circumstance when this cannot be achieved, an intraoperative cholangiogram through the distal infundibulum can sometimes clarify the anatomy. If this is not possible or not completely helpful, a dome-down dissection technique can be used. However, the surgeon must be very cautious in avoiding injury to the hepatic artery or the right hepatic duct while dissecting the distal superior edge of the gallbladder away from the liver. If the appropriate dissection techniques have not resulted in a certain and critical view of the anatomy, it is imperative to abort the laparoscopic procedure and convert to an open operation. Remember that the goal is the safe and uncomplicated removal of the gallbladder, and in this circumstance, conversion to an open procedure is not only the appropriate approach but is also the mark of a safe and mature surgeon. Finally, independent of the techniques used, the critically defined structures are individually ligated and the gallbladder is removed with the surgeon's energy source of choice.

One final note of caution involves the case of a short cystic duct. Injudicious dissection or cholangiography in the presence of a short cystic duct can lead to common duct injury or cystic duct postoperative bile leak. In this circumstance, it is better to perform cholangiography through the infundibulum and terminate the distal dissection by dividing the distal infundibulum by ligation or endostapling.

There has been an evolution in the use of intraoperative cholangiography from a routine standard to a more selective approach. Most surgeons today reserve cholangiography to situations of anatomic uncertainty or when choledocholithiasis is suspected. The overall incidence rate of common duct stones reported in conglomerate series of laparoscopic cholecystectomies is 4% to 11%; however, in patients with acute cholecystitis, the reported incidence rate has been as high as 18%. With use of cholangiography to help elucidate anatomic uncertainties, it is important to understand that the images can be misleading, especially when the right hepatic duct arises off of the cystic duct. Therefore, it cannot be overemphasized that intraoperative cholangiography, albeit often very helpful, should never be substituted for a definitive dissection creating the critical view of the vital biliary tract structures. In keeping with the noted increased incidence of ductal stones in patients with acute cholecystitis, some surgeons have advocated the routine preoperative use of MRCP or endoscopic retrograde cholangiopancreatography (ERCP). It is fair to say, however, that this practice is not mainstream, and most surgeons reserve this strategy for patients with hard signs of choledocholithiasis such as significant jaundice, cholangitis, ductal dilation, or radiologic findings of intraductal calculi.

When ductal stones are discovered during laparoscopic cholecystectomy, the growing consensus is that they should be definitively addressed at the time of the initial surgery. This is obviously more satisfactory to the patient and more cost effective and saves the patient from a potentially failed ERCP. Current options include laparoscopic common duct exploration and laparoscopic transcystic basket choledocholithotomy. Both procedures are difficult and require expertise that is not often available in every hospital. In such a situation, which is more common than not, it is well within the standard of care to plan for a postoperative ERCP choledocholithotomy.

OPEN CHOLECYSTECTOMY

Despite the mainstream acceptance of laparoscopic cholecystectomy as the procedure of choice in the management of acute cholecystitis, open cholecystectomy remains an important part of the surgical armamentarium in the treatment of this disease. The procedure is indicated when laparoscopy is contraindicated or when the laparoscopic procedure cannot be completed safely. The operation is performed through either a subcostal or a midline incision, both of which provide excellent exposure. Dissection is achieved through either a fundus-down or an infundibulum-down technique. In situations of severe inflammation, especially when the infundibular technique is too hazardous, the fundus-down technique is safer and advisable. As noted in the description of this technique done laparoscopically, it is important to proceed cautiously in the lower superior area of the gallbladder to avoid damaging the hepatic artery and duct, which can be retracted up in this dissection plane because of the inflammatory process often encountered in this situation. The principles of the rest of the operation are no different than those of the previously described laparoscopic procedure, with the exception of the situation where ductal stones are encountered. In this circumstance, the authors believe that definitive management of this problem should occur at the time of the initial open operation in the form of a common duct exploration and choledocholithotomy with T-tube drainage. If the technique of common duct exploration is not within the repertoire of the operating surgeon and not available in the hospital at the time of the surgery, it is then acceptable to close the patient and obtain a postoperative ERCP. The surgeon must be aware, however, that this exposes the patient to the possibility of a failed ERCP effort and the need of other difficult and dangerous ancillary procedures.

In the unusual, but periodic, case in which the inflammatory response is so severe as to preclude complete open safe dissection of the gallbladder, a partial cholecystectomy is the next best alternative. Key elements of this technique include leaving the back wall of the gallbladder intact, cauterizing the mucosa, and attempting, if possible, to close the distal infundibulum and place closed suction drains. Finally, for patients to whom partial cholecystectomy is deemed too hazardous or in patients with sepsis who are not operable candidates, tube cholecystotomy is the appropriate and often life-saving alternative.

NEW DEVELOPMENTS

In recent years and in keeping with the progressive minimally invasive theme in surgery, several reduced port or alternative port procedures for biliary surgery have been proposed. Single-port access surgery with one incision predominately at the umbilicus has gained some popularity. Although the procedure at the present time appears to be as safe in selected patients as a standard multiport laparoscopic cholecystectomy, the only proven advantage so far is possibly one of cosmesis. At the extreme end of this minimally invasive effort is incisionless, or natural orifice surgery (NOTES), which involves endoscopically created portals for surgery through the vagina or stomach. The NOTES procedures are currently investigational only but certainly highlight the ongoing miracles of surgical technologic development.

Finally, the application of the robot as an adjunct to the laparoscopic technique of cholecystectomy is gaining interest and popularity. Current robotic platforms allow for single-port access cholecystectomy with the advantage of three-dimensional optics, more achievable triangulation, markedly improved ergonomics, and a proposed reduction in the technical difficulty of the operation. The advantages and the appropriateness of this technology, and cost issues, are yet to be resolved and await further study.

COMPLICATIONS

A litany of recognized complications can occur after laparoscopic or open cholecystectomy. It is important to note and to be aware that the conduct of these common procedures in patients with acute cholecystitis with the coincident difficulties of dissection and anatomic recognition imposed by the inherent inflammatory process creates an environment of surgical difficulty and danger. Difficulties in structure recognition can lead to the delayed diagnosis of operative injuries, often with disastrous clinical results.

Subhepatic abscess most often occurs in patients with severely inflamed, gangrenous, or perforative gallbladders. The abscess results from the spillage of infected bile with often coincident hematoma and can be catalyzed by the presence of spilled stones that are left behind. The complication is best prevented by avoidance of bile spillage, obtaining of meticulous hemostasis in the liver bed, the retrieval of all spilled stones, copious irrigation of the subhepatic space, and the placement of closed suction drains if severe contamination has occurred. Most of these situations resolve after a short period of antibiotics, but definitive treatment with the placement of CT scan–directed drains is sometimes necessary.

Excessive bleeding, either from the bed of the dissected liver or from vascular injury, can be extremely problematic and challenging, particularly in the laparoscopic case. Liver bed bleeding, although often impressive, can almost always be controlled with the aggressive use of electrocautery and liberal use of topical chemical coagulant products. Vascular injuries often create a situation where control becomes difficult because of visual limitations from the ongoing hemorrhage and vessel retraction into areas of severe inflammation. Injudicious and poorly exposed dissection, blind clamping, or indiscriminate autoclipping often leads to ductal injury and should be avoided. In the circumstance of the laparoscopic case, if after a reasonable period of time, safe exposure and dissecting techniques have not achieved hemostasis, the patient should be rapidly converted to an open procedure. It is important to note that many bile tract injuries are complex and the surgeon should avoid missing a coincident ductal injury in this situation.

Bile duct leaks are unfortunately a common complication in this set of patients. They result from either persistent drainage of the interrupted ducts of Luschka or more commonly from a cystic duct leak from a dislodged clip. Clip dislodgement seems to occur when clips are placed across severely inflamed ducts or across ducts containing calculi. In efforts to prevent this complication, both of these maneuvers should therefore be avoided. If a good clip closure cannot be achieved, then closure of the biliary system can be accomplished by placing the endoGIA across the distal infundibulum. These patients present with low-grade fever, bloating, and hyperbilirubinemia, most commonly within the first postoperative week. The diagnosis is confirmed by the presence of a subhepatic fluid collection on ultrasound scan and a ductal leak on HIDA scan. Unless the patient presents with septic peritonitis and hemodynamic instability, the treatment is nonoperative and accomplished with CT scan drainage of the subhepatic space and endoscopic biliary stent placement.

Bile duct injury is an extremely serious and potentially catastrophic complication of cholecystectomy. The worldwide reported incidence rate of this complication is 0.1% to 0.2% in open procedures and 0.4% to 0.8% in those conducted laparoscopically. The classic injury occurs when the common bile duct is mistaken for the cystic duct, most commonly resulting from excessive cephalad retraction of the gallbladder, bringing the two ductal structures into parallel alignment. The incidence of this complication is markedly increased in situations of severe inflammation, anomalous anatomy, and excessive bleeding. As stated previously, it is important to note these injuries are often complex, with concomitant hepatic artery and portal vein branch injuries in up to 12% of patients. It is also interesting to note that the use of routine cholangiography has not been shown to prevent these injuries but certainly should be attempted after intraoperative bile duct injury has been discovered. Intraoperative recognition occurs in only about 25% of patients and is noted by evidence of a bile leak, abnormal cholangiogram, or obvious anatomic disruption at the time of surgery. In most patients, ductal injury recognition is delayed, presenting in the early postoperative period with jaundice and pain with or without sepsis, or 6 months to 1 year later, often with cirrhosis or liver failure from duct disruption or stricture. The management of this complication depends on the time of the diagnosis and the extent of the injury to the duct. The goal of treatment is the prevention of cholangitis, ductal stricture, and cirrhosis. When the common bile duct injury is discovered at the time of cholecystectomy, it is important to remain calm, not panic, and attempt to accurately define the nature, extent, and location of the injury. Minor nonelectrocautery lateral ductal injuries can be managed with simple T-tube drainage of the injury site. However, significant injuries from electrocautery and those involving damage to greater than 50% of the circumference of the bile duct wall require complex Roux-en-Y choledochojejunostomy reconstruction. Although immediate reconstruction of a major ductal injury is preferable at the time of the incident, this reconstruction requires the expertise of an experienced hepatobiliary tract surgeon who is facile in the management of this complication. If this level of expertise is not available in the hospital at the time of this injury, it is imperative not to attempt the repair but to define the injury, achieve drainage, and transfer the patient to a facility with these capabilities as soon as possible. In the patient in whom the diagnosis is delayed beyond the immediate operative period, the principles of drainage and ductal imaging also apply. Bile duct anatomy and drainage is often best accomplished in these patients with percutaneous transhepatic cholangiogram (PTC). Additional anatomic definition and drainage can be provided with ERCP and CT scan–directed catheters. In these circumstances, these patients are best treated with a delayed biliary tract reconstruction in 6 to 12 weeks, allowing for the resolution of sepsis and inflammation.

The Management of Common Bile Duct Stones

Rizwan Ahmed, MD, and Mark D. Duncan, MD

OVERVIEW

In the spectrum of biliary calculus disease, choledocholithiasis, or common bile duct (CBD) stones, provides diagnostic and therapeutic challenges to the surgeon. With advancements made in imaging and minimally invasive surgery, algorithms for optimal care have evolved. CBD stones are found in 8% to 10% of patients who have cholelithiasis. These are secondary CBD stones and are almost always cholesterol stones. Primary CBD stones are those found as a result of biliary stasis and infection; these stones are most often pigment stones composed of calcium bilirubinate. In only a small minority of these cases are CBD stones found in the absence of stones in the gallbladder.

The manifestation of choledocholithiasis is variable. Patients may have no symptoms, with either small stones passing through to the duodenum or with stones present. More commonly, stones obstruct the lumen of the CBD, causing clinical manifestations that may include obstructive jaundice, gallstone pancreatitis, or ascending cholangitis. Obstructive jaundice is evaluated to distinguish between calculus disease (CBD stone), stricture (which implies prior pancreatitis or prior surgery), and malignancy. In gallstone pancreatitis, levels of pancreatic enzymes typically rise and then rapidly fall. If the CBD is evaluated and cleared as described later, the authors perform laparoscopic cholecystectomy during the same admission.

The classic presentation of right upper quadrant pain, fever, and jaundice is described as *Charcot's triad,* after the French neurologist Jean-Martin Charcot's description of cholangitis. The presence of fever and jaundice may be indicators of locoregional infection confined to the CBD. When this condition progresses to include septic shock and mental status changes, termed *Reynold's pentad,* this indicates systemic infection, and decompression of the biliary tract is urgently needed. Fortunately, most patients with choledocholithiasis are spared this degree of illness.

Most often, cholelithiasis is detected as a result of clinical suspicion because of laboratory indicators, dilatation of the CBD on sonography or computed tomographic scan, or the history of jaundice or pancreatitis. The management of choledocholithiasis is dependent on when it is detected in relation to surgical treatment: (1) as a result of preoperative suspicion for or detection of CBD stones; (2) when CBD stones are found at the time of surgery, typically during intraoperative cholangiography (IOC); and (3) after cholecystectomy, when approximately 1% to 2% of patients who have undergone the procedure present later with symptomatic retained CBD stones. For the purpose of definition, previously undetected CBD stones found more than 2 years after cholecystectomy are defined as primary stones but are managed by the same postoperative algorithm.

CLINICAL LABORATORY FINDINGS

The classic laboratory findings with any biliary tract obstructions are elevation of the serum alkaline phosphatase level and direct hyperbilirubinemia. Elevations of the aspartate aminotransferase, alanine aminotransferase, and lactate dehydrogenase levels are often not present or are inconsistent and thus are of less diagnostic value. The finding of elevated pancreatic enzymes amylase and lipase levels in the presence of cholelithiasis raises the suspicion for gallstone pancreatitis, particularly in combination with a dilated CBD. Leukocytosis may be present with cholecystitis, cholangitis, or pancreatitis and is a nonspecific marker of biliary tract inflammation or infection. Any of the aforementioned laboratory abnormalities along with the physical signs and symptoms or with ductal dilatation observed on imaging warrant further investigation with imaging studies for treatment planning.

IMAGING WORKUP

Transabdominal Ultrasonography

The most common initial imaging modality for the evaluation of the gallbladder and biliary tract is transabdominal ultrasonography. The authors utilize the sonogram to answer the following questions. Are gallstones present? Is the gallbladder wall thickened, or is pericholecystic fluid present to suggest acute cholecystitis? Is there tenderness during the sonographic examination, the sonographic Murphy's sign? Is the CBD dilated? Is there sonographic evidence of acute pancreatitis? Ultrasonography has become the standard of care in diagnosing biliary tract dilation and biliary stones. The finding of dilation of the CBD to 1 cm or more in the presence of cholelithiasis raises the suspicion for choledocholithiasis. In at least half of patients presenting in the emergency department with suspicion of CBD stones, however, no stone is observed on subsequent definitive endoscopic retrograde cholangiopancreatography (ERCP). The sonogram itself may demonstrate actual calculi in the CBD, but this is less common. Endoscopic ultrasonography during upper endoscopy has been shown to be sensitive in 94% and specific in 95% of patients with choledocholithiasis, but this procedure requires special expertise and is rarely employed in the acute presentation.

Although hepatobiliary iminodiacetic acid (HIDA) may help clinicians detect obstructing CBD stones by virtue of nonvisualization of the duodenum and small bowel, it is seldom employed to evaluate the CBD directly.

Endoscopic Retrograde Cholangiopancreatography

The method routinely employed for diagnosis and therapeutic management of choledocholithiasis is ERCP. ERCP is standard practice

for removing stones from the CBD; indeed, with the advent of ERCP, the frequency of surgical CBD exploration declined rapidly. When performed by a skilled endoscopist, ERCP and basket stone extraction, typically combined with sphincterotomy of the sphincter of Oddi, has satisfactorily cleared the CBD in 90% to 97% of cases. There are, however, consequences of ERCP, namely post-ERCP pancreatitis which is diagnosed on the basis of enzyme levels in up to 6% of patients and on the basis of clinical symptoms in 3%. As with any acute pancreatitis, the clinical course can be of short duration and inconsequential or develop into multisystem disease with life-threatening consequences. Other less common complications of ERCP—or with any biliary instrumentation, including percutaneous transhepatic cholangiography (PTC)—include sepsis from cholangitis, hemorrhage, or intestinal perforation. A rare, late complication is papillary stenosis. Furthermore, as already noted, approximately half of results of ERCP in the setting of suspected CBD stones are negative. Thus, to spare the risk of unnecessary diagnostic ERCP, the authors now routinely employ magnetic resonance imaging (MRI) or magnetic resonance cholangiopancreatography (MRCP).

Although some technically advanced laparoscopic surgeons may advocate for surgical clearance of the CBD by laparoscopic CBD exploration, the authors believe that preoperative ERCP is a better and safer approach when stones are documented in the CBD. In 2002, the National Institutes of Health published a consensus regarding the indications for ERCP and the contraindications to unnecessary procedures. For the purpose of this text, the key points addressed were as follows. Patients scheduled for elective cholecystectomy for cholelithiasis did not require ERCP if there was a low clinical suspicion for CBD stone. ERCP combined with sphincterotomy and stone removal was considered effective in the management of choledocholithiasis. Furthermore, in the consensus statement, postoperative ERCP was approved as an acceptable and effective means to clear CBD stones left behind after laparoscopic or open CBD exploration. This is in contrast to a previously stated surgical opinion that known choledocholithiasis identified in the operating room should be definitively addressed. An acceptable alternative to surgical CBD exploration is to complete the cholecystectomy procedure and to plan for postoperative ERCP. There is no demonstrable change in overall rates of morbidity or mortality between ERCP followed by laparoscopic cholecystectomy and laparoscopic cholecystectomy followed by ERCP. Some patients, particularly those with prior gastric bypass or with duodenal diverticula, are poor candidates for ERCP. Options for them are discussed as follows.

Magnetic Resonance Cholangiopancreatography

Advances in imaging have led clinicians to change the approach to suspected CBD stones. Although ERCP provides diagnosis and management in the same setting, it is not without complications, as outlined previously. MRCP has been found to be 93% specific and 94% sensitive in diagnosing choledocholithiasis and provides a noninvasive alternative to viewing stones missed in transabdominal ultrasonography. This attribute of MRCP provides the most utility in preoperative decision making for patients undergoing elective surgery for cholelithiasis in whom there is a question of a CBD stone, without subjecting the patient to ERCP. In particular, the half-Fourier acquisition single-shot turbo spin-echo (HASTE) MRI sequence provides excellent images that are more readily interpretable by surgeons than sonograms and is an ultrafast modality. Acquisition time is 13 seconds, which allows patients to hold their breath. The authors routinely employ MRCP for all patients in whom choledocholithiasis is suspected preoperatively (Figure 1). If the MRCP confirms a stone in the duct, the patient is then directed to therapeutic ERCP. If no stone is present, and the clinical course is consistent, the authors go ahead with the planned cholecystectomy, typically laparoscopically. In rare instances, rising bilirubin or alkaline phosphatase levels even after a negative MRCP prompt reconsideration of ERCP.

MANAGEMENT

Management of choledocholithiasis depends on when CBD stones were discovered in relation to surgery. The flowchart in Figure 2 demonstrates the algorithm for cholelithiasis suspected or discovered preoperatively, intraoperatively, or postoperatively.

Preoperative

Most patients will have already undergone ultrasonography before surgical evaluation for biliary tract disease. When choledocholithiasis is suspected on the basis of the findings of a dilated CBD or elevations in bilirubin, alkaline phosphatase, or pancreatic enzyme levels, the patient next undergoes MRCP. If CBD stones are confirmed by MRCP, or if they have already been demonstrated on ultrasonography, then ERCP is employed to clear the duct. If no stones are visualized on MRCP or during subsequent ERCP, then laparoscopic cholecystectomy is performed during the same admission. When choledocholithiasis is found and ERCP with endoscopic sphincterotomy is unable to clear the CBD of stones, several options are available to the surgeon. One is to proceed to surgery for laparoscopic cholecystectomy with laparoscopic CBD exploration. The technique for this is described in the Intraoperative section, but not all surgeons are capable of performing minimally invasive CBD exploration. Another consideration would be interventional radiologic studies for PTC. The initial PTC procedure is often diagnostic and not

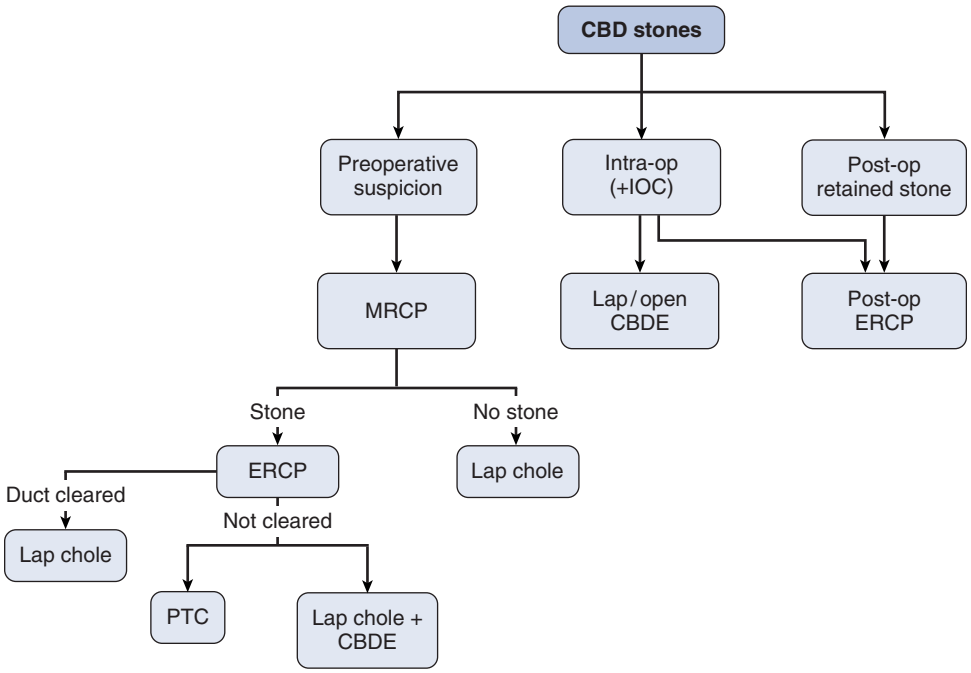

FIGURE 2 Algorithm for management of choledocholithiasis. *CBD,* common bile duct; *CBDE,* common bile duct exploration; *ERCP,* endoscopic retrograde cholangiopancreatography; *IOC,* intraoperative cholangiography; *Lap,* laparoscopy; Lap chole, laparoscopic cholecystectomy; *MRCP,* magnetic resonance cholangiopancreatography; *PTC,* percutaneous transhepatic cholangiography.

therapeutic, inasmuch as a catheter of adequate diameter to allow for instrumentation or manipulation is rarely available; thus repeated interventional radiographic studies with serial dilatation and upsizing is usually required. An effort at ERCP can also be repeated. The decision as to which option is best for a given patient is based on the clinical course of the condition and the availability of and local expertise with endoscopic, radiologic, and surgical techniques.

With the increasing number of patients undergoing bariatric procedures in which cholecystectomy is not always routinely performed, the ability to perform ERCP may be limited. In patients who have undergone Rou-en-Y gastric bypass, the duodenum and ampulla of Vater are no longer accessible to routine upper endoscopy. In this patient population, direct imaging, stent placement, or manipulation of the biliary tree may require a radiologic approach with PTC and catheter placement. Another option if PTC cannot be accomplished is to proceed to surgery: either laparoscopic cholecystectomy and CBD exploration or an open procedure. The history of previous foregut surgery does not preclude successful laparoscopic biliary tract surgery. The authors have employed, on rare occasion, placement of a polyethylene glycol (PEG) tube in the bypassed gastric remnant that can provide access for subsequent ERCP. This PEG tube can be placed either under computed tomographic guidance by an interventional radiologist or directly by a skilled endoscopist navigating up the Roux limb. In the latter case, the endoscopist may be able to reach the ampulla but, at extended endoscopy, is probably not able to cannulate and perform ERCP; instead, the endoscopist creates the more direct route via the PEG tube. These efforts to clear the CBD of stones in advance of surgery are warranted in a patient population who by virtue of either or both previous upper abdominal surgery and body habitus may be poorly suited for surgical CBD exploration. The same considerations apply to patients with prior gastric resection with gastrojejunostomy or in patients with known duodenal diverticulum.

Intraoperative

Choledocholithiasis may be suspected or found intraoperatively as a result of the presence of CBD dilation, which prompts IOC, or as a finding of IOC whether performed for specific indications or routinely. Although the authors do not perform routine IOC with laparoscopic cholecystectomy, practices vary, and the frequency of IOC varies remarkably according to geography. Arguments in favor of routine IOC cite the detection of choledocholithiasis, the recognition of CBD anatomic variations, and, perhaps of most importance, the ability to identify CBD injury. Routine IOC, when reviewed in a meta-analysis of studies conducted nationwide, showed no reduction in rate of CBD injury compared to selective use of IOC. The authors conclude that routine IOC is not necessary.

Criteria for selective IOC are not uniformly accepted but typically include a history of jaundice, a history of pancreatitis, or elevation of hepatic enzyme levels. The essential components of IOC are visualization of right and left hepatic ducts, free flow of the contrast agent into the duodenum, visualization of any filling defect or obstruction, and identification of any CBD injuries. In the event that IOC does not reveal the intrahepatic ducts, the patient can be placed in the Trendelenburg position, and morphine sulfate can be administered intravenously to cause contraction of the sphincter of Oddi, thus preventing the flow of the contrast agent into the duodenum. If the concern is from the caudal flow of the contrast agent, the patient can be placed in the reverse Trendelenburg position and given glucagon. In practice, the authors have rarely found these maneuvers to be necessary. When IOC is successful, contrast material is visualized flowing into the duodenum and clearly into both hepatic ducts with no extravasation or filling defect.

Fluoroscopy is better than static images for intraoperative viewing. When choledocholithiasis is determined during surgery, the surgeon may elect to directly address this with laparoscopic CBD exploration. It is also considered acceptable practice to perform the laparoscopic cholecystectomy and plan postoperative ERCP for clearance of the CBD. Although this practice was previously controversial, it is now recognized that postoperative ERCP is usually successful, and as the National Institutes of Health consensus noted, the overall rate of morbidity is the same as when ERCP precedes surgery. The authors no longer recommend conversion to an open procedure solely to perform CBD exploration when cholecystectomy can be performed laparoscopically; the authors believe that the overall rate of morbidity of this approach exceeds that of morbidity after ERCP, in recognition of the small risk of unsuccessful ERCP and retained stones. For surgeons less familiar with minimally invasive techniques of CBD

exploration, postoperative ERCP is the procedure of choice. Other potential barriers to a surgical approach to the CBD include the unavailability of a 3-mm endoscope/choledochoscope; the unavailability of appropriate sized Silastic tubes, biliary stents, or T-tubes; or simply the smallness of the CBD.

Technique of Laparoscopic Common Bile Duct Exploration

The simplest approach to laparoscopic CBD exploration is to avoid suture or incision in the CBD itself and instead go through the cystic duct to access the CBD (transcystic duct CBD exploration). During laparoscopic cholecystectomy, and before transection of the cystic duct and removal of the gallbladder, a transverse opening is made sharply in the cystic duct, similar to what is done during IOC. The opening can then be dilated to directly engage the CBD, but the laparoscopic approach that the authors favor is to utilize a choledochoscope (2.5- or 3-mm endoscope) with a working channel for a basket stone extractor. This instrument may be more familiar to the operating room team as the *pediatric ureteroscope*. It allows direct visualization with constant saline flow in both the distal CBD and the proximal ducts. The choledochoscope may be directly inserted or placed over a guidewire with direct visualization in either setting. With saline flush alone, the surgeon may be able to flush a stone through the ampulla. It is more likely, however, that a Dormia basket will be passed through the 1.2-mm working channel of the choledochoscope. The disadvantage of using the basket is that once the stone is within the basket, the entire apparatus, including choledochoscope and basket, must be withdrawn together for extraction and then the choledochoscope reinserted after each effort.

A completion IOC helps confirm clearance of the duct. High success rates (up to 90%) have been reported for this approach. The great advantage of the transcystic duct approach is that after successful extraction of one or more stones, the cystic duct can then simply be doubly clipped proximal to the opening in the cystic duct, just as in typical laparoscopic cholecystectomy. Further options that may afford a more secure closure of the cystic duct stump include ligation and use of an Endo Stitch loop closure. If the CBD can be satisfactorily cleared in this scenario, a T-tube is not required.

Technique of Laparoscopic Direct Common Bile Duct Exploration

If limitations at the facility, of the surgeon's skill set, or of the patient's anatomy do not enable the transcystic duct approach, either a laparoscopic or open traditional CBD exploration can be performed. This may also be necessary in the case of large stones, small cystic duct, or stones in the proximal ducts. Laparoscopic direct CBD exploration requires more advanced laparoscopic training and skills than most surgeons performing general laparoscopic cholecystectomy possess. When either of these methods is employed, the laparoscopic surgeon must first expose the anterior surface of the CBD and, if need be, confirm the identity if the CBD with needle aspiration of bile. Next, fine (4-0) sutures laterally and medially (in the 3 and 9 o'clock positions) are placed on the CBD for traction and exposure. A 15- to 20-mm opening is made longitudinally on the anterior aspect of the distal CBD, and saline flush is instituted. This alone may dislodge stones. The surgeon may then place an endoscope directly, as described previously, or use a 4F biliary Fogarty catheter to try to remove one or more stones. After successful clearance of the duct, the choledochotomy is closed over a T-tube with interrupted 3-0 or 4-0 absorbable sutures; the tube exits the CBD at the inferior end of the choledochotomy opening away from the liver and caudal to the sutures. The authors bevel each end of the T-tube and also remove the back portion of the T-shaped end, or they cut a notch to facilitate extraction. T-tubes are customized from a 14F or smaller tube (Figure 3). If a commercial T-tube is unavailable, the surgeon can split one end of a straight Silastic catheter to create a "T" shape, but this type of tube is more prone to be dislodged. The T-tube is brought out linearly through the abdominal wall to facilitate subsequent access for imaging or manipulation if needed.

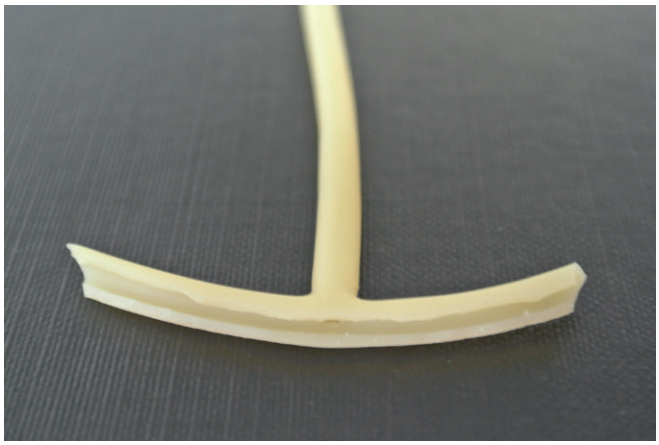

FIGURE 3 Customized 12F T-tube with beveled ends and portion of back wall removed.

The open CBD exploration follows the same steps with traction sutures on the duct, followed by a 15-mm to 20-mm anterior choledochotomy. The open approach affords more opportunities for stone extraction. These include direct saline flushing, digital palpation and manual massage of the duct, passage of Bakes dilators or Randall stone forceps, the use of a biliary Fogarty balloon catheter or a choledochoscope, and basket. Clearance of all stones from the duct can be demonstrated by removal of a known quantity of stones, by cholangiography, or by choledochoscopic visualization. The duct is closed with interrupted 3-0 or 4-0 absorbable suture over a T-tube in the inferior end of the choledochotomy caudal to the sutures.

The postoperative management of T-tubes depends on the clinical scenario and whether there is any suspicion of persistent stones in the duct. Clinical practice regarding removal of the T-tube varies widely, from 10 days to 6 weeks after placement. If multiple stones were found and extracted from the CBD at the time of surgery, there is a much higher incidence of residual stones, and the T-tube is left for a longer period and imaged with T-tube cholangiography before removal. It is the authors' practice to "internalize" the T-tube drain for most patients before discharge by clamping the tube externally and then monitoring the clinical and laboratory course. If the patient is recovering appropriately from the operation, and in the absence of fever, chills, increase in pain, or elevation of serum bilirubin or alkaline phosphatase levels, the tube remains clamped. This favorable and typical scenario indicates passage of bile from the CBD through the ampulla. The patient is then discharged with the T-tube clamped, and it is removed in 2 weeks in the outpatient clinic without T-tube cholangiography if the patient remains clinically stable. If, however, the patient has any of the aforementioned signs and symptoms after the T-tube is clamped, this implies pressure in the biliary tree from failure of the duct to empty through the ampulla, and the clamp is removed and the T-tube again drained externally to a bile bag until either the clinical scenario improves or T-tube cholangiography demonstrates patency without obstruction. In instances with known residual choledocholithiasis, the T-tube is the tract that allows interventional radiology to directly access the biliary tree for stone extraction, although dilation and upsizing of the drain may be required.

Postoperative

Patients may return to their physician after laparoscopic cholecystectomy with signs or symptoms suggesting a retained CBD stone. Such patients often present with recurrent or persistent pain, elevations

of bilirubin and alkaline phosphatase levels, and ductal dilation on ultrasonography or computed tomographic scan. The workup in this scenario is very reminiscent of the preoperative workup, with liberal use of MRCP to help determine whether bile duct calculi are present. ERCP with endoscopic sphincterotomy is utilized to image and clear the duct of stones. In a single-institution retrospective analysis, 1085 patients who underwent cholecystectomies were studied; in 25 patients (2.3%), postoperative ERCP confirmed retained CBD stones, and these patients were subsequently treated with ERCP. The analysis also revealed that patients with small gallstones (<5 mm) were more likely to present later with retained CBD stones. In patients for whom a T-tube is present after CBD exploration, a radiographic approach to the extraction of retained stones is utilized. Once the T-tube tract is matured 4 to 8 weeks postoperatively, the duct is accessed in interventional radiology for attempted basket retrieval of stones. In the rare case in which neither endoscopic nor radiographic methods are capable of clearing stones nonsurgically, another operation, probably with open CBD exploration, may be needed.

SUMMARY

Choledocholithiasis manifests in a small population of patients undergoing cholecystectomy for cholelithiasis and persists in an even smaller number of patients after cholecystectomy. With the liberal application of MCRP imaging, the nearly ubiquitous utilization of laparoscopic cholecystectomy, and the advent of minimally invasive techniques for CBD exploration available to surgeons so trained, there are now new algorithms to guide the management of CBD stones. Much of the decision making hinges either on the timing of presentation in relation to surgery or on the training and expertise of the surgeon in performing laparoscopic or open CBD exploration. The option of completing a cholecystectomy without performing CBD exploration with planned postoperative ERCP is also recognized as acceptable therapy. The availability of skilled endoscopists and interventional radiologists in the multidisciplinary approach to CBD stones further guides treatment choices. Optimal management of choledocholithiasis requires the surgeon to be cognizant of all treatment options so as to judiciously use the methods that take into account local expertise to best serve the patient's needs.

Acute Cholangitis

Gaurav Sharma, MD, MS, Edward E. Whang, MD, and Jason S. Gold, MD

OVERVIEW

Acute cholangitis is a morbid condition characterized by infection and inflammation that affects the biliary tract. It usually occurs in the setting of biliary obstruction. The spectrum of clinical severity can range from mild to potentially life-threatening disease accompanied by septic shock and multiorgan dysfunction. Because of the propensity for rapid deterioration with untreated acute cholangitis, expeditious diagnosis and therapy are essential.

EPIDEMIOLOGY

The median age of patients diagnosed with acute cholangitis is reported to range from 50 to 60 years, and incidence increases with age. The most important risk factors are biliary stasis or obstruction, for which the most prevalent etiology is choledocholithiasis. In much of the world, secondary choledocholithiasis (caused by stones originating in the gallbladder) predominates. In Southeast Asia, however, where recurrent pyogenic cholangitis (Oriental cholangiohepatitis) is endemic, primary choledocholithiasis is an important cause of cholangitis. Interestingly, although malignant obstruction may cause acute cholangitis, the probability of its development in the absence of prior instrumentation of the biliary system is low. The etiologies of acute cholangitis are listed in Box 1.

PATHOGENESIS

Despite its communication with the small intestine, the biliary tree is usually sterile. Most cases of acute cholangitis are thought to arise from direct ascent of bacteria from the duodenum into the common bile duct; hematogenous seeding of the biliary tract is likely to play only a minor role. Bacterial proliferation within the biliary tract, together with its entry into the systemic circulation via lymphatic and venous channels, results in the infectious manifestations of acute cholangitis.

Obstruction to physiologic biliary outflow plays a critical role in the pathogenesis of acute cholangitis. Predominant causes of biliary obstruction resulting in cholangitis are secondary choledocholithiasis, gallbladder stones (2/3 to 3/4 of cases), and malignant disease. Benign strictures and primary sclerosing cholangitis also underlie a significant number of cases. An increasingly prevalent risk factor is iatrogenic biliary tract manipulation (see Box 1), which in some centers, particularly those with active liver transplantation programs, is associated with up to 50% of cases of acute cholangitis. Examples include endoscopic and percutaneous instrumentation of the biliary tract, indwelling biliary stents, anastomotic (bilibiliary or bilienteric) strictures, and ischemic strictures of the biliary tract. Endoscopic retrograde cholangiopancreatography (ERCP) has been implicated in 0.5% to 1.7% of cases of acute cholangitis, particularly when therapeutic interventions are undertaken.

Bile duct obstruction can be further categorized as "high" or proximal obstruction, versus "low" or distal. Outside of Southeastern Asia, the latter is most often the result of choledocholithiasis from gallstones, and the former is typically caused by cholangiocarcinoma. The site of obstruction is critical to determining the optimal treatment.

Polymicrobial infection is found in most patients with acute cholangitis. Bowel flora constitute the most common isolates. The most

frequently identified gram-negative bacteria are *Escherichia coli* (25% to 50% of cases), *Klebsiella* species (15% to 20% of cases), and *Enterobacter* species (5% to 10% of cases). The most commonly isolated gram-positive bacteria are *Enterococcus* species (10% to 20% of cases). The contribution of anaerobes, such as *Bacteroides* and *Clostridium* species, to the pathogenesis of acute cholangitis is controversial; however, anaerobes are not uncommonly cultured in specimens obtained from elderly patients and those who have undergone biliary instrumentation. Although bacteria are responsible for the great majority of cases of acute cholangitis, other pathogens, such as helminths, fungi, and viruses (e.g., cytomegalovirus and Epstein-Barr virus) can cause this syndrome. These organisms should be considered in the appropriate clinical setting (e.g., in areas where parasitic infections are endemic and among individuals with immunocompromise).

Repeated bouts of infection can lead to strictures and secondary biliary cirrhosis.

CLINICAL PRESENTATION

In 1877, Jean Charcot described the hallmarks of acute cholangitis: fever, jaundice, and right upper quadrant abdominal pain. Note that all three features of this eponymous triad are present in only 50% to 75% of patients with acute cholangitis. Fever and abdominal pain are the most common symptoms (present in more than 80% of cases), with jaundice being slightly less prevalent (60% to 70% of cases). Reynold's pentad (described by Reynold and Dargon in 1959) denotes the presence of mental status derangements and hypotension in addition to the features of Charcot's triad. This aggregate is present in less than 5% of cases of acute cholangitis and is suggestive of severe disease and systemic sepsis.

BOX 2: Diagnostic criteria for acute cholangitis: Tokyo guidelines

A. Clinical Context and Clinical Manifestations
 1. History of biliary disease
 2. Fever or chills
 3. Jaundice
 4. Abdominal pain (right upper quadrant or upper abdominal)
B. Laboratory Data
 5. Evidence of inflammatory response*
 6. Abnormal liver function tests†
C. Imaging Findings
 7. Biliary dilation or evidence of an etiology (stricture, stone, stent, etc)

Suspected Diagnosis
 Two or more items in A
Definite Diagnosis

DIAGNOSIS

Acute cholangitis is a clinical diagnosis that is based on the presence of the clinical features discussed previously together with supportive data from laboratory tests and radiographic studies. Because acute cholangitis can present without abdominal pain, the absence of pain (or any of the individual symptoms and signs discussed previously) does not rule out this diagnosis. A high index of suspicion is warranted in elderly patients or patients with immunosuppression who may not exhibit the classic signs and symptoms of acute cholangitis until rapid decompensation and septicemia occur. Acute cholangitis should also be considered in patients who have attendant risk factors, such as choledocholithiasis or biliary strictures, with or without a history of instrumentation, and present with sepsis without abdominal pain or tenderness. The Tokyo guidelines provide criteria for diagnosis of acute cholangitis based on clinical, laboratory, and imaging findings (Box 2).

The differential diagnosis includes other conditions associated with right upper quadrant abdominal pain, jaundice, or fever such as cholecystitis, liver abscess, and hepatitis. Laboratory test findings typically associated with acute cholangitis include leukocytosis with neutrophilia and liver enzyme abnormalities suggestive of cholestasis (e.g., increased serum alkaline phosphatase, γ-glutamyl transpeptidase, and conjugated bilirubin concentrations).

Blood cultures should be performed in patients suspected of having cholangitis. In addition, cultures should be obtained from bile aspirated through percutaneous biliary catheters or obtained during biliary drainage and from any indwelling biliary prostheses that are removed. Although treatment should be initiated before culture results become available, these results can be used in directing specific antibiotic therapy.

Imaging studies have the following roles in patients with suspected acute cholangitis: (1) they can confirm the presence of dilated bile ducts (a finding present in most cases of acute cholangitis); (2) they may reveal the specific etiology responsible for biliary obstruction (e.g., gallstones); (3) they can exclude other conditions in the differential diagnosis (e.g., acute cholecystitis); and (4) they

can be used to guide therapeutic interventions (e.g., biliary drainage or removal of an obstructed biliary stent).

Transabdominal ultrasound scan is the best initial imaging study in most patients with suspected acute cholangitis. It is noninvasive, rapid, and cost effective; it spares patients from exposure to ionizing radiation; and it is highly sensitive in the detection of biliary tract dilation. The absence of biliary tract dilation does not rule out acute cholangitis, especially if the ultrasound scan is obtained soon after acute onset of biliary obstruction before the bile ducts have had time to dilate. In cases of proximal bile duct obstruction, dilated intrahepatic ducts without dilated extrahepatic ducts may be noted. Transabdominal ultrasound scan is associated with relatively low sensitivity in the detection of choledocholithiasis but is very sensitive in finding stones in the gallbladder.

Cholangiography is often indicated for therapeutic and diagnostic purposes. When available, ERCP is the preferred method of cholangiography in cases of distal bile duct obstruction. If choledocholithiasis is suspected on the basis of ultrasound scan, further imaging is usually not necessary before ERCP. Unavailability or failure of ERCP should prompt percutaneous transhepatic cholangiography (PTC). PTC is often the preferred approach for cholangiography and drainage in proximal bile duct obstruction. Patients with externally accessible indwelling biliary catheters (e.g., T-tubes or U-tubes) can undergo cholangiography with contrast instilled into these tubes.

Computed tomographic (CT) scanning can reveal biliary tract dilation and allows for global assessment of intraabdominal pathology, but it has poor sensitivity for the detection of intraductal stones. Magnetic resonance cholangiopancreatography (MRCP) has greater sensitivity for choledocholithiasis than CT scan (80% to 92% vs 33% to 40%, respectively) but is less widely available. MRCP can also be useful in assessing and characterizing biliary strictures. The prolonged duration of MRCP examination also limits the application in unstable conditions. CT scan or magnetic resonance imaging (MRI) may be useful when malignancy is in the differential diagnosis because these studies can identify masses and detect metastases. Endoscopic ultrasound scan (EUS) is another imaging option with excellent sensitivity for choledocholithiasis (93% to 95%).

THERAPY

Therapy for acute cholangitis consists of three main components: (1) resuscitation; (2) antibiotics; and (3) biliary drainage (Figure 1).

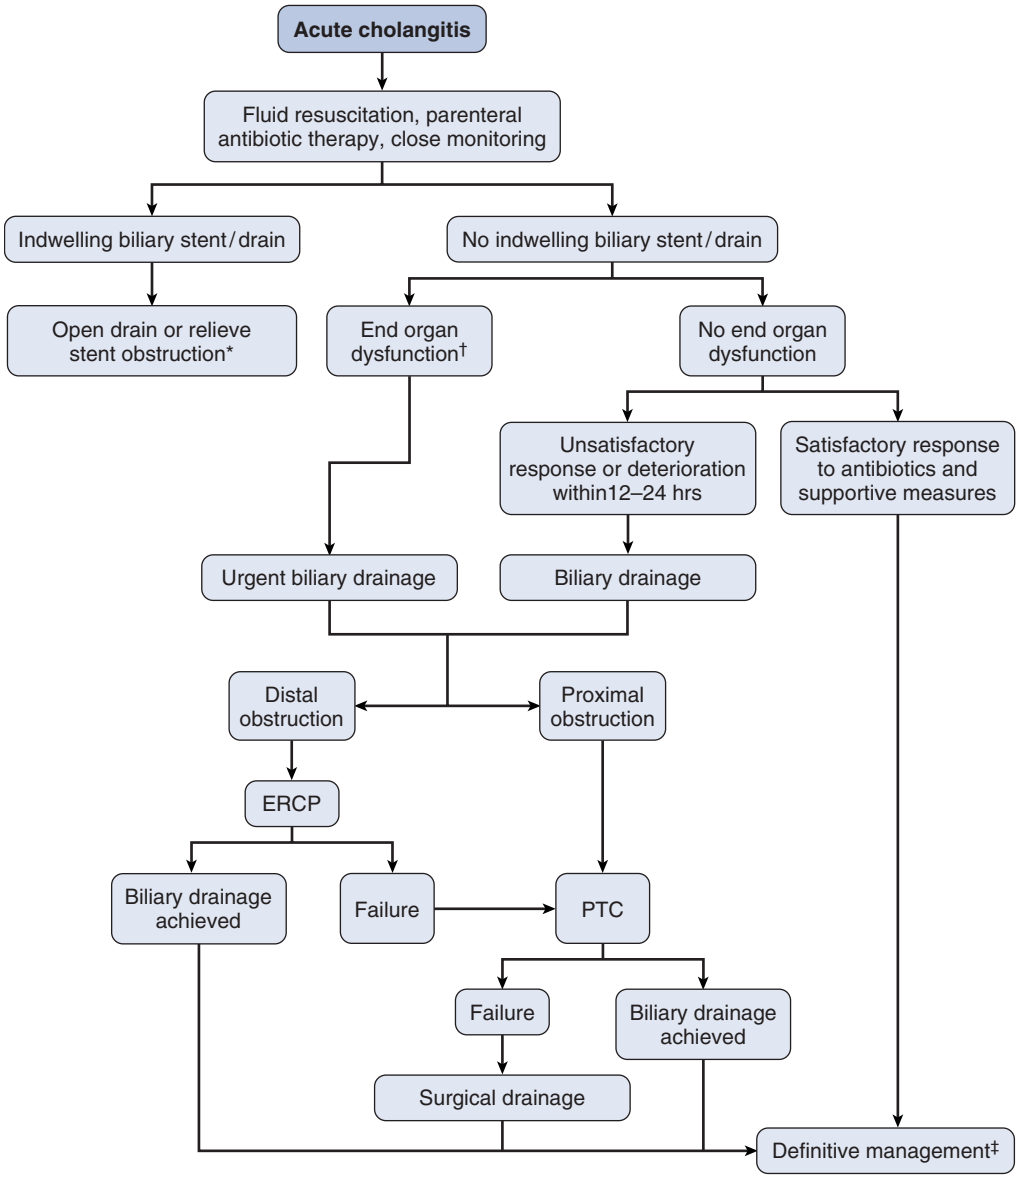

FIGURE 1 Clinical algorithm for management of acute cholangitis.
ERCP, Endoscopic retrograde cholangiopancreatography; *PTC,* percutaneous transhepatic cholangiography.
*For changing internal stents, urgency is determined by presence or absence of end-organ dysfunction.
†For example, altered mental status or hemodynamic lability.
‡Timing of definitive management is determined by the severity of the episode of cholangitis and the comorbidities of the patient.

Resuscitation with administration of intravenous fluids and correction of electrolyte abnormalities should be initiated without delay. Patients with external biliary drains should have these drains placed to gravity drainage as soon as the diagnosis of acute cholangitis is considered. Given that urgent interventional or surgical procedures are often required, attention should be directed to identifying and correcting coagulopathies that may exist (e.g., those resulting from vitamin K deficiency or sepsis-induced thrombocytopenia). Vigilant monitoring to ensure adequacy of resuscitation and early recognition of clinical deterioration (e.g., end-organ dysfunction) is essential. Patients with significant comorbidities and those exhibiting signs of hemodynamic lability or end-organ dysfunction are best monitored in a dedicated intensive care unit (ICU), where invasive monitoring and inotropic support can be instituted.

When the diagnosis of acute cholangitis is considered, empiric broad-spectrum antibiotic administration should commence without delay once peripheral blood cultures have been drawn. The foremost concern in selection of empiric agents is effectiveness against both gram-negative and gram-positive bacteria (especially *Enterococcus*). A secondary concern is ability of the antibiotics to achieve high concentrations within bile even in the presence of biliary obstruction. Despite the low frequency with which anaerobes are isolated from bile cultures, coverage of anaerobes should be considered because standard culture techniques underestimate the true prevalence of anaerobic infections and anaerobes are prevalent in cultures of bile obtained from some patient groups (e.g., those with prior biliary instrumentation).

Several appropriate antibiotic choices exist for empiric therapy. Selection is often guided by institutional antibiotic stewardship policies. Options include the combination of ampicillin and gentamicin, fluoroquinolones (e.g., ciprofloxacin or levofloxacin) alone or with metronidazole, carbapenems (e.g., imipenem or meropenem), extended-spectrum penicillins (e.g., piperacillin), and penicillin/beta-lactamase inhibitor combinations (e.g., piperacillin-tazobactam, ampicillin-sulbactam, ticarcillin-clavulanate). Given the substantial risk of aminoglycoside-induced nephrotoxicity, the authors prefer to avoid gentamicin-based regimens unless specific reasons for their administration exist. Although they provide excellent activity against gram-negative bacteria, second-generation and third-generation cephalosporins provide poor coverage against *Enterococcus* species and are therefore not recommended. The authors often use piperacillin-tazobactam because of its broad gram-negative, gram-positive, and anaerobic coverage; penetration into bile; and ease of administration.

With resuscitation and empiric antibiotic therapy, up to 85% of patients with acute cholangitis have improvement, even in the absence of interventional therapy. When culture results become available, antibiotics should be tailored to sensitivity findings. The duration of antibiotic therapy should be based on clinical response; for patients documented to have bacteremia, antibiotic courses that last 1 to 2 weeks are recommended. Response to initial treatment with antibiotics and the presence or absence of infection-induced organ failure are critical in determining the need and timing of subsequent interventions.

Patients without end-organ dysfunction and with resolved signs of infection with initial antibiotic treatment usually require no further treatment beyond that for the underlying condition. Relapse after initial response requires biliary drainage. In patients with cholangitis caused by choledocholithiasis, drainage of the biliary tree is not indicated when the stone passes spontaneously.

Patients who do not have organ dysfunction but who do not have a satisfactory response to initial treatment with antibiotics of 12- to 24-hour duration require biliary drainage. Persistence or worsening of abdominal pain, fever, or leukocytosis despite antibiotic therapy indicates the need for biliary drainage. If required for choledocholithiasis, a cholecystectomy can often be performed on the same hospital admission in patients with cholangitis that does not result in end-organ dysfunction.

Patients with cardiopulmonary, neurologic, renal, hepatic, or hematologic dysfunction typically require organ support in an ICU setting and urgent biliary decompression without a prolonged trial of antibiotics. Interval treatment of the underlying condition typically occurs after recovery from the episode of cholangitis.

Techniques of Biliary Drainage

Considerations for selection of the optimal drainage technique in acute cholangitis are: (1) site of obstruction, (2) results of previous drainage attempts, and (3) availability of equipment and expertise for each drainage approach. ERCP is the first-line modality for establishing biliary drainage in most cases because the majority of cases of cholangitis are precipitated by distal obstruction as a result of choledocholithiasis. PTC is the preferred approach in cases in which ERCP fails or is unavailable and is often preferred for patients with proximal obstruction (e.g., as with hilar cholangiocarcinoma). Urgent surgical biliary drainage is associated with high mortality and is reserved for only those rare circumstances in which nonoperative techniques have been exhausted or are unavailable.

Endoscopic Drainage

ERCP is effective in establishing biliary drainage in 90% to 98% of cases, although this efficacy is lower in certain circumstances (e.g., cholangitis resulting from hilar cholangiocarcinoma). In procedures performed for acute cholangitis, bile should be aspirated from the common bile duct to decompress it *before* injection of contrast for cholangiography. Occlusive cholangiography performed before ductal decompression, particularly in cases of suppurative cholangitis, can induce bacteremia, sepsis, and rapid decompensation. Other complications of ERCP include pancreatitis, duodenal injury, and complications associated with upper endoscopy in general. For patients in whom endoscopic sphincterotomy is contraindicated, such as those with persistent coagulopathy, temporizing biliary drainage can be achieved by placement of a nasobiliary drain or an internal biliary stent without sphincterotomy. For instance, a 10F or smaller internal biliary stent can be safely placed across the major papilla without need for a biliary sphincterotomy. More definitive therapy (e.g., endoscopic sphincterotomy and removal of intraductal stones) can then be accomplished electively, after conditions have stabilized. If biliary access at ERCP is unsuccessful, an additional modality in some specialty centers is EUS-directed access of the biliary tree, followed by biliary drainage via this access. However, this is a consideration only in patients with stable conditions, and the same results are more commonly achieved with PTC. Other therapeutic applications facilitated by ERCP in patients with acute cholangitis include replacement of obstructed biliary stents and stenting or dilation of benign biliary strictures. ERCP with fluoroscopy-free methodologies (wire-guided cannulation or endoscopic ultrasound scan guidance) has been used to treat cholangitis during pregnancy, with varying results.

Percutaneous Transhepatic Drainage

Indications for PTC include: (1) proximal or intrahepatic biliary obstruction (e.g., hilar cholangiocarcinoma or hepatolithiasis), (2) unavailability of ERCP, (3) failed endoscopic drainage, and (4) challenging endoscopic access (e.g., complete obstruction or division of the bile duct; prior upper gastrointestinal surgery that altered intestinal anatomy, such as a Billroth 2 or Roux-en-Y reconstruction; or a large periampullary duodenal diverticulum). Furthermore, because PTC does not require oral passage of an endoscope, it can be performed in some patients with hemodynamically labile conditions without the requirement of sedation or airway protection. PTC

involves fluoroscopically guided, percutaneous puncture of a peripheral bile duct; thus, this technique may be difficult in patients without dilation of the intrahepatic biliary system. PTC is reported to be successful in establishing biliary drainage in 90% of patients with biliary obstruction. Serious complications of PTC include intraperitoneal hemorrhage, hemobilia, and bile peritonitis. Percutaneous cholecystostomy is a technically easier alternative to PTC; however, it only provides drainage when the obstruction is distal to the junction of the cystic duct and the common hepatic duct, and it requires patency of the cystic duct.

Surgical Drainage

Because of the high efficacy of ERCP and PTC, surgical biliary decompression in the acute setting should be applied only if these nonoperative procedures fail to achieve biliary drainage or are unavailable. Historic series suggest that emergency surgery in unstable conditions with acute cholangitis is associated with perioperative mortality rates as high as 40%. If surgery is required in acutely ill patients, the initial approach should be limited to drainage of the bile duct. For distal bile duct obstruction, this can be most easily accomplished with choledochotomy and placement of a large-diameter (at least 16F) T-tube. Latex-free T-tubes are commercially available for allergic patients. Surgical drainage of proximal bile duct obstruction in patients with cholangitis is much more of a challenge. A hilar obstruction can be relieved with choledochotomy, dilation of the obstruction, and placement of a U-tube (in which the tube enters the biliary tree through a choledochotomy, traverses the obstruction, and the exits the intrahepatic biliary system through a rent in the liver, with both ends of the tube being brought out through the abdominal wall). More extensive procedures such as formal common bile duct exploration, transduodenal sphincteroplasty, and biliary enteric bypass are usually inappropriate in unstable conditions.

Principles of Management of Cholangitis Caused by Proximal Obstruction

Management of cholangitis is particularly challenging in the case of obstruction at or proximal to the biliary bifurcation and warrants special consideration. This should be suspected when initial imaging (e.g., ultrasound scan) shows dilation of the intrahepatic biliary tree without extrahepatic biliary dilation or in patients with previously known tumors, strictures, or surgery of the hepatic ducts or biliary confluence. In the setting where portions of the biliary system are obstructed and isolated from one another by the obstructions, multiple portions of the biliary tree that are infected and do not communicate with one another may require independent drainage to relieve cholangitis. In contrast, the overall approach to patients with isolation of different portions of the biliary tree is to minimize the extent of the biliary tree that is instrumented, particularly when the source of obstruction cannot be relieved (e.g., unresectable cholangiocarcinoma). In these cases, the risk of cholangitis incurred by instrumentation of an uninfected but obstructed division of the ductal system outweighs the loss of function of the parenchyma that occurs from unmitigated obstruction. Thus, before drainage is planned, a detailed anatomy of the biliary system should be constructed from records of prior procedures in combination with high-quality cross-sectional imaging such as CT scan or MRCP. Because cholangitis rarely develops from tumors or strictures without prior instrumentation, initial attention should focus on areas that have previously been instrumented. For instance, in a patient with cholangitis who has a hilar cholangiocarcinoma that originally isolated the right and left biliary systems and was drained with a stent draining the right anterior sectoral and main right hepatic ducts into the common hepatic duct, where the tumor has now progressed to isolate the right anterior and right posterior sectoral ducts, an initial attempt at drainage should address the right posterior sectoral duct because this was previously drained but is now isolated. Unlike ERCP, PTC facilitated by image guidance allows precise drainage of the area desired, minimizing unintended instrumentation of other divisions of the biliary tree. Considerations for drainage in the setting of proximal bile duct obstruction are best evaluated on an individualized basis with a multidisciplinary team approach.

Regardless of the etiology of acute cholangitis, patients should undergo definitive therapy, if indicated, on an elective basis. In this context, surgery plays an important role, most frequently as interval cholecystectomy for secondary choledocholithiasis and Mirizzi's syndrome, but also in the form of biliary reconstruction for benign biliary strictures and resection of periampullary tumors.

Benign Biliary Strictures

William G. Hawkins, MD, and Steven M. Strasberg, MD

Benign biliary strictures are usually the result of trauma or inflammation. Most traumatic biliary strictures result from iatrogenic operative injuries. These are the most common benign strictures requiring surgical treatment today. This chapter focuses on strategies for avoidance of iatrogenic injuries and management of the established injury. Inflammatory strictures are the result of pancreatitis and less commonly primary sclerosing cholangitis, septic cholangitis, and inflammatory pseudotumors. These noniatrogenic benign strictures are discussed at the end of the chapter.

IATROGENIC BILIARY INJURIES

Biliary injury during laparoscopic cholecystectomy and after conversion to open cholecystectomy continues to be an important clinical problem. Injury rates have decreased from levels in the early 1990s when laparoscopic cholecystectomy was introduced but have probably not fallen to levels recorded in the era of open cholecystectomy. Unfortunately, accurate current statistics for the incidence of biliary

injuries are lacking, but a reasonable estimate is that there is 1 injury for every 300 cholecystectomies (0.3%). The anatomic injury classification used in this chapter was published in 1995 (Figure 1). It is a modification of the Bismuth classification adapted to better characterize injuries seen in the laparoscopic era.

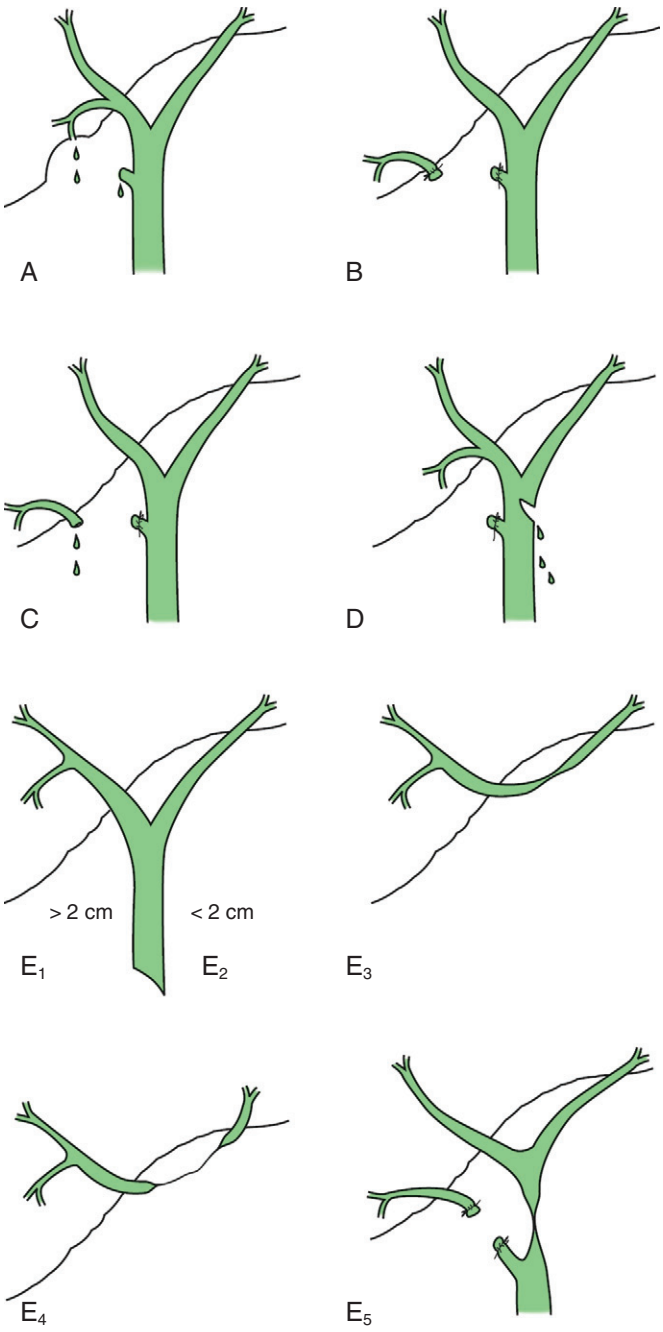

FIGURE 1 A classification of laparoscopic bile duct injuries. Type A injuries are leaks from the cystic duct or from ducts at the hepatic resection bed (e.g., ducts of Luschka). Types B and C involve injuries to aberrant right hepatic ducts. Type E injuries involve injuries to major bile ducts. *(From Strasberg SM, Hertl M, Soper NJ, et al: An analysis of the problem of biliary injury during laparoscopic cholecystectomy,* J Am Coll Surg *180:101, 1995.)*

Risk Factors for Biliary Injuries

Patient-Related Factors

Inflammation

Acute Inflammation. In population studies, the incidence of biliary injury is higher when laparoscopic cholecystectomy is performed for acute cholecystitis than for elective indications. Acute inflammation causes thickening of tissues, increases friability and vascularity, and promotes adhesions. These factors obscure normal anatomic relationships and increase difficulty of exposure and dissection. Severe inflammation is more likely to be encountered when the time between onset of symptoms and surgery for acute cholecystitis is greater than 72 hours, when the white blood cell count is greater than 18,000 cells/mm^3, or when a definite tender palpable mass is present in the right upper quadrant.

Severe Chronic Inflammation. Repeated episodes of acute cholecystitis may result in marked scarring and contracture of the gallbladder and adjacent tissues with the result that the gallbladder may become shrunken and bound to surrounding viscera. Fibrosis and retraction may result in fusion of the gallbladder to the common hepatic duct and right hepatic artery, effectively obliterating the hepatocystic triangle and dissection planes between these structures, which then may appear to be part of the gallbladder. Such inflammation makes dissection very difficult and contributes to visual deception when certain techniques are used.

Congenital Abnormalities

Aberrant Right Hepatic Ducts. A low-lying aberrant right hepatic duct may cross through the hepatocystic triangle or even unite with the cystic duct 1 to 2 cm before terminating in a confluence with the common hepatic duct. The appearance of the confluence of the aberrant duct with the common hepatic duct is similar to the appearance of a normal confluence of the cystic duct with the common hepatic duct; consequently, great potential exists for misidentification of the aberrant duct as the cystic duct.

Other congenital abnormalities that may expose patients to a greater risk of biliary injury include parallel union cystic duct, in which the cystic duct runs parallel to the common hepatic duct and exposes the latter to injury during dissection of the cystic duct; aberrant high termination of the cystic duct into a normally positioned right hepatic duct, which exposes the latter to injury during dissection of the cystic duct; congenital adhesions between the gallbladder and common hepatic duct, which obscure the hepatocystic triangle and make the common duct appear as if it is emanating from the gallbladder like a cystic duct; and intrahepatic gallbladder, which is difficult to grasp and thus contributes indirectly to injury by making exposure of the cystic duct difficult. In extremely rare cases, a major duct such as the right hepatic duct or the common hepatic duct may enter the gallbladder directly. Injury to such a structure is virtually unavoidable.

Other Patient-Related Factors

Large Impacted Gallstones. Large impacted gallstones impair retraction and hide the cystic duct, which again gives the appearance that the common bile duct is coming out of the gallbladder. Large stones may also erode and efface the cystic duct, thus shortening or obliterating it ("absent cystic duct"), and in severe cases may cause common bile duct compression or erosion and with severe pericholecystic inflammation (Mirizzi's syndrome) and sometimes bile duct obstruction.

Obesity and Body Habitus. Morbid obesity and large body size make operative exposure more difficult, as do skeletal deformities.

Procedure-Related Factors

Misidentification: A Concept Problem

The two main types of bile duct misidentification are misidentification of the common bile duct as the cystic duct and misidentification of an aberrant right hepatic duct as the cystic duct, the latter discussed previously. The key to understanding why misidentification occurs rests with examining the rationale for identification of the cystic structures during cholecystectomy.

Infundibular Technique. In this fallible method, the putative cystic duct is traced to the gallbladder or the gallbladder is traced down to the cystic duct, at which point, after circumferential dissection of these structures, the infundibulum (funnel) is displayed. The bowl of the funnel is the gallbladder and the stem is the cystic duct. However, with severe inflammation in which the common hepatic duct is fused to the side of the gallbladder and the cystic duct is in the inflammatory mass (hidden cystic duct syndrome), a funnel shape may also be observed in which the bowl of the funnel is the fused gallbladder/common hepatic duct and the stem of the funnel is the common bile duct (Figure 2). This visual deception is most likely to occur when one or more inciting factors described previously are present. Once the common bile duct is divided, the surgeon naturally dissects up the left side of the common hepatic duct with the belief that the dissection is on the gallbladder. Then, to get to the cystic plate, the common hepatic duct must be divided. In this step, the right hepatic artery is frequently injured. This sequence is referred to as the classical injury (Figure 3).

Intraoperative Cholangiography. Intraoperative cholangiography (IOC) reduces the incidence of biliary injury. Operative cholangiography is best at detection of misidentification of the common bile duct as the cystic duct and prevention of excision injuries of bile ducts. Unfortunately, operative cholangiograms are sometimes misinterpreted. IOC is not usually effective at detection of aberrant right ducts, which unite with the cystic duct before joining the common duct.

Dissection of the Cystic Duct to the Confluence with the Common Hepatic Duct/Common Bile Duct. This is a common and usually safe technique in performance of open cholecystectomy. Its use during laparoscopic cholecystectomy has been associated with an increase in lateral injuries to the common hepatic duct (type D), especially in the presence of a parallel union cystic duct.

The Critical View of Safety Technique

In the critical view of safety (CVS) technique, the hepatocystic triangle is cleared of fat and fibrous tissue and the gallbladder is freed from the lower one third of its attachment to the cystic plate. Only two structures are connected to the lower end of the gallbladder once this is done. Raising the gallbladder off the lower one third of the cystic plate is an essential step, without which the critical view cannot be said to have been attained (Figure 4). It is equivalent in the open technique to taking the gallbladder off the gallbladder bed, before clipping the cystic duct and artery. No attempt is made to expose the common bile duct or common hepatic duct.

Top-Down Cholecystectomy. The cholecystectomy is started at the fundus, taking the gallbladder off the gallbladder bed before identification of structures in the hepatocystic triangle. Although this may be an effective technique of identification in most instances, the authors have shown that it may lead to serious vasculobiliary injuries when severe inflammation exists. The contracture associated with chronic inflammation results in loss of planes and an increased

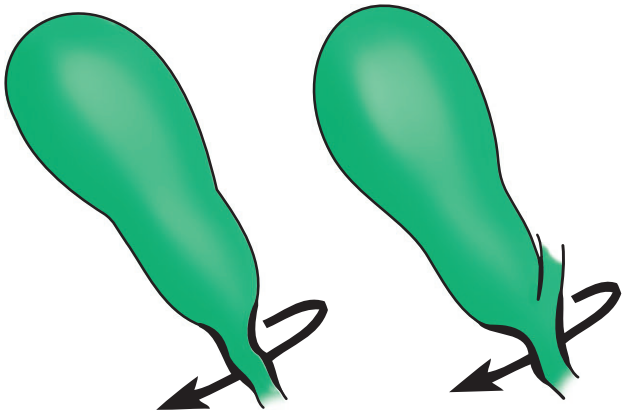

FIGURE 2 The deception of the hidden cystic duct and the infundibular technique of laparoscopic cholecystectomy. *Left:* Appearance to surgeon when a duct appearing to be the cystic duct is dissected first. Note that the duct appears to flare *(heavy black line)*, giving the appearance that the cystic duct has been followed on to the infundibulum. *Right:* True anatomic situation in the case of some classical injuries. The misleading flare or funnel *(heavy black line)* results from fusion of the common hepatic duct with the gallbladder and the hiding of the cystic duct in the inflammatory mass. *(From Strasberg SM, Eagon CJ, Drebin JA: The "hidden cystic duct" syndrome and the infundibular technique of laparoscopic cholecystectomy: the danger of the false infundibulum,* J Am Coll Surg *191:661–667, 2000, Fig. 4.)*

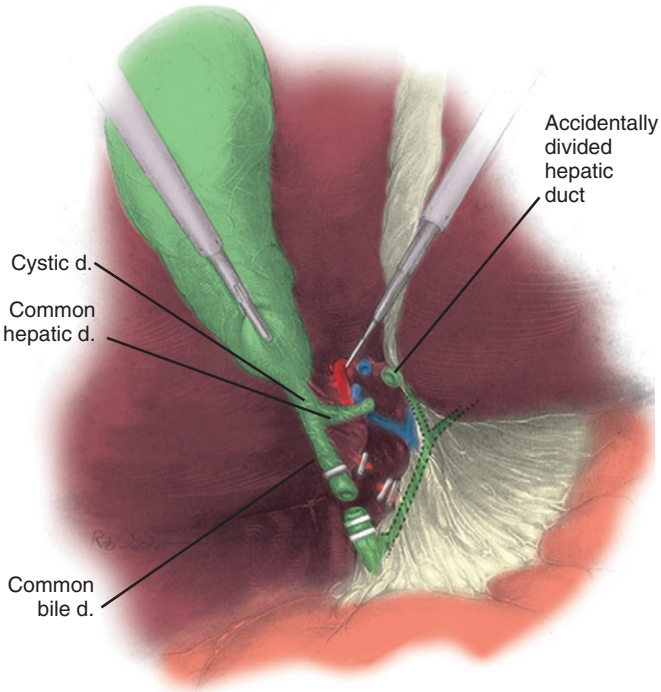

FIGURE 3 Classical bile duct injury. The steps in the classic injury are: 1, The common bile duct is mistaken to be the cystic duct and is divided; 2, the dissection proceeds along the left side of the common hepatic duct; and 3, to reach the cystic plate, the common hepatic duct is divided, often injuring the right hepatic artery at the same time. *(From Branum G, Schmitt C, Baille J, et al: Management of major biliary complications after laparoscopic cholecystectomy,* Ann Surg *217:532, 1993.)*

chance of entering the right portal pedicle when the gallbladder is taken down from above under these conditions (Figure 5).

Technical Problems

Bile ducts may be injured in the course of dissection much in the same way that an enterotomy occurs in the course of dissecting adhesions. Inflammation, aberrant anatomy, small duct size, and large body habitus contribute to the likelihood of this occurrence. About 10% of patients have a sizable hepatic duct that lies immediately deep to the cystic plate and is therefore prone to injury.

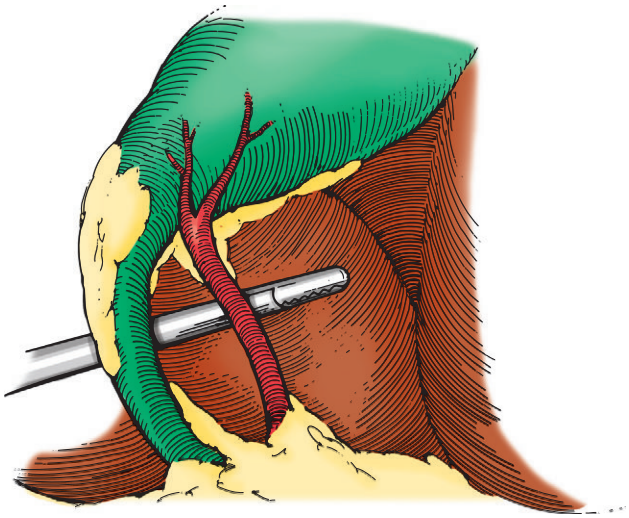

FIGURE 4 The three requirements of the Critical View of Safety are: 1, the hepatocystic triangle is dissected free of all tissue except for putative cystic duct and artery; 2, The lower one third of the gallbladder is dissected off the cystic plate; and 3, two and only two structures are seen to be attached to the gallbladder. It is not necessary to see the common bile duct. *(From Strasberg SM, Eagon CJ, Drebin JA: The "hidden cystic duct" syndrome and the infundibular technique of laparoscopic cholecystectomy: the danger of the false infundibulum,* J Am Coll Surg *191:661–667, 2000, Fig. 1.)*

Failure to Obtain Secure Closure of the Cystic Duct. The cystic duct is normally occluded with metallic clips. When the duct is thick, rigid, or wide, clips may fail; their use should usually be avoided in these circumstances. Retained common duct stones may contribute to clip failure by raising bile duct pressure.

Thermal Injuries. Thermal injuries are more likely to occur in the presence of severe inflammation because hemorrhage is more common when dissecting in the face of acute inflammation and higher power settings may be used to control hemorrhage. These injuries are often not recognized at surgery and usually result in bile duct stenosis rather than loss of continuity. Avoidance requires use of low power settings and lifting of tissue off underlying structures and a culture of safety.

Tenting Injuries. The junction of the common bile duct and hepatic bile ducts may be occluded when clipping the cystic duct while pulling up forcefully on the gallbladder. This is an uncommon laparoscopic injury perhaps as a result of the magnification afforded by laparoscopy and is avoided by not pulling up strongly on the gallbladder during the act of clipping the cystic duct.

Surgeon-Related or Hospital-Related Factors

Learning Curve Effect

Inexperience with laparoscopic cholecystectomy was a well-documented cause of bile duct injuries in the 1990s. The likelihood of biliary injury was much greater during the early experience of a surgeon than subsequently. Inexperience with the procedure during acute cholecystitis possibly still contributes to injury.

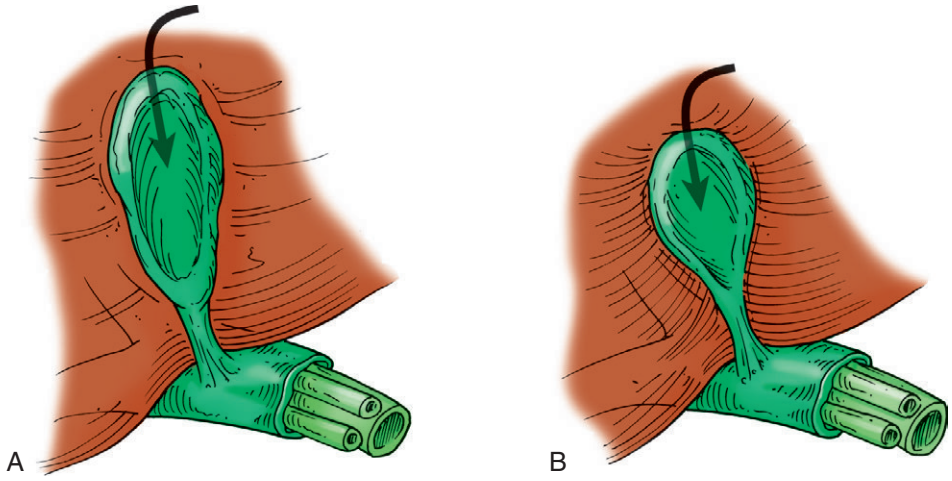

FIGURE 5 The relationship between the cystic plate and the right portal pedicle: **A,** under normal circumstances; and **B,** in the presence of severe contractive inflammation. The cystic plate attaches to the anterior surface of the right portal pedicle. Dissection downward in the plane deep to the plate *(arrow)* leads to the pedicle, with injury to the vessels and bile duct. When inflammation is mild, as in **A,** entry into the plane is usually readily detected with visualization of liver tissue. When there is severe contractive inflammation, the cystic plate is thickened, as in **B,** and determination of the position of the dissection in relation to the plate is difficult. In addition, the plate is foreshortened so that the distance from the top of the plate to the pedicle is very short. Both of these factors greatly increase the likelihood of injury to the pedicle. *(From Strasberg SM, Gouma DJ: "Extreme" vasculobiliary injuries: association with fundus-down cholecystectomy in severely inflamed gallbladders,* HPB *14:1–8, 2012, Fig. 5.)*

The Psychology of Human Error

Certain traits of human behavior may contribute to biliary injury. Surgery is a complex task in which visual disorientation occurs occasionally, and persistence in error from a deadly mindset is a common human failing. The mindset error is the tendency to interpret information incorrectly after one has first made a decision. The point of departure of the authors with this view is that the visual disorientation is more likely to occur with certain methods of procedure and can be greatly diminished with the use of routine cholangiography or the critical view technique of identification.

Equipment

Laparoscopic equipment must be maintained in good operating condition. Focal loss of insulation on cautery instruments can result in arcing and thermal injuries to bile ducts or bowel.

Vasculobiliary Injuries

A vasculobiliary injury (VBI) is a combined injury to a bile duct and to a hepatic artery or portal vein. The bile duct injury is usually caused by direct operative trauma but also may be ischemic in origin or the result of both. Various degrees of hepatic ischemia may also be present. The most common VBI involves the right hepatic artery and a major bile duct such as the common hepatic duct. For instance, the right hepatic artery is probably injured in about 25% of type E biliary injuries**.** The right hepatic artery is injured more commonly than other arteries because it lies close to the common hepatic duct and the injury usually occurs as the common hepatic duct is divided in the classical injury described previously. Injury to the artery results in ischemia to the bile duct and may result in propagation of injury to a higher level than the mechanical injury. Consequently, repairs to the common bile duct when there has been an injury to the right hepatic artery tend to fail because of ischemia of that portion of the duct. As a result, assessment of the hepatic arteries should be part of the investigation of all major biliary injuries. In addition, in the face of a right hepatic artery occlusion, consideration should be given to delaying repair for about 3 months to give the ducts an opportunity to "die back" so that only adequately vascularized ducts remain. This avoids repair to an ischemic segment of duct. Right hepatic artery VBI may also result in hepatic ischemia. It is manifested as slow spotty infarction of the right liver, and the areas of infarct may become infected and develop abscesses. Another pattern is asymptomatic atrophy of the right liver.

Extreme Vasculobiliary Injuries

These injuries usually involve both a major hepatic artery and the main portal vein or one of its primary branches. Extreme VBIs account for only 5% of vasculobiliary injuries. However, they are important because their consequences are very serious. Hepatic infarction is frequent, often with rapid onset and frequently necessitating emergency hepatectomy or urgent liver transplantation. Death has occurred in about 50% of such cases. The pathogenesis involves two elements: severe inflammation necessitating conversion to an open procedure and the fundus-down technique. The gallbladder rests on the cystic plate, whose tapered lower end inserts into the front of the right portal pedicle (see Figure 5). If the plane of dissection in a cholecystectomy is behind rather than in front of the cystic plate and the dissection is continued downward in this plane, the sheath of the right portal pedicle containing the major vascular and biliary structures supplying the right liver is incised, exposing the structures to injury.

To prevent injury, surgeons should be aware that fundus-down cholecystectomy in the face of severe inflammation tends to bring the dissection onto the right portal pedicle with predicable consequences. Contracture of the gallbladder, with puckering of the liver; dense adhesion of pericholecystic structures such as omentum, colon, and duodenum; and difficulty in finding the gallbladder are warning signs that can serve to steer the surgeon away from trying to take the gallbladder out from above. In the authors' opinion, fundus-down cholecystectomy in the face of severe inflammation should be avoided because it is an error trap.

The Culture of Safety in Cholecystectomy

Probably the most important part of prevention of biliary injury is the adoption of a culture in which the surgeon's mindset is tuned to safety first. This means adopting secure methods of ductal identification and meticulous dissection techniques, knowing when to get help from another surgeon, and knowing when to back away from completing a difficult cholecystectomy when local conditions are so adverse that the safety of the procedure is questionable. It includes readiness to switch strategies to perform lesser operations such as cholecystotomy or partial cholecystectomy. The warning signs of severe inflammation and indistinct anatomy should serve to direct the surgeon to perform a limited safe procedure such as cholecystotomy or subtotal cholecystectomy in which the gallbladder is not taken off the liver bed at all. This culture of cholecystectomy, which emphasizes safety, is much like that which is used throughout the aviation industry.

Presentation and Investigation

About one third of the more serious injuries are diagnosed during surgery. Most of the rest are identified within 30 days of surgery, but a few may appear years later. Intraoperative recognition may occur as a result of observation of bile in the field, by cholangiography, or rarely by actual visualization of the lacerated or divided duct. Sometimes the diagnosis is made after conversion for bleeding or inability to proceed in a difficult dissection.

Postoperative presentations of bile duct injury are influenced by the type of injury and whether a drain has been left. The most common presentations are pain with sepsis, with or without jaundice, and jaundice without other symptoms. Biliary fistula is also a common presentation. Some patients present only with abdominal distension and malaise. The latter is a particularly insidious presentation and is usually the result of bile ascites, which may not provoke much of an inflammatory reaction.

Pain and Sepsis

Computed tomographic (CT) scan is performed first to localize fluid collections, which may be aspirated to determine whether they contain bile. In most cases, a drain is placed in the biloma and an endoscopic retrograde cholangiopancreatography (ERCP) follows. Magnetic resonance imaging (MRI) with magnetic resonance cholangiography (MRC) has the potential to replace these investigations with a single one, but MRC does not show collapsed ducts well and is more likely to be useful with obstruction of the biliary tree than perforation with free drainage of bile into the peritoneal cavity. Many patients with pain or sepsis have type A or D injuries, and definitive treatment is possible at the time of endoscopy. Whether CT scan or MRI is used, an examination of the arteries and veins in the hepatoduodenal ligament should be part of the evaluation for all types of presentations.

Jaundice

The presence of jaundice suggests that the patient has sustained a type E injury. Duct occlusion is usually present if jaundice is the only symptom. Pain and sepsis from bile collections also tend to be present

when a major duct is transected. ERCP is the first-line investigation, although some advocate starting with MRC. The duct may be found to be completely transected or occluded; often clips are seen at the point at which the dye column stops with loss of continuity to the upper biliary tract. Percutaneous transhepatic cholangiography (PTC) should then be performed to delineate the proximal ducts and to provide external drainage of bile. Often it is best to wait to perform the PTC until the biloma has contracted and the biloma drain can be injected in a retrograde manner to display the bile ducts for transhepatic puncture. If partially occluded (stenotic) rather than totally occluded ducts are found, the entire extent of injury may be diagnosed with ERCP.

Bile Fistula

The first-line investigation is a fistulogram. Subsequent management depends on anatomic findings.

Management of Biliary Injuries

Management of Injuries Recognized at the Initial Operation

Little has been written about the conduct of a laparoscopic cholecystectomy, subsequent to the discovery of a biliary injury. Highly suggestive evidence shows that repair of difficult biliary injuries frequently fails when performed by surgical teams engaged infrequently in surgery of the upper biliary tree.

When injury is suspected, it is helpful to ask for assistance from another surgeon. Intraoperative recognition of a biliary injury is an indication for conversion. The following two guidelines are suggested when laparotomy is undertaken for suspected injury: (1) repair should be attempted only if the techniques required for reconstruction are commonly used by the operating team, and (2) the injury should not be worsened by attempting a dissection for the purpose of an exact diagnosis. When appropriate expertise is not available, closed suction drains should be placed laparoscopically and the patient referred to a center of expertise in biliary surgery.

Type A injuries, recognized at the time of surgery, are repaired with suture of the cystic duct and drainage. Simple type D injuries are repaired by closure of the defect with fine absorbable sutures over a T-tube and placement of a closed suction drain, in the vicinity of the repair. The T-tube should be brought out through a separate incision in the duct, if possible. Avulsion of the cystic duct, a variant of type D injury, may be managed in the same manner. Type D injuries that are thermal in origin or that are complex (e.g., involving most of the circumference of the wall or with tissue loss) are best repaired with hepatojejunostomy. Complete transection should be repaired with a Roux-en-Y hepatojejunostomy, with application of the principles of anastomosis given subsequently.

Management of Biliary Injuries Diagnosed After Surgery

Management depends on type of injury, on type of initial management and its result, and on time elapsed since the initial operation or repair. This section focuses specifically on strictures or injuries that may lead to strictures.

Type A Injuries

These can almost always be managed with endoscopic sphincterotomy and stenting. A biloma drain may also be necessary for large collections of bile.

Type B Injuries

Type B injuries often remain asymptomatic or present only years later with right upper quadrant pain or cholangitis. Symptomatic patients need hepatojejunostomy or hepatic resection if biliary-enteric anastomosis is not possible. In asymptomatic patients, treatment is not recommended when the section of liver affected is small or the injury is remote and atrophy has occurred. When the injury is recent and the section of liver is large (e.g., the whole right liver), repair is empirically recommended.

Type C Injuries

Type C injuries require drainage of the bile collections and biliary-enteric anastomosis or ligation of the duct. If the duct is very small (e.g., 1 mm), then ligation is preferable. Occasionally, when reconstruction of the duct is not possible, resection of the part of the liver drained by the injured duct may be needed.

Type D Injuries

Treatment with ERCP and stenting is the treatment of choice in the postoperative period. When operation is necessary, the technique of repair is the same as when the problem is discovered at time of initial surgery.

Type E Injuries

The best chance for lasting repair is the first one. Strictures and sometimes clip occlusions may be treated with dilation and stents placed either with ERCP or percutaneously through the liver. In the authors' experience, nonsurgical therapy is most likely to be successful when the strictures are mild, appear months to years after surgery, or are of short length. Lillemoe and associates reported a 64% success rate with the use of stents.

Timing of Surgery

Factors that favor immediate repair are early referral, a stable patient, absence of bile collections, simpler injuries that can be rapidly diagnosed, and absence of a vasculobiliary injury. Often patients are referred several weeks after cholecystectomy when local inflammation may be expected to be great. In these patients, percutaneous tubes are placed to relieve obstruction of affected segments, drain subhepatic collections, and control sepsis. Repair is performed when inflammation has settled, usually about 3 months after the last operation. This delayed approach is sometimes used even when the patient is referred within the first week, especially in complex, hard-to-diagnose injuries an hose with a thermal or vasculobiliary injury. Immediate repair may also be undertaken when the injury is diagnosed months after surgery (e.g., after failure of stenting of a stenosis or late failure of a biliary-enteric anastomosis).

Preoperative Preparation

Complete diagnosis of the injury before operation is essential. Failure to do so may result in exclusion of bile ducts from the repair. The percutaneous transhepatic tubes placed to ensure biliary drainage from all liver segments also serve as guides to the position of the injured ducts at surgery. The authors' policy is to perform conciliation between CT scan and PTC studies to be sure that all ducts in the liver are accounted for.

Technical Aspects of Repair

Exposure

The incision must allow for good visualization of the porta hepatis. The authors prefer a right upper quadrant incision about 8 cm below the costal margin with extension up the midline to the xiphoid (hockey stick). If the dissection proves difficult or full mobilization of the liver is necessary, the incision may be extended further laterally

or medially into a Mercedes type incision. If a previous Kocher incision has been made, this incision may be modified towards the midline and laterally to allow better visualization. A retractor fixed to the operative table is used to elevate the right costal margin and secure the abdominal exposure. Loupe magnification (2.5× to 3.5×) of the operative field is helpful.

Identification and Repair

The operative field is carefully examined, and the extent of the injury including vascular injury is documented. If the cholecystectomy is not completed, it is completed at this time. The principles of repair are that the anastomosis be tension free, have good blood supply, be mucosa-to-mucosa, and be of adequate caliber. Hepatojejunostomy is used in preference to either choledochocholedochostomy or choledochoduodenostomy because a tension-free anastomosis is always possible with hepatojejunostomy. Choledochocholedochostomy also fails frequently because blood supply to the upper end is inadequate in low transections and inadequate to the lower end in high transections. Whenever possible, an anterior longitudinal opening is created in the bile duct, and a long side-to-side anastomosis (sideways repair) is performed. Often this is done to the extrahepatic portion of the left hepatic duct after it is lowered by dividing the hilar plate (Hepp-Couinaud approach). This approach is particularly suitable for injuries at or just below the confluence of the right and left hepatic ducts (types E2 and E3).

When isolated right hepatic ducts exist, as in E4, E5, B, and C types of injury, the Hepp-Couinaud approach is not sufficient. For identification of the right ducts, the same initial steps to lower the hilar plate are followed, but then the dissection is extended to the right in the same coronal plane as the left duct (Figure 6). The liver capsule is divided, and then the cystic plate is encountered at its narrow lower end where it attaches to the right portal pedicle. The cystic plate is divided, exposing the sheath of the right main portal pedicle. Exposure of a larger area of the anterior surface of the sheath may be attained by coring out part of the overlying liver. Inside this sheath may be one or more ducts, depending on the level of injury and anatomic variances. Fine (5-0) holding sutures are placed in the duct, and then it is incised on the anterior surface to spatulate the orifice for anastomosis. The use of biliary probes helps ensure that all the segments are accounted for. Transhepatic drains that were placed to control leaks can be left in place during the dissection and facilitate identification.

Exposure is also facilitated during these procedures by dividing the bridge of tissue between segments 3 and 4 and fully opening the gallbladder fossa, which often collapses with adherence of its walls after cholecystectomy. If these maneuvers are not sufficient, resection of part of segment 4b or 5 opens the upper porta hepatis. The latter is an invaluable adjunct in the very difficult case.

The actual anastomosis is performed with fine absorbable sutures (usually 5-0). The order of suture placement is important. Usually, the anterior row of sutures is placed in the bile duct, and the ends of these sutures are laid upward over the patient's chest and kept in order on a spindle. If more than one duct is to undergo anastomosis, the anterior row sutures are placed in all the ducts, unless the ducts lie in a sagittal plane with one duct in front of the other, which is quite uncommon. Next, the posterior row is placed between the bile duct and the intestine, and the knots tied on the inside. The anastomosis is completed with use of the previously placed anterior row duct sutures to pick up the anterior lip of the opening in the bowel. When the ducts lay in the sagittal plane, the posterior duct is repaired first, followed by the anterior duct.

The use of postoperative stents is controversial. No evidence shows that they are helpful if a large mucosa-to-mucosa anastomosis has been achieved. The authors use them when very small ducts have undergone anastomosis.

Sometimes biliary reconstruction is not possible or advisable. When ductal reconstruction to a part of the liver is impossible, resection should be performed. Occasionally, prior failure of reconstruction leads to secondary biliary cirrhosis and end-stage liver failure. Then, liver transplantation is required. In almost all examples of this unfortunate outcome, high reconstructions have been attempted by surgeons who lack experience in the procedures. Treatment of failed repairs with metallic stents gives very poor results in the long term, with 50% of treated patient having repeated cholangitis.

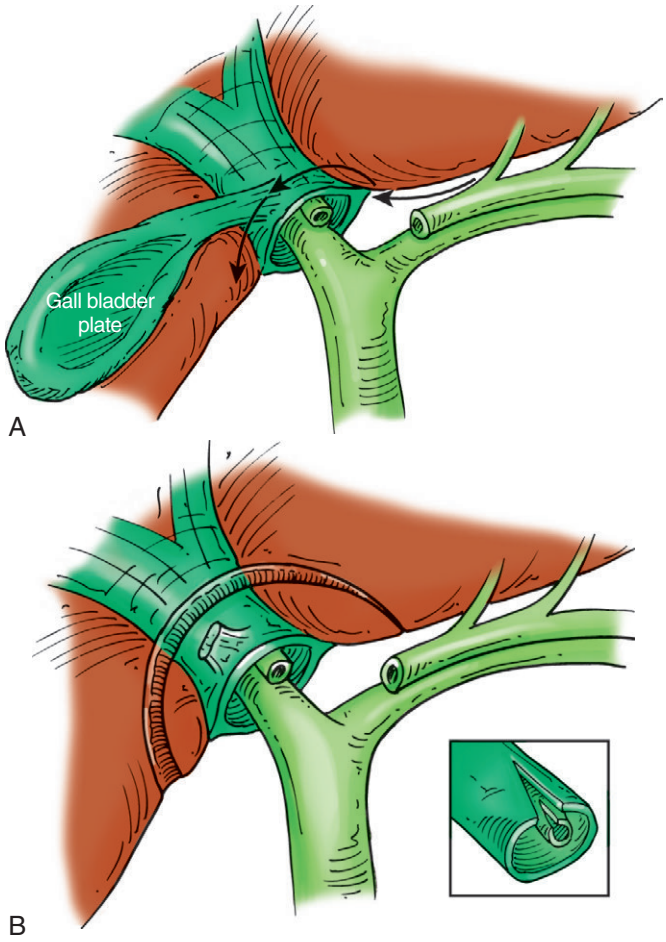

FIGURE 6 **A,** Operative technique for display of the isolated right ductal injuries. The amputated left and right ducts are shown, as are the portal vein and the sheath of the right portal pedicle. Note that the cystic (gallbladder) plate is a part of the Wallerian system of fibrous connective tissue that invests portal structures as they enter the liver. It attaches to the sheath of the right portal pedicle. The left and right hepatic ducts lie in the same coronal plane. The dissection is shown at a stage when the left hepatic duct has been isolated by the Hepp-Couinaud approach. The *arrows* indicate the direction of dissection from that point. **B,** A later stage in the dissection. The gallbladder plate has been cut and the liver pushed back off the right portal pedicle. The liver at the base of segment 5 has been cored away. The duct is isolated with the aid of the indwelling stent and opened on its anterior surface *(right and below on the diagram). (Modified from Strasberg SM, Picus DD, Drebin JA: Results of a new strategy for reconstruction of biliary injuries having an isolated right sided component,* J Gastrointest Surg *5:266–274, 2001, Figs. 2 and 3.)*

Treatment of Vasculobiliary Injuries

Immediate repair of the right hepatic artery has been performed either with end-to-end anastomosis or with a graft, usually taken

from the inferior mesenteric vein. When a major arterial injury has been diagnosed, the size of the vessel, extent of injury, timing of the injury, and absence of pulsatile back bleeding all help determine the need for arterial reconstruction. If arterial repair is deemed necessary, this repair is performed first. The opportunity for repair is limited both because the procedure has to be done in close proximity to the injury, ideally within hours, and because the injury is frequently too severe to repair. Because only 10% of patients with a right hepatic artery/bile duct injury have clinically significant hepatic ischemia develop, the alternate strategy of allowing slow infarction to take place in a minority of patients and treating it with resection, if necessary, might result in better overall outcomes than routine early reconstruction.

Outcome of Treatment

Most surgical series cite very good short-term results. However, it is well known from older literature that there is a progressive restenosis rate. Two thirds of recurrences are diagnosed in the first 2 years after repair, but restenosis has been described after 10 years. Valid comparison among surgical series is difficult because of lack of standard reporting and effect of differences in the severity of injuries. Injuries above the confluence involving several bile ducts have a much worse prognosis than do injuries of the common hepatic duct, as do vasculobiliary injuries. Reporting of treatment failure is not uniform. Length of follow-up is another obvious variable that affects outcome and is not uniform among series.

OTHER BENIGN BILIARY STRICTURES

Biliary Strictures Secondary to Pancreatitis

Severe chronic pancreatitis such as alcoholic chronic pancreatitis and autoimmune pancreatitis may produce benign biliary strictures in the intrapancreatic segment of the common bile duct. Sometimes, the bile duct narrowing is the result of compression by a pseudocyst. In these cases, relief of compression or spontaneous resolution of the pseudocyst may relieve the stenosis.

Presenting symptoms are jaundice with or without pain. Diagnosis is made with CT scan or MRI combined with ERCP. ERCP permits brushings that may diagnose malignancy. Characteristically, the stricture is of the long smooth rat-tail type. One of the continuing conundrums in pancreatic surgery is the differentiation between benign and malignant causes of intrapancreatic bile duct stricture. Focal pancreatitis can produce a mass in the head of the pancreas, cause jaundice, and thereby mimic cancer. Cancer is more likely to arise in the chronically inflamed gland. The cancers are often scirrhous, making diagnosis with needle biopsy more difficult, especially in an already chronically inflamed gland. Endoscopic ultrasound scan (EUS)–guided fine needle aspiration (FNA) and core biopsies are very helpful in making the diagnosis, and the Ca19-9 level is also helpful.

Treatment depends on whether biliary stricture is an isolated problem or whether it is part of a more general problem such as unremitting pancreatic pain, whether a pseudocyst is present, or whether cancer is a serious consideration. For isolated strictures, endoscopic dilation and stenting with multiple stents has become the procedure of choice. When this fails, biliary enteric anastomosis with Roux-en-Y hepatojejunostomy or choledochoduodenostomy may be used. Treatment of the biliary stricture may simply require endoscopic drainage of a pseudocyst. Treatment may be part of a wider procedure such as the Frey's procedure that relieves the obstruction with removal of the surrounding compressive scar or with addition of biliary enteric anastomosis to the basic procedure. Pylorus-preserving or standard Whipple's procedures, which relieve the biliary obstruction with resection, are sometimes used when cancer is suspected. Metallic stents should not be used in this or other benign strictures

Stricture From Noniatrogenic Bile Duct Injuries

Noniatrogenic bile duct injuries are usually caused by nonpenetrating trauma and are often a part of wider injuries. Isolated bile duct injury from penetrating trauma may occur, but more often, it is not isolated and is often fatal as the hepatic artery and portal vein are usually also injured. The injury is often missed, and diagnosis is delayed. The principles of complete diagnosis and repair enunciated previously apply to these injuries as well. Combined biliary and arterial injuries may occur, and the surgeon must be aware that the bile duct may be devascularized to a higher level than the laceration or transection.

Strictures From Calculous Disease

Oriental cholangiohepatitis is a disease associated with biliary parasite infestation leading to the development of intrahepatic and extrahepatic bile duct stones, usually of the brown pigment type. Recurrent pyogenic infections are common and lead to strictures. Treatment is with a combination of therapies, including eradication of the parasites, removal of the stones, dilation of the strictures, and occasionally local liver resection. Sometimes much of the therapy can be accomplished percutaneously. At other times, operative removal of stones and hepatojejunostomy is required; the Roux loop may be placed in proximity to the skin to permit later percutaneous access.

Choledocholithiasis occurring in Western countries may lead to biliary strictures through repeated bouts of cholangitis or local stone ulceration and resultant stricture formation often near the lower end of the bile duct. Such papillary stenosis is uncommon today. Endoscopic sphincterotomy (ES) is the treatment for low strictures, and biliary enteric anastomoses are used when unsuccessful or not applicable. Large stones within the gallbladder may cause biliary obstruction by external compression (Mirizzi's syndrome).

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is an idiopathic autoimmune disease, frequently associated with inflammatory bowel disease. It causes biliary strictures, which are usually both intrahepatic and extrahepatic and multiple. Stones are not usually present. Degeneration to cancer may occur, and these cancers are difficult to diagnose early. Treatment of symptomatic localized strictures in the larger bile ducts is usually endoscopic. Resection of the confluence has been advocated when the major area of stricture is localized to that area. Many of these patients require liver transplantation as the definitive surgical procedure; this is done when end-stage liver disease appears or when cancer is suspected. Prior surgery on the bile ducts may make transplantation more difficult.

Benign Inflammatory Pseudotumors

Benign inflammatory tumors, also called hepatic inflammatory pseudotumors, mimic extrahepatic cholangiocarcinomas but consist of chronic inflammatory cells and fibrosis. They occur most frequently in extrahepatic upper ducts, and less commonly in lower ducts. About 10% of resected cholangiocarcinomas are actually pseudotumors.

Cystic Disorders of the Bile Ducts

Seth Goldstein, MD, Bulent Salman, MD, and Barish H. Edil, MD

OVERVIEW

Choledochal cyst disease is defined by dilation of the intrahepatic or extrahepatic biliary tree. Once thought to be exclusively a pediatric condition, it is now an increasingly recognized entity in adults. Regardless of age, choledochal cyst disease must be promptly recognized and treated to avoid biliary and hepatic complications. In addition, and most importantly, early intervention is necessary to prevent malignant degeneration.

CLASSIFICATION

Choledochal cyst is technically a misnomer because cystic dilations of the biliary tree often extend beyond the common bile duct (ductus choledochus). In this chapter, we refer to choledochal cysts with Todani's modification of the Alonso-Lej classification, which defines five types of cyst based on the pattern of biliary tree involvement as illustrated in Figure 1.

Type I (A, B, C) is the most common classification and consists of a dilation of the extrahepatic biliary tree: cystic, focal, and fusiform, respectively. Type II cyst is an extrahepatic supraduodenal saccular diverticulum of the common bile duct. Type III refers to dilation of the intraduodenal segment of the common bile duct, known as a choledochocele. Type IV cysts typically involve both intrahepatic and extrahepatic bile ducts (type IVA) or can be multiple extrahepatic dilations (type IVB). Type V, or Caroli's disease, is confined to intrahepatic ductal dilation alone and can be either unilobar or bilobar (see Figure 1).

ETIOLOGY

The exact pathogenesis of choledochal cyst is unknown; however, several theories exist to explain this unusual biliary disorder. The first hypothesis for the formation of choledochal cysts is a congenital defect in maturation and ductal plate malformation. The belief is that arrested or faulty bile duct plate remodeling takes place during embryogenesis and results in dilated bile ducts. This hypothesis relates primarily to the development of Caroli's disease and can be seen in either sporadic or inherited scenarios. The second hypothesis is an acquired condition as a result of biliary system obstruction from a stricture, web, or sphincter of Oddi's dysfunction. However, the most commonly accepted hypothesis is pancreaticobiliary maljunction. Studies have indicated 57% to 96% of patients with choledochal cyst disease have this anatomic variant. The maljunction is defined by pancreatic and bile duct joining outside of the duodenal wall. A long common channel allows the milieu of pancreas and bile juice to mix and regurgitate up the biliary system, setting off a cascade of damage and inflammation and resulting in dilation of the ducts. Despite the association with pancreaticobiliary maljunction, no single theory can clearly explain the formation of different choledochal cyst types.

EPIDEMIOLOGY

Estimates of incidence range from 1 in 13,000 in East Asia to 1 in 2,000,000 in the United States. A female predominance of approximately 4:1 is found. The associated risk of malignancy at the time of diagnosis is 10%; the malignancy can be either gallbladder carcinoma or cholangiocarcinoma. The risk of malignancy also increases with age from 0.7% in the first decade, to 2.3% in the third decade, and up to 75% when diagnosed with a choledochal cyst disease in the ninth decade.

DIAGNOSIS AND PREOPERATIVE EVALUATION

The classic triad of abdominal pain, jaundice, and a palpable mass is actually observed in a minority of patients. In children, the usual symptoms are episodic abdominal pain, nausea with vomiting, and slowly progressive jaundice. Adults can present with signs of calculous biliary tract disease or pancreatitis and often have already undergone cholecystectomy before diagnosis.

Preoperative imaging is essential in determining the operative plan. Neonates and children are often evaluated first with abdominal ultrasound scan, which is safe and cost effective. Adults generally benefit from computed tomographic (CT) imaging, which defines the anatomy of the hepatobiliary and pancreatic regions. Magnetic resonance cholangiopancreatography (MRCP) can also be used to demonstrate biliary anatomy, including cyst pattern and pancreaticobiliary maljunction with a long common channel. In addition to biliary anatomy, cross-sectional imaging can evaluate for occult malignancy.

Cholangiography is the gold standard of choledochal cyst imaging and can be accomplished with endoscopic retrograde cholangiopancreatography (ERCP), with percutaneous transhepatic cholangiography (PTC), and now more commonly, with MRCP. This allows detail of the ductal dilation and shows whether a long common channel is present, which helps with the diagnosis of choledochal cyst.

Patients may have medical complications from choledochal cyst disease that necessitate attention before operative intervention. Cholangitis should be adequately treated with broad-spectrum intravenous antibiotics and, if necessary, with biliary decompression. Severe liver damage can be seen with long-standing choledochal cyst disease and can manifest as portal hypertension, uncorrected coagulopathy,

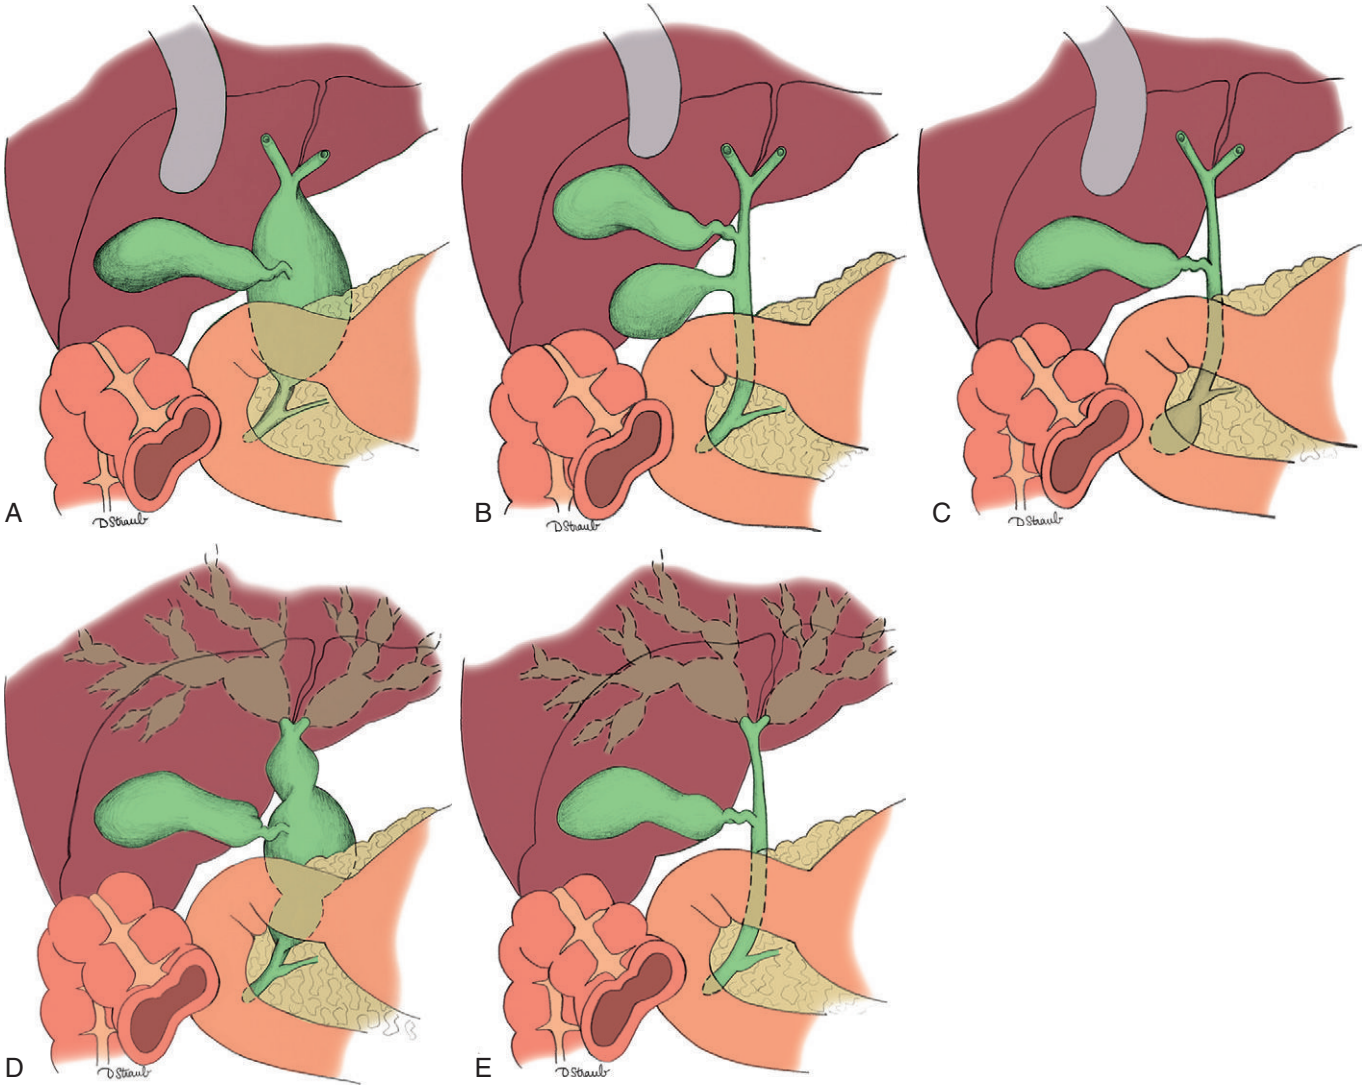

FIGURE 1 Classification of biliary cysts. **A,** Type I; **B,** type II; **C,** type III; **D,** type IVA; and **E,** type V. *(From Lipsett PA, Pitt HA, Colombani PM, et al: Choledochal disease: a changing pattern of presentation,* Ann Surg *220:644, 1994.)*

and end-stage liver failure, which are contraindications for operative intervention.

MANAGEMENT

Treatment of choledochal cyst disease requires surgical excision of the abnormal biliary tree with biliary-enteric reconstruction. Surgical intervention most importantly removes the biliary tissue at risk for malignant transformation and excludes the liver from further pancreas and biliary juice exposure. In addition, it can relieve biliary obstruction, preventing future episodes of cholangitis, stone formation, or biliary cirrhosis that results in an interruption of the inflammatory injury cycle.

Type I: Extrahepatic Bile Duct Cyst

First, the peritoneal cavity is explored for signs of malignancy, either via laparoscopy or via midline or right subcostal incision. The gallbladder is removed in standard retrograde fashion from the liver bed with ligation of the cystic artery. The mobilization of the cystic duct to the common bile duct facilitates identification of the choledochal cyst. The duodenum undergoes full kocherization to allow access to the posterior pancreas and distal bile duct/cyst. The dissection on the anterior cyst is continued down posterior of the duodenum and the head of the pancreas until the bile duct narrows at the inferior portion of the cyst, with care taken to not injure the pancreatic duct. This area is ligated and transected to allow for cephalad reflection and posterior dissection with identification of the portal vein. This dissection continues until the hepatic duct confluence is reached. Pathologic analysis of the resected specimen is obtained, along with frozen-section analysis of the proximal and distal margins, to exclude malignancy.

A standard 60-cm Roux-en-Y loop is used for an end-to-side hepaticojejunostomy. The anastomosis is constructed with a single layer of absorbable suture. Recent experiences of pancreaticobiliary surgeons have described cyst excision done laparoscopically. The experience and long-term outcomes of this approach have yet to be determined.

Type II: Extrahepatic Biliary Diverticulum

For type II cyst, complete excision of the cyst is again recommended. This can be performed with extrahepatic biliary resection and

Roux-en-Y reconstruction or complete excision with primary closure over a T tube. The defect in the wall of the common bile duct should be closed transversely to prevent narrowing of the lumen.

Type III: Choledochocele

Type III cysts are unusual; their malignant potential seems to be lower, but this is unclear. Typically, when a surgeon is faced with a type III cyst, it is because of obstructive symptoms. Complete excision can be done after kocherization through a lateral duodenostomy in the second portion of the duodenum. The common bile duct and pancreatic duct must be identified to prevent pancreatic duct injury. The cyst is excised, and a sphincteroplasty can be done with sewing of duct to duodenal mucosa with interrupted absorbable suture. ERCP with sphincterotomy is an alternative in patients who may not tolerate excision to facilitate drainage and potentially relieve symptoms. On a very rare occasion, the Whipple procedure may be necessary and may be considered if malignancy is suspected.

Type IV: Multiple Bile Duct Cysts

The surgical management of type IV choledochal cysts can be difficult because of the presence of intrahepatic cystic disease that makes complete excision of the disease impossible. In this situation, complete extrahepatic cyst excision with biliary enteric anastomosis is recommended. In addition, if one lobe of the liver is involved, then hepatectomy should be performed. However, in many situations, diffuse bilobar cyst disease remains, which is at risk for malignant transformation. Removal of the extrahepatic choledochal cyst and proper decompression of the intrahepatic disease may prevent or facilitate the management of long-term complications of biliary stasis, stones, cholangitis, cirrhosis, and malignant transformation in this condition.

Type V: Caroli's Disease

Type V choledochal cyst (Caroli's disease) is a difficult condition to manage and is unsettled. Initial management entails treatment of infectious complications with drainage, stone extraction, antibiotics, and ursodiol to help with the dissolution of stones to increase biliary flow. Occasionally, the ductal abnormalities are confined to one lobe of the liver, and in this situation, hepatic lobectomy can be considered. The main objective with diffuse disease is proper drainage of the liver to disrupt the inflammatory cycle and prevent further liver injury and malignancy. In the case of severe portal hypertension, or after failure of the biliary-enteric drainage procedure with or without partial hepatectomy, patients may be considered to be candidates for orthotopic liver transplantation.

PROGNOSIS

Surgical management has significantly changed over the last 30 years. Originally, surgical draining of the cyst with a cyst duodenostomy or Roux-en-Y cyst jejunostomy was advocated. This resulted in disease being left behind and continued risk of malignant degeneration. Complete cyst resection is necessary to mediate future cancer risks and should be done whenever possible. However, if this is not possible, as seen with type IV and V, then close surveillance and proper drainage is needed. Furthermore, patients with a history of enteric drained cysts without complete excision should be offered complete resection even if they are asymptomatic and technical challenges are anticipated to remove that cancer risk.

The perioperative complications are typical of hepatobiliary surgery and include bleeding, wound infection, and anastomotic leak. In the long term, the postoperative benign biliary stricture rate may be as high as 40%, commonly presenting as cholangitis. Patients should undergo lifelong surveillance, particularly if intrahepatic cystic disease remains because it is at risk for malignant degeneration.

PRIMARY SCLEROSING CHOLANGITIS

Shirin Sabbaghian, MD, and Steven A. Ahrendt, MD

Primary sclerosing cholangitis (PSC) is a disease characterized by chronic inflammation and destruction of both intrahepatic and extrahepatic bile ducts resulting in multifocal strictures of the biliary tree, chronic cholestasis, and eventually biliary cirrhosis. Although etiology is uncertain, the disease is most likely an immune-mediated disorder influenced by genetic factors. Most patients (up to 80%) with PSC also have inflammatory bowel disease (IBD), more often ulcerative colitis (UC). Although many patients are asymptomatic at diagnosis and are only found to have the disease on investigation of persistently elevated liver function test results, typical initial symptoms on presentation include right upper quadrant pain, fatigue, pruritus, and weight loss. Symptomatic patients also commonly have jaundice on physical examination. The diagnosis of PSC is usually established with abnormal liver function test results and an abnormal cholangiogram (endoscopic or magnetic resonance) after secondary causes of sclerosing cholangitis are ruled out. The overall goals of treatment are to slow progression of disease and reduce the risks for cancer and end-stage liver disease. Liver transplant is the only effective therapeutic option for patients with this disease once cirrhosis develops.

DEMOGRAPHICS

A recent meta-analysis of studies from North America and Europe suggests that the incidence rate of PSC is 1 per 100,000 person-years

at risk. The disease affects men predominantly, although patients with PSC who do not have IBD are more often women. PSC is most commonly diagnosed in the fourth decade of life.

ETIOLOGY

The cause of PSC remains unknown and is thought to be multifactorial; most investigators suspect the disease is an immune-mediated process, and some evidence suggests a genetic role. In support of an immune-mediated etiology, up to 80% of patients with PSC also have IBD, particularly UC. An increased frequency of other autoimmune diseases has also been observed in patients with PSC. In support of immune-mediated and non-Mendelian genetic causes, an increased frequency of certain genes in the human leukocyte antigen (HLA) complex and closely linked genes has been observed. These associated genes include HLA-B8 in the major histocompatibility complex (MHC) class I region; DR3, DR2, and DR6 in the MHC class II region; and certain MHC class I chain-related alleles (MICs). Other non–HLA-related genes have been suggested to play a role in this disease, although only conflicting evidence exists. Additional evidence of genetic influence for this disease is the finding of an approximately fourfold increased risk of PSC in first-degree relatives of patients with PSC.

ASSOCIATED DISEASES AND COMPLICATIONS

Primary sclerosing cholangitis has been associated with several diseases and potential complications (Table 1). The strongest association is with IBD, usually UC. Although as many as 80% of patients with PSC have IBD, only 3% to 8% of patients with IBD have PSC. Patients with both PSC and IBD are much more likely to have pancolitis than more limited colonic involvement. PSC has also been shown to be an independent risk factor for colon cancer in patients with UC. In addition, the risk of development of colorectal cancer in patients with PSC and UC appears to increase further after liver transplant. Colonoscopy is warranted in all patients with PSC either to exclude the diagnosis of IBD in patients without a history or for cancer surveillance in patients with UC or Crohn's disease.

An increased frequency of autoimmune disease has been found in PSC. This includes disorders unrelated to the liver and colon, such as type I diabetes mellitus and thyroid disease. Autoimmune hepatitis (AIH) has also been seen in up to 17% of patients with PSC and has been designated separately as PSC-AIH overlap syndrome.

TABLE 1: Diseases associated with primary sclerosing cholangitis

Disease	Frequency (%)
Ulcerative colitis	60-75
Gallstones	25
Autoimmune disease	20
Cholangiocarcinoma	7-14
Autoimmune hepatitis	1.4-17
Crohn's disease	5-10
Colon cancer	2

PSC is associated with an increased frequency of hepatobiliary malignancies, including cholangiocarcinoma (CCA), gallbladder cancer, and hepatocellular carcinoma (HCC). PSC is considered a risk factor for CCA, which is one of the most feared complications of this disease. In population-based studies, CCA has been shown to occur in 7% to 14% of patients with PSC. It is common (30% to 42% incidence rate) in autopsy series of patients with PSC, and it is has been diagnosed in up to 10% of patients undergoing liver transplant despite an extensive preoperative evaluation to exclude this diagnosis. CCA is often diagnosed early in the clinical course of PSC, with up to half of patients diagnosed within 1 year of a PSC diagnosis. The subsequent annual incidence rate is 0.5% to 1.5%. Unfortunately, CCA is usually not an operable lesion once discovered because it is diagnosed either at an advanced stage or because the background liver disease precludes resection as an option. Strong suspicion for malignancy should be maintained for patients with PSC and a dominant stricture (defined as a stenosis with a diameter of ≤1.5 mm in the common bile duct or of ≤1 mm in the hepatic duct) and for patients who have clinical signs of rapidly increasing jaundice, abdominal pain, and weight loss. Cytologic examination of biliary brushings and biopsies may be helpful, but they generally have low sensitivity for diagnosis of CCA. Periodic testing for carbohydrate antigen 19-9 (CA19-9) has been recommended by some investigators to evaluate for an elevated level, particularly a sustained elevation, although a high false-positive rate exists because of factors such as bacterial cholangitis.

Patients with PSC are predisposed to gallbladder disease, both benign and malignant. Gallstones have been found in 25% of patients with PSC. Gallbladder polyps are commonly seen on ultrasound scan in patients with PSC (4% to 6%), and more than half of these contain an invasive cancer. Cholecystectomy should be performed in patients with PSC with gallbladder polyps regardless of lesion size. Annual ultrasound scan screening of the gallbladder has been recommended for patients with PSC.

Hepatocellular carcinoma (HCC) is a risk among patients with PSC with end-stage liver disease. Two percent to 4% of explanted livers from patients with PSC were found to have concomitant HCC.

NATURAL HISTORY AND PROGNOSTIC MODELS

PSC affects both quality of life and life expectancy. Median survival time in symptomatic patients ranges from 10 to18 years after diagnosis, with patients dying of complications of PSC, such as liver failure or CCA, or of advanced associated disease, such as colorectal carcinoma in patients with IBD. Median survival in asymptomatic patients with PSC is longer than in patients presenting with symptoms, although survival is decreased when compared with matched, healthy individuals. The course of PSC is highly variable among individual patients; some patients have rapid progression to liver failure or development of a biliary malignancy early in their course, whereas others remain asymptomatic for years. Mathematic prognostic models have been developed to help determine when a patient should be considered for liver transplant and to help evaluate response to certain therapies. The revised Mayo Model, which considers age, total bilirubin level, serum aspartate transferase (AST) value, serum albumin value, and history of variceal bleeding, has been developed to estimate survival over 4 years.

PRESENTATION

PSC is more often diagnosed in men, typically during the fourth decade of life. Patients present with either abnormal liver function test results or manifestations of cholestatic liver disease. In earlier observational studies, 15% to 40% of patients were found to be

asymptomatic at the time of diagnosis. Diagnosis is pursued in asymptomatic patients typically when persistently cholestatic biochemical tests are discovered. Symptomatic patients usually present with right upper quadrant pain, fatigue, pruritus, and weight loss. Cholangitis is uncommon on presentation in patients who have not undergone biliary surgery or biliary tract manipulation, such as endoscopic retrograde cholangiopancreatography (ERCP). Physical examination findings for symptomatic patients may include jaundice, hepatomegaly, and splenomegaly. Certain biochemical tests are commonly abnormal in patients with PSC. An elevated serum alkaline phosphatase is the "biochemical hallmark," although a normal value does not exclude the diagnosis. Serum aminotransferase levels are usually two to three times higher than normal, but again, normal values do not exclude the diagnosis. Total bilirubin level is normal in 60% of cases.

DIAGNOSIS

The diagnosis of PSC is normally supported with typical findings on cholangiogram. Magnetic resonance cholangiography (MRC) is the diagnostic procedure of choice when PSC is suspected. The diagnosis can usually be established noninvasively with MRC with a sensitivity and specificity exceeding 80%. The diagnosis may also be established with endoscopic retrograde cholangiography (ERC) or percutaneous transhepatic cholangiography (PTC). The typical cholangiographic findings in PSC include multifocal strictures with a resultant and characteristic beading pattern in both the intrahepatic and extrahepatic bile ducts. The hepatic duct bifurcation is often the most severely strictured segment of the biliary tree (Figure 1). Isolated involvement of the intrahepatic ducts and proximal extrahepatic ducts occurs in approximately 20% of patients. Conversely, only 5% to 10% of patients have sclerosing cholangitis involving only the extrahepatic duct without intrahepatic duct involvement. Visualization of the entire biliary tree is critical to avoid missing a CCA.

The role of liver biopsy for the diagnosis of PSC has evolved. A liver biopsy often shows nonspecific findings in patients with PSC and rarely adds additional diagnostic information in patients with typical findings of the disease on cholangiography. However, a liver biopsy is warranted in patients with a cholestatic liver function panel and a normal cholangiogram to diagnose small duct PSC. Liver biopsy can also help diagnose patients suspected to have PSC-AIH overlap syndrome in whom immune suppressive therapy should be used for treatment.

PSC must be distinguished from secondary sclerosing cholangitis (SSC) that results from identifiable causes of biliary tree injury and stricture such as chronic obstruction, infection, chemical agents, drugs, and ischemia. Other diagnostic possibilities that are important to consider when pursuing a diagnosis of PSC are small duct primary sclerosing cholangitis, PSC overlap syndromes, and immunoglobulin G 4 (IgG4)–associated cholangitis. A cholestatic pattern to liver function studies supports the diagnosis of PSC and is useful for monitoring the course of the disease. Serum bilirubin is not commonly elevated early in the course of the disease but does increase as the disease progresses. The serum tumor marker CA19-9 may also be elevated in patients with PSC and CCA.

Occasionally, surgical resection may be necessary to make the diagnosis. For example, differentiation of localized sclerosing cholangitis from CCA can be difficult, especially when the stricture is in the perihilar region. Also, the combination of CCA and bacterial cholangitis may mimic sclerosing cholangitis. In cases like these, resection of the dominant stricture may be necessary to establish a diagnosis.

FIGURE 1 Percutaneous cholangiogram shows hepatic bifurcation *(lower right)* and right hepatic ducts in a patient with primary sclerosing cholangitis. Cholangiogram shows diffuse strictures of the intrahepatic bile ducts.

THERAPY

The overall goals of treatment of PSC are to slow progression of disease and reduce the risks for cancer and end-stage liver disease. A management algorithm is pictured in Figure 2. In general, asymptomatic patients should not be treated. No currently available medical therapy has shown any effect on disease progression. Symptomatic patients with persistently elevated liver function tests, pruritus, pain, or fatigue; evidence of significant extrahepatic or hilar strictures;

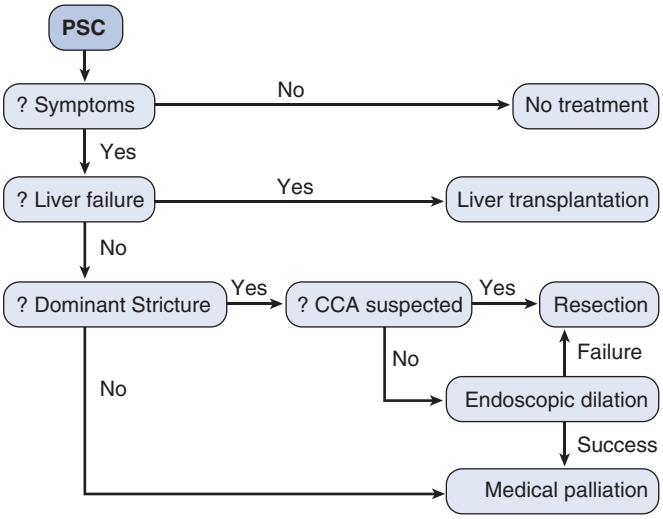

FIGURE 2 Management algorithm for primary sclerosing cholangitis *(PSC). CCA,* Cholangiocarcinoma.

and no clinical or imaging signs of cirrhosis are candidates for an endoscopic or surgical approach to improve biliary drainage. In addition, patients with dominant biliary strictures suspicious for CCA should undergo surgical exploration and resection of the extrahepatic bile ducts rather than prolonged efforts to establish a tissue diagnosis. When patients have cirrhosis develop, liver transplant is the only reasonable therapy.

Medical Therapy

Ursodeoxycholic acid (UDCA), which is used to treat primary biliary cirrhosis, initially showed promise as patients experienced improvement in liver function tests over time. However, in randomized studies that compared UDCA with placebo, the rates of treatment failure, including death, liver transplant, progression to cirrhosis, worsening of fatigue or pruritus, inability to tolerate the drug, or voluntary withdrawal from the study, were similar among the two treatment arms. Currently, the American Association for the Study of Liver Diseases (AASLD) recommends against use of UDCA as medical therapy for patients with PSC.

Antiinflammatory and immunosuppressive drugs, such as corticosteroids, penicillamine, azathioprine, colchicines, and anti–tumor necrosing factor (TNF) antibodies, have been tried in small studies. None of these drugs have proved to be beneficial in patients with classic PSC.

Symptoms of PSC are managed individually. Pruritus, for example, is managed with cholestyramine or UDCA and possibly antihistamines. Fatigue is managed symptomatically after hypothyroidism is ruled out. With advanced disease, fat malabsorption and steatorrhea may be present with subsequent deficiency of fat-soluble vitamins, vitamins A, D, E, and K. This can usually be treated with oral replacement of these vitamins.

Nonoperative Interventional Therapy

Dominant hilar and extrahepatic strictures occur in 15% to 20% of patients with PSC. They are defined as stenoses with a diameter of 1.5 mm or less in the common bile duct or of 1 mm or less in the hepatic duct. The initial approach to patients with a dominant stricture is endoscopic balloon dilation with or without stenting. The endoscopic approach avoids dissection of the porta hepatis before the need for hepatic transplant, allows treatment of both the right and left hepatic ducts simultaneously, and is associated with fewer complications than percutaneous or surgical procedures. Endoscopic therapies to treat dominant strictures include balloon dilation and stenting. Endoscopic stents are associated with a higher risk of complications, including cholangitis, and should be reserved for strictures that recur after balloon dilation. Endoscopic intervention can result in clinical improvement, and studies show that patients need fewer annual hospitalizations and have a short-term decrease in serum bilirubin and cholestatic symptoms after treatment. However, PSC is characterized by fluctuations in symptoms and degree of cholestasis, and to date, no controlled data show that endoscopic therapy alters the natural history of the disease.

The possibility of an existing CCA should be considered in all patients with a dominant stricture. Up to 9% of patients with dominant strictures managed endoscopically are ultimately diagnosed with CCA. Brush cytology or biopsy should be obtained at the time of dilation in all patients.

Dilation of biliary strictures also can be performed percutaneously in patients in whom an endoscopic approach has been unsuccessful. These strictures may be approached more easily via the percutaneous route than via the endoscopic route. In addition, the percutaneous approach may also be beneficial before surgery to aid in the intraoperative placement of large-bore transhepatic biliary catheter. Morbidity for the percutaneous approach is higher when compared with endoscopic methods.

Operative Therapy

Surgical Resection

Surgical resection of the extrahepatic biliary tree is less commonly used now with the application of endoscopic therapy. In appropriately selected patients, resection of the extrahepatic biliary tract and hepatic duct bifurcation, which is frequently involved with a dominant stricture, may provide lasting relief from jaundice, may be used to exclude or make the diagnosis of CCA in a dominant biliary stricture, and may postpone the need for liver transplant. Operative management entails resection of the extrahepatic biliary tree, including the hepatic duct bifurcation, which is frequently involved with a dominant stricture. A cholecystectomy is performed if the gallbladder is still in place, and the distal common bile duct is divided at the level of the superior edge of the pancreas. Frozen sections are taken of each margin and of any suspicious areas to exclude the presence of CCA. If stents are planned for reconstruction, percutaneous stents can be placed before surgery to aid in the dissection of the hepatic duct bifurcation and to guide stent exchange with large-bore transhepatic biliary catheter at the time of surgery. Bilateral Roux-en-Y hepaticojejunostomies are created over these transhepatic stents, which are intended for removal approximately 1 year after placement if no obstruction exists at the anastomosis.

The overall morbidity rate after Roux-en-Y hepaticojejunostomy in PSC is 35%. Common complications include cholangitis, hemobilia, bile leak, and wound infection. Rarely, hepatic arterial bleeding related to the transhepatic stent has necessitated embolization for control. In a series of 40 patients without cirrhosis undergoing biliary reconstruction, the operative mortality rate was 2.5%.

Although used less frequently over the past decade, resection of the extrahepatic biliary tree in selected patients may delay the need for liver transplant. In a series of 77 patients followed for more than 5 years, the overall 3-year, 5-year, and 10-year survival rates after bile duct resection were 85%, 76%, and 53%, respectively. Patients without cirrhosis fared better with 1-year, 5-year, and 10-year survival rates of 95%, 83%, and 60%, respectively. Furthermore, in comparison of outcomes of surgical resection with endoscopic intervention, overall survival for patients without cirrhosis managed with bile duct resection was significantly longer than for a group of 35 concurrent patients without cirrhosis managed with endoscopic balloon dilation. Survival free of liver transplantation for the 40 patients who did not have cirrhosis at the time PSC was diagnosed was 95%, 92%, and 82% at 1, 3, and 5 years, respectively, after resection (Table 2). This was also significantly better than transplant-free survival in patients undergoing endoscopic intervention. None of the patients with surgical resection had CCA develop, with long-term follow-up exceeding 10 years, and only one patient (2%) needed a second operation for focal extrahepatic biliary obstruction and cholangitis.

Liver Transplant

Once cirrhosis develops, nonoperative biliary dilation or operative resection has little role in patient management because of the high morbidity. Complications of portal hypertension (e.g., variceal bleeding, ascites, hepatic encephalopathy, and recurrent cholangitis) are clear indications for liver transplant. Survival after hepatic transplant for PSC is similar to that for other end-stage liver disease. In three large series, 5-year patient and graft survival rates are approximately 70% to 80% and 60%, respectively. Patients with prior biliary tract or portal venous surgery do not appear to have increased hospital mortality after liver transplant.

TABLE 2: Survival in patients without cirrhosis with primary sclerosing cholangitis by treatment method

Overall Survival in Years (%)

ES/BD, Endoscopic sphincterotomy plus balloon dilation.
*Multicenter risk score.
†P <0.01 versus resection, overall survival includes patients undergoing liver transplant.
‡P <0.05 versus resection, overall survival includes patients undergoing liver transplant.

The development of CCA before liver transplant significantly affects the long-term outcome. In the combined University of Pittsburgh and Mayo Clinic experience, 11 of 216 patients had an unsuspected CCA, and the survival rate was only 47% at 2 years. Preoperative diagnosis of CCA before transplant remains difficult. Long-term survival has been reported with a neoadjuvant regimen of external and bile duct luminal radiation therapy with concurrent chemotherapy before liver transplant for perihilar CCA.

Another potential problem after transplant is recurrent sclerosing cholangitis. Nonanastomotic biliary strictures are more common after liver transplant for PSC than for other diseases and have been diagnosed in up to 20% to 25% of patients within a median follow-up of 5 to 10 years after transplant. Male gender and the presence of intestinal inflammation after transplant in patients with IBD have been strongly associated with recurrent PSC in the transplanted liver.

SUMMARY

Medical therapy can improve liver function tests in patients with PSC but has not been proven to delay progression of disease to cirrhosis and the need for liver transplant, the development of CCA, or survival. Thus, patients managed medically should be included in clinical trials. Balloon dilation or stenting of dominant strictures has provided short-term symptomatic relief but has not been proven to improve survival and may, in fact, delay the diagnosis of CCA. Surgical resection of hilar and extrahepatic strictures in patients without cirrhosis may postpone or prevent the need for transplant in carefully selected patients. Surgical resection should be considered in patients particularly if CCA is suspected. Liver transplant is the treatment of choice for patients with PSC and cirrhosis. However, liver transplant has significant short-term and long-term morbidity and should not be used too early in the natural history of the disease.

Management of Cholangiocarcinoma

Sabino Zani, Jr., MD, and Theodore N. Pappas, MD

OVERVIEW

Cholangiocarcinomas consist of a rare group of malignancies that arise from the biliary epithelium. They consist of three distinct subclasses (intrahepatic cholangiocarcinoma, perihilar cholangiocarcinoma, and distal cholangiocarcinoma) determined by the location at which they arise in the bile duct. Historically, a nihilistic attitude has been seen toward treatment because of the relatively advanced stage of disease at initial presentation and the technically challenging aspects of diagnosis and surgical resection. Most patients with unresectable cholangiocarcinoma die within 6 months to 1 year of diagnosis. Surgical excision is the most effective form of therapy and the only potential for cure, without which patients die of hepatic failure or biliary obstruction.

Hepatobiliary malignancies account for 3% of the 560,000 annual cancer-related deaths within the United States, with cholangiocarcinoma accounting for only a small portion (10% to 20%). On average, presentation occurs in the seventh decade of life, with a slight male predominance (1.5:1). Autopsy series have reported an occurrence rate of 0.01% to 0.46%, with an actual incidence rate of 1 to 2 cases per 100,000. Cholangiocarcinoma is the second most common primary hepatic malignancy, with approximately 2500 cases of intrahepatic cholangiocarcinoma occurring yearly. An additional 2000 to 3000 cases/year consist of perihilar tumors (70%), periampullary tumors (20%), and multifocal or diffuse tumors (10%).

Although a number of identified risk factors have been linked to the development of cholangiocarcinoma, the overwhelming majority are likely sporadic. Patients with primary sclerosing cholangitis are at increased risk of cholangiocarcinoma with an associated prevalence rate of 30% to 42% and an annual incidence rate of 0.6% to 1.5%. Chronic inflammatory processes including hepatolithiasis, parasitic infestation *(Clonorchis sinensis),* bacterial infection *(Salmonella),* congenital biliary cystic disease (choledochal cyst, Caroli's disease), toxic compounds (thorium dioxide), and hepatitis C are associated with an increased risk of development of cholangiocarcinoma. Increasing evidence is linking a possible association between cholangiocarcinoma and alcohol use, obesity, and diabetes.

Cholangiocarcinomas represent a group of invasive, slow-growing tumors that have the potential to progress rapidly. This invasive nature allows for the subepithelial extension of tumor and characteristic spread via neural, perineural, and lymphatic routes. This makes nodal metastases a common occurrence. Most tumors are adenocarcinoma (>90%), with rare occurrences of additional malignant cell types arising within the biliary system leading to obstruction (i.e., carcinoid).

The three distinct morphologic subtypes of cholangiocarcinoma include sclerosing, nodular, and papillary. Sclerosing tumors account for 90% of tumors that occur mostly at the hilum. They consist of firm tumors associated with a dense desmoplastic reaction that contribute to the technical difficulties associated with surgical resection. Nodular tumors present as a firm, irregular nodule that project into the lumen of the bile duct. Many tumors present with a combination of these two subtypes, hence the classification of nodular-sclerosing. In contrast, papillary tumors are often soft and friable tumors that arise from a well-defined stalk. With occurrence commonly at the distal bile duct, these tumors account for less than 10% of all cholangiocarcinomas. This subtype is associated with a greater likelihood of resection and a more favorable prognosis.

CLINICAL PRESENTATION

Intrahepatic Cholangiocarcinoma

Patients with intrahepatic cholangiocarcinoma usually present with an asymptomatic liver mass, frequently characterized only by changes in liver function tests. Associated symptoms, when present, include pain, weight loss, early satiety, and anorexia. The presence of jaundice and cholangitis is rare in this patient population and is usually indicative of advanced disease from tumor compressing or invading the biliary confluence or portal vein, or extensive replacement of liver by tumor. Physical examination is usually unremarkable.

Perihilar and Distal Cholangiocarcinoma

More than 90% of patients with perihilar and distal cholangiocarcinoma present with obstructive jaundice. For the small subset of patients with early stage disease, obstruction may not be present and findings include vague abdominal pain and abnormal liver function test results. Patients with incomplete biliary obstruction of only the right or left hepatic duct or segmental duct do not present with jaundice. This delays tumor diagnosis and allows tumor growth, resulting in the potential for ipsilateral lobar atrophy. Often elevated alkaline phosphatase or γ-glutamyltransferase (GGT) levels may be the only signs to elicit further evaluation. The presence of a papillary tumor may cause intermittent jaundice via a ball valve mechanism of the tumor mass or as fragments of the tumor detach and pass to the distal common bile duct. Other symptoms may include weight loss, anorexia, acholic stool, pruritus, and fatigue. Cholangitis is rare in this population unless there is prior percutaneous or endoscopic biliary manipulation.

Physical examination often yields findings of jaundice with hepatomegaly associated with advanced disease. A distended gallbladder may be palpable in patients with distal cholangiocarcinoma. Abnormal live enzymes are often present, allowing the use of total bilirubin level to give insight into an underlying malignant or benign pathology. A malignant process often results in bilirubin levels of more than 10 mg/dL, with an average of 18 mg/dL. This is in contrast to benign processes such as choledocholithiasis associated with bilirubin levels of 2 to 4 mg/dL.

DIAGNOSIS

The diagnosis of cholangiocarcinoma can be technically difficult because pathologic confirmation can be daunting. Often surgical therapy is offered based on clinical suspicion and radiographic appearance. Patients with intrahepatic masses suspicious for cholangiocarcinoma are further evaluated with guidelines for the workup of a primary liver tumor. Patients with findings suspicious for perihilar and distal cholangiocarcinoma share many similarities as discussed subsequently.

Perihilar and Cholangiocarcinoma

Ultrasound Scan

Often initial investigation includes ultrasound scan as the evaluation of patients begins before consultation with hepatobiliary surgical

specialists. It is a noninvasive cost-effective modality that can exclude benign pathology as the underlying cause of symptoms (i.e., cholelithiasis). Although findings are operator dependent, ultrasound scan is sensitive for confirming biliary duct dilation and localizing the site of obstruction. In cases of perihilar cholangiocarcinoma, typical findings include intrahepatic duct dilation with normal-caliber extrahepatic duct anatomy and a normal decompressed gallbladder. Findings of dilated intrahepatic and extrahepatic ducts are consistent with distal cholangiocarcinoma. The yield of this information may contribute to the ultimate diagnosis of disease but has minimal role in definitive diagnosis of cholangiocarcinoma.

Contrast-Enhanced, Triple-Phase, Helical Computed Tomographic Scan

The use of contrast-enhanced computed tomographic (CT) scan allows for greater understanding of the extent of disease process. Similarly sensitive for detection of the level of biliary obstruction, CT scan offers the added potential to assess vascular involvement, lymphadenopathy, and presence of lobar atrophy. The ability to evaluate metastatic disease is crucial because detection of bilobar metastases or extrahepatic disease precludes resection.

Magnetic Resonance Cholangiopancreatography

Similar to CT scan but with a greater sensitivity, magnetic resonance cholangiopancreatography (MRCP) offers a noninvasive modality that can assess the extent of bile duct invasion, vessel encasement, invasion of adjacent liver parenchyma with perihilar cholangiocarcinoma, lobar atrophy, lymphadenopathy, and distant metastases. Three-dimensional computerized reconstruction of the biliary tree provides superior imaging comparable with endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) with high positive and negative predictive values for detecting the level and features of biliary obstruction. This allows for defining the anatomy of tumors, assessing the potential for resection, and planning surgical treatment. Additional advantages over ERCP include the visualization of undrained bile ducts without injection of contrast, thus avoiding the risk of cholangitis.

Endoscopic Ultrasound Scan

Endoscopic ultrasound scan (EUS) offers the ability to evaluate the biliary system while avoiding contamination and potential for biliary sepsis. With an associated high sensitivity for detection of the level of obstruction and vascular involvement, this modality plays a crucial role in the staging of the disease process and predicting surgical resectability. The close proximity of the bile duct to the duodenum allows the added benefit of fine-needle aspiration (FNA) or core needle biopsy of tumor tissue or abnormal lymph nodes. This offers a greater sensitivity for detection of malignancy than brush cytology, increasing the diagnostic yield to 40% to 70%. This information is crucial to advise patients of surgical versus palliative options.

Tumor Staging

Optimal staging of cholangiocarcinoma allows the surgeon to formulate a treatment plan to accurately predict resectability, need for hepatic resection, and survival. Staging of cholangiocarcinoma requires careful patient selection and interpretation of imaging studies to accomplish this goal. Approximately 30% of cases are deemed not resectable based on this review. Laparoscopy is helpful for further assessment, as 25% to 30% of patients undergoing surgery are found to have unresectable disease, thereby minimizing surgical morbidity.

Radiologic review of surgical candidacy begins with evaluation of proximal and distal tumor margins to identify the potential for surgical resection. Identification of vascular encasement of the contralateral liver precludes surgical resection. Segmental or lobar atrophy may give insight to portal vein occlusion or obstruction in the assessment of vascular patency. Portal vein compression or narrowing, encasement, or occlusion as seen on ultrasound scan, CT scan, or magnetic resonance imaging (MRI) vascular studies are usually signs of tumor involvement. Patients with regional metastases are not candidates for surgical resection

Intrahepatic, perihilar, and distal cholangiocarcinoma are staged independently according to the 7th edition of the American Joint Committee on Cancer (AJCC) with the tumor node metastasis (TNM) staging system (Tables 1 to 3). Historically, perihilar cholangiocarcinoma have been classified based on the modified Bismuth-Corlette classification (Figure 1). Limitations to this system include critical information regarding vascular encasement or distant metastases. A more recent staging system based on this Bismuth-Corlette classification includes tumor size, extent of disease in the biliary system, vascular involvement, lymph node involvement, distant metastases, and functional liver remnant (Table 4).

PREOPERATIVE EVALUATION

Preoperative planning begins with a review of patient performance status. Surgical fitness of the patient is based on the extent of comorbidities, underlying liver disease, and nutritional status. Significant comorbidities including chronic liver disease or portal hypertension preclude resection, leaving palliation and biliary drainage options for therapy. Patients with unresectable conditions must have a tissue diagnosis before undergoing palliative treatments, including chemotherapy and radiation.

Patients determined to be adequate surgical candidates require meticulous review of radiologic studies to determine the potential success of tumor excision and need for concomitant liver resection, allowing an adequate future liver remnant. Selective ipsilateral portal vein embolization before resection can induce compensatory hypertrophy of the future liver remnant. Although controversial, this procedure is useful if the predicted liver remnant volume is less than 25%, reducing morbidity and mortality from liver dysfunction after resection.

Patients at high risk or those with sepsis are candidates for biliary stenting because it alleviates cholestasis. For the remainder of patients, biliary stenting remains controversial, predisposing to biliary infection and prolonging the postoperative hospitalization. Localized inflammatory effects of stenting may make the determination of tumor extent difficult at the time of operation. Patients requiring hepatic resection may benefit from stenting if the liver remnant is obstructed.

In the authors' practice, stenting is considered when the bilirubin value is more than 10 mg/dL or when the patient is malnourished and in need of nutritional support. The decision to use ERCP or PTC depends on local expertise and tumor location. ERCP is superior for distal cholangiocarcinoma. PTC is superior for perihilar cholangiocarcinoma as assessment of the biliary duct anatomy through proximally dilated ducts offers better visualization of the extent of perihilar stricture and perihilar anatomy. Each modality allows for biliary drainage, which is essential in the septic case. Additional advantages include the ability to obtain washings, brushings, and intraductal biopsies. Because of the desmoplastic nature of this disease, tissue-proven diagnosis remains low, yielding positive results in only one third of patients.

TABLE 1: Tumor node metastasis (TNM) staging for intrahepatic cholangiocarcinoma

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ (intraductal tumor)
T1	Solitary tumor without vascular invasion
T2a	Solitary tumor with vascular invasion
T2b	Multiple tumors, with or without vascular invasion
T3	Tumor perforating the visceral peritoneum or involving the local extrahepatic structures by direct invasion
T4	Tumor with periductal invasion*

Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis

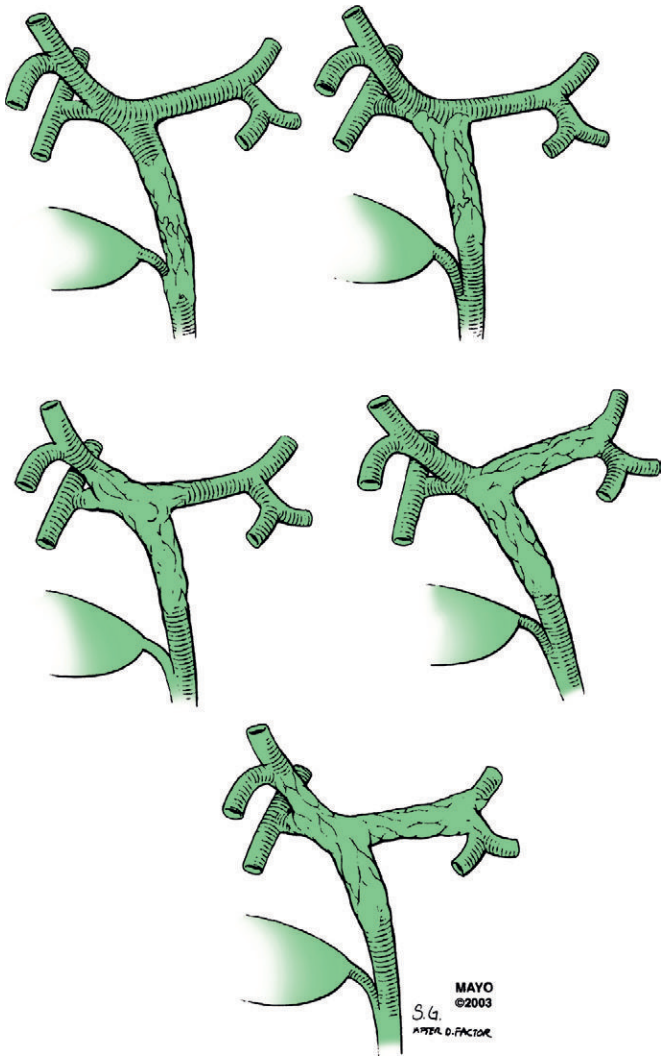

FIGURE 1 The Bismuth-Corlette classification of perihilar cholangiocarcinomas. Type I tumors are located distal to the hepatic ductal confluence. Type II cancers involve the junction of the right and left hepatic ducts. Type IIIA bile duct cancers involve the confluence and the right hepatic duct, whereas type IIIB tumors involve the confluence and the left hepatic duct. Type IV cancers involve both the proximal left and right hepatic ducts to the segmental bile ducts. *(Courtesy Mayo Clinic.)*

SURGICAL TREATMENT AND OUTCOMES

Perihilar Cholangiocarcinoma

Appropriate candidates for resection based on radiologic criteria can undergo surgical exploration to determine whether the tumor is resectable. Laparoscopy allows the ability to evaluate for peritoneal metastases without the morbidity of a laparotomy. In the absence of metastases, laparotomy is performed via a subcostal or J-type hockey stick incision.

Resection can be challenging because of the proximity to major vascular structures and the potential for extension into the right and left hepatic ducts. Initially, the distal bile duct is isolated at the level of the pancreas. A portion of the distal duct can be evaluated with frozen section to ensure negative margins. The bile duct is retracted cephalad and dissected off the portal vein posteriorly and the hepatic artery medial. Portal-caval lymphatic vessels are removed as part of this specimen. Cholecystectomy is then performed en bloc or separately. Bile duct bifurcation exposure is accomplished with individual dissection of the right and left duct to determine the extent of disease. The left hepatic duct is dissected proximal to the tumor, identified with stay sutures, and divided. Frozen section is obtained to ensure negative margins. If negative, the right hepatic duct is dissected, identified with stay sutures, and divided. Again, frozen section of the duct is obtained. If both ducts are found to be negative, resection is

completed and reconstruction via Roux-en-Y is performed with individual anastomoses to each duct.

Tumor extension from the left hepatic duct into the caudate requires a caudate lobectomy. Pancreatoduodenectomy may be performed in patients who are considered suitable candidates for positive tissue margin at the distal bile duct. Postoperative chemoradiotherapy is appropriate for the presence of positive tissue margins or positive lymph node status.

Patients with findings of metastases during laparoscopy can be appropriately palliated with biliary stenting, chemotherapy, or radiotherapy. Unresectable disease determined after laparotomy may undergo either segment III or IV bypass in conjunction with cholecystectomy.

Patients with locally advanced, unresectable cholangiocarcinoma without evidence of metastases pose a difficult problem. Reports of liver transplantation in highly selected patients treated with neoadjuvant chemoradiation resulted in 5-year survival rates as high as 76%. The Mayo Clinic has pioneered this modality and developed a liver transplantation protocol that resulted in a 5-year disease-free survival rate of 82%. Currently, orthotropic liver transplantation (OLT) is not standard of care and is only performed for highly selected patients in specialized centers.

Alhough most patients are found to have unresectable disease at presentation, exploration should be offered to all patients with potentially resectable tumors. Associated perioperative morbidity (30% to 50%) and mortality (5%% to 10%) can be expected for patients undergoing surgery. Margin-negative 5-year survival rates range from 21% to 56% in various series. Tumor recurrence occurs in a majority of patients, commonly in the liver (37% to 70%), with additional sites involving lymph nodes, lungs, and bones (4% to

30%). Associated factors that influence the risk of recurrence include presence of multiple tumors, vascular invasion, and tumor size. Death usually results from liver failure or biliary sepsis.

Distal Cholangiocarcinoma

Appropriate candidates for resection based on radiologic criteria can undergo surgical exploration to determine whether the tumor is resectable. Laparoscopy allows the ability to evaluate for peritoneal metastases without the morbidity of a laparotomy. In the absence of peritoneal disease, laparotomy via a subcostal incision is performed to continue the evaluation for unresectability. Resection typically involves pancreatoduodenectomy with reconstruction as discussed elsewhere. Historically bile duct excision alone was performed but rarely successful as only 10% of patients obtained curative resection margins on final pathology.

Patients with findings of metastases during laparoscopy can be appropriately palliated with biliary stenting, chemotherapy, or radiotherapy. Unresectable disease determined after laparotomy can be treated with hepatojejunostomy or choledochojejunostomy as surgical bypass is associated with improved patency and fewer episodes of cholangitis than stenting.

Historically, distal cholangiocarcinoma was associated with a higher potential for resection and improved prognosis compared with perihilar cholangiocarcinoma. This was largely because of the delay in diagnosis associated with perihilar cholangiocarcinoma. Currently, adjusting for stage and completeness of resection, survival after resection for distal cholangiocarcinoma and perihilar cholangiocarcinoma is similar. After margin-negative resection, 5-year survival rates approach 30% to 50%. Tumor recurrence occurs commonly at the bile ducts, nodes, and liver. Associated factors that influence the risk of recurrence include margin positivity and positive nodal status.

PALLIATION

Patients with unresectable cholangiocarcinoma without evidence of metastatic disease who are not candidates for liver transplantation may benefit from photodynamic therapy (PDT). This process consists of intravenous administration of a photosensitizing agent (porphyrin) that accumulates within the tumor cells. Cholangioscopy then allows the introduction of a specific wavelength of light that activates the agent, resulting in cell destruction. PDT has been shown to improve cholestasis and quality of life. Patients require careful monitoring after therapy. The regional availability of this modality limits its utilization.

Although no chemotherapy is consistently effective, patients with unresectable cholangiocarcinoma are candidates for palliative chemotherapy. Historically, reports of 5-fluorouracil (5-FU)–based chemotherapy offered response rates of less than 10%. Additional studies that evaluated alternative regimens including mitomycin C, doxorubicin, gemcitabine, and capecitabine have shown minimal effect on response rates and increased associated toxicity. Similarly, patients without evidence for metastatic disease may be candidates for radiotherapy. Although few retrospective studies show a benefit to radiotherapy, further studies are needed to reach a consensus.

SUMMARY

The diagnostic and technical aspects of cholangiocarcinoma make this a challenging disease process to treat. Although surgical resection is the only effective therapy and potential for cure, most patients present with advanced disease that is often found to be unresectable. Patients who undergo resection face a high likelihood of recurrence, predicted by margin positivity and locoregional lymph node involvement. Liver transplantation is applicable to a highly selected patient population, which makes palliation a key component of care in most patients with unresectable disease. Key therapies include adequate biliary drainage, with the benefit of PDT offering reduced cholestasis and improved quality of life. Despite characteristic tumor resistance to chemotherapy and radiotherapy, these modalities may still serve a role in the treatment of unresectable cholangiocarcinoma.

GALLBLADDER CANCER

Reid B. Adams, MD, and Todd W. Bauer, MD

OVERVIEW

Gallbladder cancer (GBC) is a challenging disease, often due to its advanced stage at presentation and aggressive biology. An improved understanding of its natural history, however, has led to more appropriate patient selection for treatment; likewise, advances in surgical techniques have resulted in better long-term survival. Consequently, surgical therapy in appropriately selected patients is effective, and the past despair associated with GBC should be tempered. This discussion focuses on patient selection for treatment and an approach to therapy based on currently available data.

GBC incidence varies widely by geography and ethnicity throughout the world. In the United States, it is relatively uncommon, with fewer than 5000 cases per annum (1 to 2 per 100,000). However, it is the most common biliary tract malignancy and the fifth most common gastrointestinal malignancy. The incidence is higher for women (twofold to threefold) and whites (compared to African Americans); it increases with age and in those with obesity. Native Americans and Hispanic women have the highest incidence in the United States.

Chronic gallbladder inflammation is the most common unifying theme associated with potential risk factors for gallbladder cancer. In the United States, this association typically means cholelithiasis, which is present in 75% to 90% of GBCs. The presence of gallstones

does not appear sufficient for malignancy, however, because only 0.5% to 3% of patients with cholelithiasis develop GBC.

NATURAL HISTORY, BIOLOGY, AND THE ROLE OF SURGICAL TREATMENT

The natural history of GBC has been defined by studies over the past 50 years leading to our solid understanding of the disease outcomes. Most of these reports have median survivals of 6 months or less, with overall 5-year survivals of 5%. Thus, the fatalistic mindset associated with GBC in the past is understandable. Only recently, based on reports beginning in the early 1990s, has a more optimistic attitude emerged based on evidence that radical surgical therapy can alter this dismal course. While randomized trials are lacking, cumulative evidence strongly supports the contention that liver resection and portal lymphadenectomy provide a survival advantage for selected groups of patients with GBC.

Poor survival in the past for GBC was likely due to the advanced stage of disease at presentation. Advanced disease results from its propensity to spread via the lymphatics, hematogenously, and by shedding into the peritoneal cavity. Tumor dissemination probably is facilitated by the structure of the gallbladder. Due to its thin wall, even minimal invasion permits penetration deep into the muscular layer, thereby allowing access to the lymphatic and vascular channels. This presents the possibility for dissemination early in the disease process. Similarly, minimal invasion can penetrate the connective tissue between the gallbladder and the liver (the cystic plate), ultimately allowing invasion of the adjacent liver. Therefore, dissection within this fibrous plane, as done during a standard cholecystectomy, typically leaves residual tumor at this site. Likewise, tumor penetration of the wall covered by peritoneum allows peritoneal seeding. The lymphatic drainage of the gallbladder is well described; it initially travels to the cystic and pericholedochal lymph nodes. From there, drainage leads to the retroportal and posterior-superior pancreaticoduodenal nodes. Finally, flow continues to nodes associated with the celiac and superior mesenteric arteries and the aortocaval region. However, direct drainage from the pericholedochal nodes to the aortocaval nodes does occur, possibly accounting for advanced disease early in the course.

STAGING

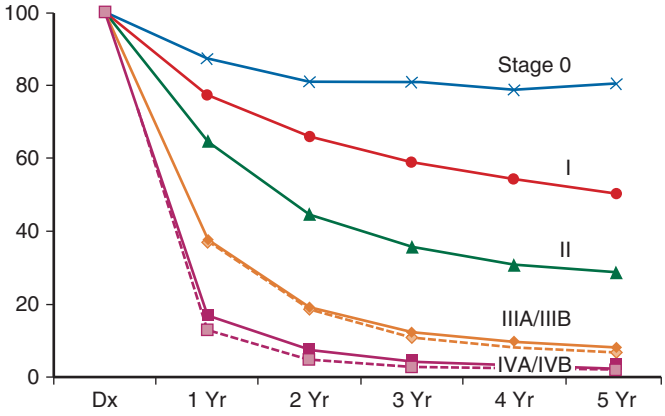
Understanding the patterns of spread and their relationship to outcomes is recognized by the recent changes for staging GBC published in the *American Joint Committee on Cancer Staging Manual* (Table 1). Changes to the current system correlate with resectability and patient survival. Based on this reorganization, the new staging correlates well with outcomes as validated with data from the National Cancer Data Base (Figure 1).

Thus, a detailed understanding of the patterns of spread and biology of the disease, combined with the outcomes associated with the new staging system, allow development of a rational approach for the evaluation and treatment of patients with GBC.

Clinical Scenarios

GBC presents as one of three common scenarios: suspicion prior to surgery based on symptoms and imaging or incidentally found on imaging done for an unrelated reason; discovered at the time of surgery; and discovered incidentally on the final pathology. Recent data show that approximately 50% of patients present with advanced or disseminated disease, and the other half are discovered incidentally following cholecystectomy.

TABLE 1: Gallbladder cancer stages



Primary tumor (T)			
Tis	Carcinoma in situ		
T1	Tumor invades lamina propria (T1a) or muscular layer (T1b)		
T2	Tumor invades perimuscular connective tissue		
T3	Tumor perforates serosa and/or invades the liver and/or one adjacent structure		
T4*	Tumor invades main portal vein or hepatic artery or invades two or more extrahepatic structures		
Regional lymph nodes (N)			
N0	No regional lymph node metastasis		
N1	Metastases to nodes along the cystic duct, common bile duct, hepatic artery, and/or portal vein		
N2†	Metastases to periaortic, pericaval, superior mesenteric artery, and/or celiac artery lymph nodes		
Distant metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Staging groups (TMN)			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage IIIA	T3	N0	M0
Stage IIIB	T1-T3	N1	M0
Stage IVA	T4	N0-N1	M0
Stage IVB	Any T	N2	M0
	Any T	Any N	M1

*T4 denotes locally advanced, unresectable tumors.
†N2 nodes are considered distant metastatic disease.
Modified from AJCC cancer staging manual, *ed 7, New York, 2010, Springer.*

Suspicion Prior to Surgery

Abdominal imaging, whether done for right-upper-quadrant symptoms or unrelated reasons, may show gallbladder findings that raise concern for GBC. Typical findings range from diffuse wall thickening to an obvious infiltrative gallbladder mass. The nature of these findings influences the level of concern for GBC and affects the preoperative evaluation and treatment options.

In this situation, transabdominal ultrasonography (US) is commonly the initial study, although similar incidental abnormalities are increasingly being seen on computed tomographic (CT) and

Stage	Survival				
0	87	81	81	81	81
I	77	66	59	54	50
II	65	45	36	32	29
IIIA	38	19	12	10	8
IIIB	37	19	11	9	7
IVA	17	7	4	3	3
IVB	13	5	3	2	2

FIGURE 1 Staging correlated to outcomes as validated with data from the National Cancer Data Base. *(From Fong Y, et al: Evidence-based gallbladder cancer staging: changing cancer staging by analysis of data from the national cancer database,* Ann Surg *243(6):767–771, 2006.)*

magnetic resonance (MR) imaging. Findings of diffuse gallbladder wall thickening and cholelithiasis are common and rarely raise the specter of GBC. Consequently, the difficulty diagnosing GBC preoperatively stems from the similarity of symptoms to those of biliary colic, and/or chronic cholecystitis. The high rate of incidentally discovered disease likely results from this overlap.

Several studies reviewing GBC detection show that the rate of incidentally found GBC can be decreased; with modern imaging, a preoperative diagnosis can be made in approximately 80% of cases. However, to achieve this level of detection, a high index of suspicion is necessary because the overall preoperative detection rate in most series remains around 50%. Thus, preoperative review of the actual images by the operating surgeon can improve GBC detection.

On the other end of the spectrum are findings consistent with advanced disease. These include a heterogeneous mass replacing, or within, the gallbladder or infiltration of the surrounding liver. Between these extremes are findings that suggest, but are not diagnostic of, GBC. Concerning features include focal/asymmetric wall thickening, a disrupted mucosa, a fixed mucosal mass, or obliteration of the interface at the cystic plate.

Once a gallbladder abnormality is noted on US, the extent of additional evaluation is based on the findings and degree of suspicion for GBC. For instance, gallbladder polyps (GBPs) are common, seen in up to 4.5% of patients on US. The majority of GBPs are cholesterol followed by adenomyomas (adenomyomatosis), both nonneoplastic lesions. Less common are neoplastic polyps such as adenomas. Only adenomas are associated with a risk of malignancy, but the frequency with which they will progress to carcinoma remains unclear. The key feature related to malignancy is the size of the adenoma. Thus, the primary issue with polyps is distinguishing these from one another and from more ominous gallbladder abnormalities suggestive of GBC. The lack of firm guidelines for their evaluation hampers a standardized approach.

A general approach, then, is to examine the US features of polyps. These are very useful for distinguishing one from the other, and often, US is the only study required. Evaluation for mucosal vascularity by color Doppler ultrasound can differentiate indeterminate findings into benign or neoplastic lesions. Endoscopic ultrasonography also is reportedly helpful in delineating benign from neoplastic lesions, although its use in the United States appears limited. Cholesterol polyps characteristically are less than 5 mm, multiple, and frequently pedunculated. They are nearly always less than 1 cm in size and typically appear hyperechoic. Usually asymptomatic, they do not require treatment. Adenomyomatosis takes three forms: diffuse, segmental, and localized. All three can mimic GBC, so the diagnosis often is made at pathology. The localized type typically presents as a mass in the gallbladder fundus. These lesions often have characteristic features on US such as areas of cystic dilation, suggesting the diagnosis. If the diagnosis is likely but cannot be confirmed by US, MR imaging has typical features that can help confirm the diagnosis. If confirmed, adenomyomatosis does not require treatment. Adenomas are single, often sessile, polypoid lesions. Usually they are found in the absence of cholelithiasis. Although some debate persists, most studies report a low, to no, incidence of carcinoma in adenomas less than 1 cm. The incidence increases for adenomas between 10 and 18 mm; a high rate of carcinoma is reported in lesions 18 mm or larger, so all of these should be considered malignant.

Gallbladder imaging abnormalities suspicious for GBC should undergo high-resolution cross-sectional imaging, either CT or MRI, based on institutional expertise and experience. MRI is our choice for concerning lesions because it is more sensitive for detecting liver involvement or metastasis, and it allows cholangiography and angiography. This additional imaging can confirm GBC and assess its extent.

In general, laboratory studies are not useful. However, carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA19-9) may be of value when lesions remain indeterminate by imaging. A CEA greater than 4 ng/mL is 93% specific and 50% sensitive for GBC. CA19-9 is 79% specific and sensitive for GBC. Together with the imaging features of an indeterminate lesion, these may modify the level of concern that a gallbladder abnormality is more likely to be benign versus malignant.

If the diagnosis of suspicious findings remains uncertain or GBC is suspected, there is no role for preoperative biopsy in patients with potentially resectable disease. GBC has a high propensity to seed biopsy tracts and the peritoneum, and an unnecessary biopsy increases this risk. When unresectable or metastatic disease is present, percutaneous biopsy is very accurate and appropriate if histologic confirmation will influence disease management.

Discovery at the Time of Surgery or Final Pathology

Due to the difficulty distinguishing GBC from benign disease, routine inspection of the gallbladder mucosa following cholecystectomy is recommended; suspicious areas should be examined by frozen section biopsy. If carcinoma is found, additional treatment may be required.

Incidentally discovered GBC on the final pathology is a common presentation. Treatment is based on the stage; staging prior to definitive therapy may be necessary.

RADIOLOGIC EVALUATION

When GBC is suspected or confirmed, CT or MR imaging is necessary for preoperative staging. The goals are to establish the diagnosis, evaluate its extent to plan definitive therapy, and limit patient exposure to nontherapeutic laparotomy. Based on the patterns of spread, imaging is directed primarily to the liver, adjacent organs, and regional/distant lymph nodes. While peritoneal disease is common in more advanced disease, it is difficult to identify preoperatively by imaging. Chest radiography should be done to complete the staging evaluation, although the risk of lung metastasis is rare unless locally advanced or abdominal metastatic disease is already present.

When patients have GBC discovered incidentally on pathologic review, staging as outlined for preoperatively suspected GBC may be indicated. The results of this imaging evaluation will dictate the treatment options.

While most GBCs are detectable by FDG-PET, its role in staging remains unclear. It appears most useful in detecting metastatic disease when evaluating primary GBC rather than recurrence. Several studies report PET altering surgical therapy 17% to 23% of the time. When GBC is incidentally discovered on pathology, PET has limited utility distinguishing residual tumor in the cholecystectomy bed from postoperative inflammation. If preoperative imaging suggests T1 disease, there is likely no benefit from PET. Because the likelihood of metastatic lymphadenopathy increases with T2 or greater GBC, PET may be more useful in this situation.

MANAGEMENT

Polyps

Cholecystectomy is the primary treatment for gallbladder polypoid lesions, and it should be considered in symptomatic patients. While polypoid lesions rarely cause symptoms, some patients have typical biliary symptoms such as colic or pancreatitis; cholecystectomy is indicated because the majority of them improve following surgery. The efficacy of cholecystectomy for polyps in patients with nonspecific upper-abdominal symptoms is less clear, and routine cholecystectomy should not be done unless another indication for polyp resection is present or no other cause for their pain is found. In the latter group, the expectation for symptom relief following cholecystectomy is low.

For patients with asymptomatic GBPs, the principal issue is determining which patients require treatment. As stated earlier, when asymptomatic cholesterol polyps or adenomyomatosis is confirmed, cholecystectomy is not indicated. Otherwise, for indeterminate polyps, cholecystectomy is recommended when specific criteria are met. When these criteria are absent, serial observation may be appropriate.

The main goal of cholecystectomy for polypoid lesions is to prevent malignant transformation or treat a GBC at its earliest stage. Features most consistently predicting malignancy include a single polypoid lesion larger than 10 mm in size in patients older than 50 years. These characteristics, coupled with other reported features, define several populations where routine cholecystectomy is recommended due to the increased risk of malignancy:

- Polyps larger than 10 mm
- Polyps in the presence of cholelithiasis, regardless of polyp size or symptoms
- Polyps in patients with primary sclerosis cholangitis

Several issues require attention when contemplating cholecystectomy for GBPs. The first consideration is the surgical approach, either laparoscopic or open cholecystectomy. We have favored open cholecystectomy in these patients to ensure no compromise in their oncologic outcome in the event GBC is present. There seems to be little justification for a smaller incision if it has the potential to contribute to a worse outcome. However, accumulated data support laparoscopic cholecystectomy alone as adequate treatment for Tis and T1a tumors. Additional evidence supports no difference in outcomes for patients treated with a laparoscopic cholecystectomy initially, followed by a delayed definitive operation for GBC if no perforation occurred. These findings support the contention that a properly done laparoscopic cholecystectomy is a reasonable approach for GBPs. Our primary concern remains, though, because approximately 20% to 30% of laparoscopic cholecystectomies are associated with an incidental cholecystotomy and bile spillage during the procedure. The aggressive biology and propensity for seeding of GBC makes bile spillage an unacceptable risk, potentially converting a curative situation to an incurable one. Thus, if a laparoscopic approach is considered, a very low threshold for conversion to an open procedure should be adopted, and gallbladder perforation should be fastidiously avoided. If done laparoscopically, the specimen should be removed in an extraction bag.

A second issue to consider is readiness to perform definitive therapy. If a cholecystectomy is performed for a patient with a GBP, the specimen must be examined by frozen section biopsy at the time of surgery. If invasive (>T1a) GBC is present, the definitive procedure, an extended cholecystectomy, must be performed. Consequently, all patients undergoing cholecystectomy for GBP should be counseled about the risk of malignancy and consented for extended cholecystectomy at the same operation if GBC is found. If local expertise is not present to perform an extended cholecystectomy, the patient should be referred preoperatively to an experienced hepatobiliary unit.

The third issue is location of the polyp. Careful review of the preoperative imaging is important to identify the location of the polyp within the gallbladder. If it is adjacent to the cystic plate, we favor cholecystectomy with en bloc excision of the cystic plate to avoid dissection between the wall of the gallbladder and the cystic plate. If the polyp is not adjacent to the cystic plate, a standard cholecystectomy is performed.

When a polyp is 18 mm or larger, it should be considered malignant and treated as such. These patients should undergo preoperative staging as outlined previously. Appropriate treatment is an extended (radical) cholecystectomy.

The second important issue is surveillance for patients with polyps who do not undergo resection, a subject that remains unclear. This group primarily includes asymptomatic polyps less than 10 mm in size. The problematic issue for these patients is the lack of consensus regarding recommendations for the frequency and duration of follow-up. There is relatively uniform agreement that polyps in this group require serial ultrasound evaluation to ensure stability of the polyp. If a polyp increases in size during observation, cholecystectomy is indicated. There is general agreement that after initial discovery, repeat US should be done at 6 and 12 months. If no change is noted, then annual US is recommended. Emerging data suggest that ethnicity and geographic location modify the risks for GBC, likely explaining the wide variability in the risk of GBPs developing into GBC. For instance, Aldouri and colleagues reported a prevalence of GBC with GBP of 0.08% in a white population. Thus, some authors advocate no further surveillance after 2 years for a stable GBP. Another study observed neoplastic GBP growth over an 8-year surveillance period. Thus, some authors recommend annual US without a clear endpoint. Evidence exists that dysplasia to malignant transformation can take more than 10 years; this also suggests that a longer surveillance period may be appropriate. The tension in these discussions is balancing the substantial costs for surveillance with identification of a diminishingly small number of neoplastic GBPs.

Suspicious Findings Prior to Surgery

When the preoperative concern for GBC is greater than that described for GBPs, complete preoperative staging should be done and the patient prepared for a definitive oncologic operation. Findings precluding curative resection include a medically unfit patient or imaging showing metastatic disease (liver, peritoneum, extra-abdominal), lymph node involvement outside the hepatoduodenal ligament, or encasement/occlusion of the main portal vein and hepatic artery. Jaundice in patients with GBC is a relative contraindication to curative therapy. While these patients may have technically resectable disease, a large study of this population reported 7% of patients with jaundice and GBC were resectable, and all those having resection died within 2 years of treatment. On the other hand,

a more recent study reported a 45% resection rate and 5-year survival of 19%. Only patients with N0 disease had long-term survival; they recommended extensive lymph node sampling prior to resection. If any were positive, no resection should be done. These results were associated with a 16% operative mortality in patients undergoing curative resection for GBC presenting with jaundice. Thus, jaundice is an indicator of advanced disease in patients with GBC, and resection is feasible only in a highly selected population.

CT or MRI detects direct liver or adjacent organ involvement and guides treatment planning and counseling. If major hepatectomy may be necessary for complete resection, assessment of postoperative hepatic reserve is necessary to determine the need for portal vein embolization. If N2 nodal involvement is suspected preoperatively, PET scan or EUS and biopsy can determine disease presence, thereby avoiding unnecessary laparotomy.

Since the incidence of occult metastases is high, the procedure should start with staging laparoscopy for all patients. If negative, laparotomy and the definitive operation for GBC can proceed. In patients with a high degree of concern for GBC, a simple cholecystectomy to make the diagnosis is inappropriate. Thus, some patients may undergo partial hepatectomy for benign disease, a possibility they should be informed of preoperatively.

GBC Discovered at Time of Surgery

If a laparoscopic cholecystectomy is done and intraoperative frozen section shows GBC, several options are available. If this is truly incidental, the stage appears greater than T1a, and the operating surgeon has the necessary expertise, one option is to proceed to definitive resection. If the stage is uncertain or the expertise for definitive resection is not available, no further procedures should be done. The patient is recovered, the final pathology reviewed, appropriate staging completed, and then a definitive operation, if indicated, done. In this circumstance, our preference is to recover the patient and await the final pathology because accurate determination of the T stage on the frozen section can be difficult. In addition, this allows a full discussion with the patient and appropriate consenting. The patient is taken back to the operating room several days later for the definitive procedure.

During laparoscopic cholecystectomy, if GBC is suspected and this was unknown prior to the procedure, no dissection or biopsy should be done, a careful laparoscopic staging exam should be performed, and the patient should be closed and recovered. If a definitive resection cannot be done locally, the patient should be referred. Otherwise, completely stage the patient, appropriately consent him or her, and proceed to definitive resection. If GBC is suspected after the laparoscopic dissection has begun, we recommend stopping and converting to an open procedure. Usually, the issue in this case is difficulty dissecting the gallbladder from the fossa. We favor resecting a rim of liver around the gallbladder fossa in this case and doing a frozen section biopsy. If GBC is found, we proceed to a definitive resection at that procedure. If this circumstance is encountered and local expertise for a partial hepatectomy is not available, the dissection is stopped and the patient recovered, followed by transfer that day for definitive care.

GBC Incidentally Found on Final Pathology

When GBC is found incidentally on the final pathology, the need for additional treatment is based on the depth of tumor invasion. Hence, the slides should be carefully reviewed with the pathologist to verify this stage. Margin negative Tis and T1a tumors are adequately treated with simple cholecystectomy alone. Patients with tumors greater than T1a require more extensive resection. These patients should undergo complete staging, and if no contraindications are found, they should proceed to definitive surgery.

There is no role for port site resection of incidentally discovered GBC resected laparoscopically. While advocated by some in the past, port site disease is a marker for peritoneal disease and carcinomatosis. Excision is not curative or associated with improved overall or disease-free survival.

Definitive Surgical Therapy

Current data support partial hepatectomy and regional lymphadenectomy as essential elements of a definitive resection. This is referred to as an extended, or radical, cholecystectomy. It is appropriate treatment for T1b to T3 tumors. The principal components of the operation are resection of the liver around the gallbladder fossa and lymph node dissection of the hepatoduodenal ligament. While the goal of the liver resection is to obtain a margin of approximately 2 cm around the gallbladder fossa, a wedge resection of this site is often compromised as one approaches the hilum. Consequently, most major hepatobiliary programs, including ours, favor an anatomic resection of segments IVb/V.

Whether the extended cholecystectomy is the index operation or done for reresection of an incidentally found GBC, the approach is similar. We begin all these operations with staging laparoscopy, because the risk of disseminated disease is significant. If laparoscopy is negative, a right subcostal incision is made and used to explore the abdomen. Intraoperative ultrasonography is performed to define the extent of any liver involvement. A Kocher maneuver is done and a search for abnormal lymphadenopathy outside the hepatoduodenal ligament is made. Any suspicious nodes are excised and sent for frozen section. If nodes outside the N1 distribution are positive, the procedure is aborted because these represent distant metastatic disease. If the gallbladder is present, an en bloc cholecystectomy and segment IVb/V hepatectomy is completed. This is sent to pathology for frozen section biopsy of the cystic duct margin. If this is negative, there is no role for routine extrahepatic bile duct resection. Bile duct resection is only necessary to achieve a negative cystic duct margin. Likewise, routine hepatectomy larger than IVb/V is unnecessary, except when it is required to achieve a negative margin. This might be necessary for T3 tumors extending into the right lobe past segment V or for involvement of the right portal structures. The routine use of a larger hepatectomy or bile duct resection is associated with a higher morbidity and mortality without a concurrent improvement in survival. If a cholecystectomy was previously done, hepatectomy of segments IVb/V is done. While awaiting the frozen section results, the hepatoduodenal structures are skeletonized, removing all the soft tissue from the hepatic artery, portal vein, and extrahepatic bile ducts from the duodenum to the hepatic plate. If an adjacent organ has limited involvement by direct extension, en bloc resection is appropriate to achieve a negative margin. Extensive involvement may preclude a margin negative resection, and a debulking operation should not be performed. Involvement of more than one extrahepatic organ is T4 disease and considered locally unresectable.

Stage-Based Therapy

Tis and T1a: Simple cholecystectomy is sufficient because cure rates approach 100%. If the cystic duct margin is positive, additional cystic duct resection to a negative margin is required. If this is inadequate, then excision of the extrahepatic bile ducts and hepaticojejunostomy is appropriate.

T1b: The role of simple versus extended cholecystectomy for treatment has been controversial in the past. T1b tumors have a higher incidence of lymph node metastasis and locoregional recurrence. Current evidence shows improved survival compared to simple cholecystectomy in this group; thus, extended cholecystectomy is recommended for fit patients.

T2: Extended cholecystectomy is recommended for this group of patients. Patients with T2 tumors appear to derive the greatest benefit from radical resection. Long-term survival following extended cholecystectomy is 60% to 80% versus less than 50% with simple cholecystectomy.

T3: Extended cholecystectomy is recommended for these patients, with evidence supporting improved long-term survival around 15% to 20% in well-selected patients. A more extensive hepatectomy, such as an extended right hepatectomy, may be necessary to achieve negative margins when the right portal pedicle is involved. Likewise, resection of a single adjacent organ for direct extension may be necessary for margin clearance.

T4: These are considered locally unresectable tumors. Reports of resected T4 tumors are very limited and seem to be in the context of a finding at pathology when resection was done for what appeared to be a lower-stage tumor. Anecdotal cases of improved survival for these T4 tumors versus unresected T4 tumors have been published. Any improvement in survival is likely associated with a margin negative resection and N0 disease. In general, resection of T4 tumors is not feasible because these conditions are typically not present.

Adjuvant Therapy

Studies of recurrence following complete resection show that a majority of patients (85%) recur at a distant site, while only 15% have locoregional recurrence. This has implications for the choice of adjuvant therapy and suggests that systemic therapy should be part of any adjuvant strategy. However, no randomized phase III trials are available to establish a standard of care for patients with resected GBC. Several small studies and retrospective series suggest a survival benefit following radiotherapy for T2 or larger tumors or N1 disease. A recent phase III randomized trial showed a benefit for a gemcitabine-cisplatin combination versus gemcitabine alone when used for palliative therapy for metastatic biliary cancers. It is unknown whether this benefit would translate to the adjuvant setting.

PALLIATIVE CARE

Because a high proportion of patients with GBC are unresectable, providing palliation is an important role for the surgeon. Common symptoms include pain, jaundice, and bowel obstruction. Due to the poor prognosis and limited life expectancy, nonoperative approaches to palliation are optimal. We prefer endoscopic stenting for jaundice, when possible; a percutaneous approach is done when an endoprosthesis cannot be placed or provides inadequate palliation. A percutaneous gastrostomy with a jejunal feeding extension is preferable to operative bypass due to the short life expectancy in patients with duodenal or small bowel obstruction from direct extension or peritoneal disease.

GALLSTONE ILEUS

Ellen Hunter Bailey, MD, and Kenneth W. Sharp, MD

Gallstone ileus is a rare cause of intestinal obstruction accounting for less than 3% of intestinal obstructions. It was originally described by Courvoisier in 1890 as an unusual cause of bowel obstruction. The most common cause is erosion of a large gallstone into the duodenum, where the stone passes until it lodges at the ileocecal valve. Other causes include erosion of a large gallstone into the stomach with obstruction of the stone at the pylorus or proximal duodenum causing gastric outlet syndrome, a condition also known as Bouveret's syndrome. Rare cases have been reported of the gallstone obstructing the colon (from cholecystocolic fistula) or lodging in small bowel strictures such as occurs with Crohn's disease.

Gallstone ileus is a disease of older adults, the average age at presentation exceeds 70. It is much more common in older women, and female-to-male ratios are between 3:1 and 5:1. The diagnosis should be suspected in the differential diagnosis of an older woman presenting with small bowel obstruction with no antecedent history of abdominal operations and without abdominal or inguinal hernias on physical examination.

PATHOGENESIS

Gallstone ileus requires a preceding biliary enteric fistula between the gallbladder and the intestine—most commonly the duodenum adjacent to the gallbladder—but may also exist between the gallbladder and the stomach, colon, or small bowel. It is theorized that a large stone impacts in the neck of the gallbladder and leads to inflammation, pressure necrosis, and then erosion into an adjacent hollow viscus. There are reports of coexisting fibrotic common hepatic or common bile duct obstructions (Mirizzi's syndrome) from the intense inflammatory reaction required for such fistulae to form. It is rare for stones smaller than 2 cm to cause obstruction, and the most common sites for impaction are the distal ileum, the sigmoid colon, and the second portion of the duodenum. The cholecystenteric fistula may close spontaneously after passage of the stone or may stay patent in some cases. Additional unusual cases have been described after endoscopic sphincterotomy for common bile duct stones has been performed, when large stones are extracted from the common duct and not endoscopically retrieved.

DIAGNOSIS

Patients will most often present with fairly classic symptoms of bowel obstruction such as abdominal pain, nausea, vomiting, and obstipation or constipation. The patients will rarely have fever, peritonitis, or signs of sepsis. A history of previous biliary colic is not commonly

elicited, and a history of jaundice is rare. It may be possible to obtain a history suggestive of acute cholecystitis, but since the process is slow in progression, the episode may have happened years previously. Individuals present with crampy abdominal pain that may be sporadic in nature if the stone is not impacted; this pain has been attributed to the stone "tumbling" proximal to distal in the small bowel and causing intermittent obstruction. If the biliary enteric fistula is cholecystogastric, the gallstone may obstruct the gastric outlet. Individuals with this type of fistula complain predominantly of severe nausea and vomiting.

Laboratory evaluation of the patient is not diagnostic; there are no diagnostic findings in the electrolytes, liver tests (although elevated liver tests or bilirubin are not infrequent), amylase, lipase, or blood counts. Plain abdominal radiographs usually show dilated loops of small intestine with air fluid levels consistent with small bowel obstruction. Pneumobilia appears only half of the time on plain films and it is rarer still to see a radiopaque gallstone in the alimentary tract. The classic finding in gallstone ileus, Rigler's triad (distended loops of small bowel, air in the biliary tree, and a radiopaque stone in the right lower quadrant), is found in relatively few cases on plain radiographs. Computed tomographic (CT) scans are much more sensitive for visualizing pneumobilia and will show this finding more frequently than plain films. CT scans are used increasingly for the diagnosis of intestinal obstruction and can further delineate the cause of a bowel obstruction with air or even oral contrast in the biliary tract, a fistulous connection between the gallbladder and a surrounding hollow viscus, radiographic evidence of alimentary tract obstruction, and the obstructing stone (Figure 1).

Ultrasonography of the gallbladder shows cholelithiasis and choledocholithiasis in a variable number of patients. If there is air in the gallbladder, it will degrade the ultrasonographer's ability to visualize stones. Finally, a firm preoperative diagnosis of gallstone ileus is not essential. A proper diagnosis of bowel obstruction is sufficient to indicate the need for an operation. Many cases of gallstone ileus have not been diagnosed until the finding is made at laparotomy.

MANAGEMENT

Patients with gallstone ileus generally present dehydrated from poor oral intake and volume losses secondary to bowel distention and emesis. They frequently have significant electrolyte abnormalities. Initial therapeutic efforts should be focused on resuscitation: monitoring of vital signs and volume status, nasogastric decompression, judicious fluid resuscitation, and focused electrolyte correction. It is critical to focus on general physiologic optimization since this is an older patient population with significant preexisting medical comorbidities. Many of these patients fit into category 3 or 4 of the American Society of Anesthesiologists physical status classification system. Preoperative optimization of the dehydrated older patient with heart failure, coronary disease, renal failure, or respiratory failure may be best done in an intensive care unit for several hours prior to the stress of inducing a general anesthetic. Since these patients rarely present with sepsis or peritonitis, there is usually no need for truly emergent operation.

It is important to remember that there are always two separate disease processes present in the gallstone ileus patient: (1) a bowel obstruction and (2) an inflammatory biliary process that may be a chronic fistula or an active inflammatory phlegmon. The absolute priority is relief of the bowel obstruction by removing the obstructing gallstone. Biliary sepsis that demands drainage or cholecystectomy during the same operation is uncommon. Classically this is performed with a laparotomy during which the abdomen is thoroughly examined, the site of obstruction is identified, and the inflammatory process surrounding the gallbladder is assessed. The point of obstruction is found most commonly at the ileocecal valve, and the stone generally should not be forced distally through the obstructing point because of concern for splitting the bowel. The gallstone is milked backward and removed through a proximal longitudinal enterotomy in a healthy-appearing bowel, and the enterotomy is closed transversely. Some authors advocate for a transverse enterotomy and closure. If the stone is so tightly impacted it cannot be milked proximally, the bowel should be opened over the stone and the area resected (some advocate resection without opening the bowel in this circumstance). Although uncommon, any nonviable-appearing bowel is resected and anastomosed. It is unusual to perform bypass of an obstructed area rather than enterolithotomy. The remainder of the alimentary tract is examined for additional stones that are found in up to 5% of cases, and these should be removed. Repeat episodes of gallstone ileus are rare and occur in about 5% of postoperative patients (usually within 6 months of first presentation); more than 80% of recurrences resolve spontaneously.

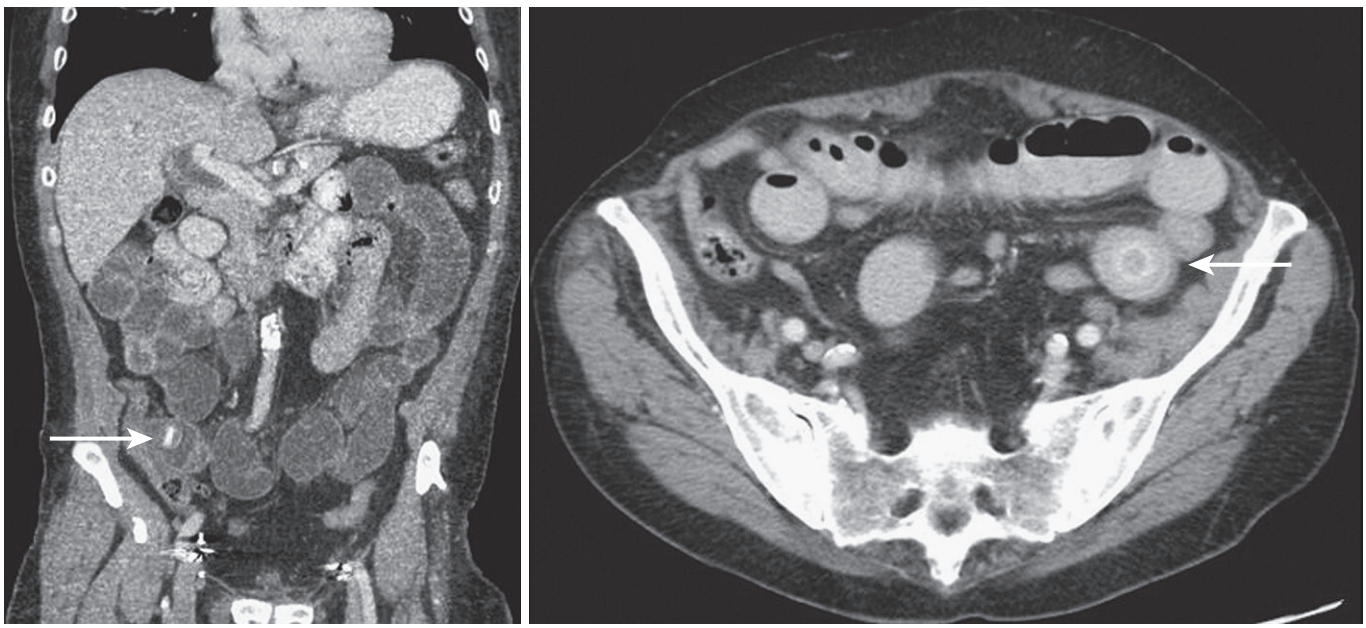

FIGURE 1 Coronal and axial images from a computed tomographic scan of the abdomen demonstrating gallstone ileus, with the gallstones (*arrows*) in the small bowel (photo shows two separate patients).

The management of duodenal or colonic obstruction is controversial. These cases are so unusual that there is little consensus as to proper management. Duodenal obstruction is problematic as the obstructing stone is often intimately associated with the inflammatory gallbladder process and may require taking down the fistula as well as making an extension of the duodenal fistula or a separate duodenotomy. If the area is extremely inflamed or there is an abscess, this is truly a formidable issue. Colonic obstruction is most common in the sigmoid, and several approaches have been described, including milking the stone back into the proximal colon with extraction and transverse colostomy formation as well as sigmoid resection and colostomy formation.

Performing a concomitant and definitive biliary procedure at the same time as management of the bowel obstruction (a "one-stage" operation) has been associated with significantly higher mortality rates in several review studies supporting enterolithotomy alone, and it remains controversial. Significant pericholecystic inflammation, fibrosis, and distortion of the normal biliary anatomic landmarks, duodenal fibrosis, and the presence of a fistula often complicate cholecystectomy in this process, and bile duct injuries have been sustained in this setting. Many of the fistulas (up to 80%) appear to close spontaneously, especially in the absence of residual cholecystolithiasis. It is rare that the management of the biliary process is emergent and must be done at the same operation as the enterolithotomy. It is unclear as to how many patients will have symptoms of biliary colic or symptoms from a persistent cholecystenteric fistula since many of these patients are older and have a limited life span. Many surgeons now opt to forgo a one-stage operation and instead offer interval cholecystectomy to patients who have persistent symptoms. The published experience with laparoscopic cholecystectomy as a staged second procedure after enterolithotomy for gallstone ileus is not large enough to determine how often a subsequent laparoscopic cholecystectomy may be performed instead of an open cholecystectomy (Figure 2).

Cholecystectomy at the time of enterolithotomy should be a careful and deliberated decision. Important considerations focus initially on the stability of the patient during the operation. Proceeding to cholecystectomy should not be done if the patient has any hemodynamic instability, poor urine output, hypothermia, significant uncorrected metabolic abnormalities, or unstable medical conditions. If the patient is stable and it is safe to add a significant amount of additional operative time, then a careful inspection of the right upper quadrant may be done. The amount of acute and chronic inflammation, edema, and anatomic distortion should be carefully assessed. Drainage should be the only procedure in the unusual situation when there is gross purulence. Cholecystostomy may be considered as part of the drainage procedure. Cholecystectomy and division of the enteric fistula is best done if the tissues have mature adhesions without significant edema and friability. The patient who has no pneumobilia on good preoperative imaging may indicate that the fistula has closed since the passage of the gallstone, and this may sway the surgeon to delay cholecystectomy. There is no consensus on the technical performance of the cholecystectomy as to a "dome down" versus an "infundibulum up" technique. Liberal use of intraoperative cholangiography should be pursued for two reasons: (1) there are a significant number of patients who will have common duct stone, and (2) it is useful in delineating the anatomy in a distorted field to avoid common duct injury. The experience of the operating surgeon in managing difficult open cholecystectomies should be an important judgment. If the surgeon has little experience in difficult open cholecystectomy, then the cholecystectomy should not be performed and the patient should be referred to a specialized hepatobiliary center for consideration of cholecystectomy at a later time.

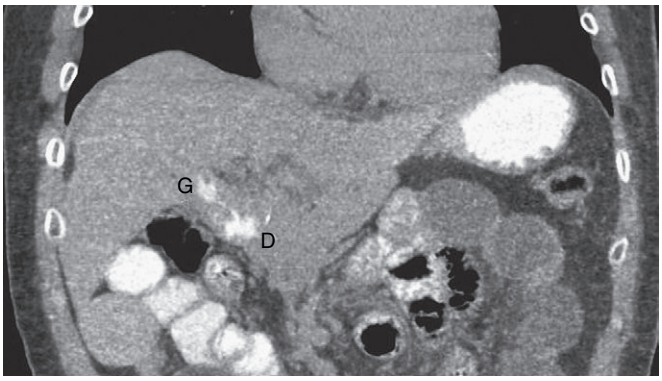

FIGURE 2 Coronal image of a computed tomographic scan of the abdomen showing cholecystoduodenal fistula. The oral contrast from the duodenum (*D*) has filled the gallbladder (*G*) through the fistula.

The number of reports of laparoscopic approaches to managing gallstone ileus is increasing. Gaining safe laparoscopic entry to the abdominal cavity in the presence of distended loops of bowel can be fraught with difficulty, and open trocar placement is recommended to minimize the chance of injury to viscera. Just as in laparoscopic management of any small bowel obstruction, there may not be sufficient space to manipulate and run the bowel. The presence of hugely distended or edematous bowel loops may be a relative contraindication to use of laparoscopy. Two approaches are (1) laparoscopy with identification of the obstructing stone and exteriorization of the segment and extracorporeal management of the enterolithotomy and return of the repaired bowel segment to the abdomen, and (2) laparoscopy with intracorporeal enterotomy and stone extraction with intracorporeal repair of the enterotomy. The benefits of minimally invasive enterolithotomy to reduce morbidity or mortality have not yet been proven, but the technique seems attractive, especially in this patient population where mortality and morbidity have been reported to be between 10% and 30%.

Nonsurgical means of managing gallstone ileus have been described in highly selected cases. Lithotripsy of stones has been successful in a very small number of cases. This has been coupled with endoscopic fragment retrieval after electrohydraulic or extracorporeal lithotripsy. Upper endoscopy can be used for therapeutic maneuvers to remove proximal gallstones and to diagnose biliary proximal alimentary fistulas. Single-balloon enteroscopy, double-balloon enteroscopy, and colonoscopy are also described as successful endoscopic approaches to gallstone ileus.

Obstructive Jaundice: Endoscopic Therapy

Reem Zeyad Sharaiha, MD, MSc, and Zhiping Li, MD

INTRODUCTION

Obstructive jaundice is caused by an interruption of bile flow through the biliary system. It can be the result of extrinsic compression or intrinsic obstruction and can be further divided into neoplastic and benign causes. Cholelithiasis and pancreatic cancer are the most common benign and neoplastic causes of jaundice, respectively, and comprise 40% of total cases. Other causes are listed in Table 1. Jaundice can be diagnosed on examination, based on the yellowness of the skin or the icterus of the cornea. (Total bilirubin levels of 4 mg/dL and above can be detected clinically). Biochemical liver function tests show an elevation in the direct bilirubin, alkaline phosphatase (ALP), and γ-glutamyltransferase (GGT) values and to a lesser degree, aspartate transferase (AST) and alanine transferase (ALT) values. Noninvasive imaging studies, such as transabdominal ultrasound scan (US), computed tomographic (CT) scan, and magnetic resonance cholangiopancreatography (MRCP) are common diagnostic modalities for the underlying cause of jaundice. Endoscopic studies, such as endoscopic ultrasound (EUS) and endoscopic retrograde cholangiopancreatography (ERCP), can be used for both diagnostic and therapeutic reasons.

Obstructive jaundice used to be mainly treated with surgical interventions or percutaneous transhepatic cholangiography (PTC) drainage. Endoscopic therapies have become a major component for management of obstructive jaundice. In many cases, it has become first-line therapy. This chapter focuses on the current standard of endoscopic therapy of obstructive jaundice.

ENDOSCOPIC THERAPIES FOR OBSTRUCTIVE JAUNDICE

Endoscopic Retrograde Cholangiopancreatography

ERCP was first introduced in 1968. It has quickly evolved from a purely diagnostic procedure to a mainly therapeutic one. Once the biliary system is accessed either directly through the papilla or, if the papilla is obscured, through EUS-guided needle puncture, both plastic and metal stents are used for endoscopic drainage. The advantage of a plastic biliary stent is the low cost and the large varieties of sizes available. However, plastic stents can be only used in the short term because they can occlude within 2 to 3 months from a small lumen (<3 mm). Recently, a plastic stent with a concept of drainage via enhanced surface area but without lumen (Wing stent) has provided a longer patency. Plastic stents can be removed endoscopically and reinserted as needed. Metal stents have the advantage of a large diameter (8-mm to 11-mm) lumen, longer patency, and an easier deployment option, but they are more expensive. Metal stents come in three different types: fully covered, uncovered, and partially covered. Uncovered and partially covered metal stents are permanent once they are deployed inside bile ducts. They are mostly used in malignant conditions when the life expectancy is greater than 6 months. The advent of fully covered metal stents has changed the paradigm for management of biliary strictures because they can be removed. The fully covered metal stents are now widely used in the setting of benign strictures.

The overall complication rate of ERCP ranges from 4% to 15%. The most common complication is pancreatitis, which occurs between 1.8% and 10%. Pancreatitis can be prevented with inserting a prophylactic pancreatic stent and giving 100 mg rectal indomethacin after the procedure, as shown in a recent randomized trial, especially for individuals at high risk. Risk factors for pancreatitis include female gender, young age, sphincter of Oddi dysfunction, difficult cannulation, pancreatic duct injection, precut sphincterotomy, and low endoscopic volume. Other complications include bleeding and perforation, especially after sphincterotomy, at rate of 1% to 2%. Most ERCP complications can be managed conservatively. Rarely do patients need surgical intervention.

Cholangioscopy

These miniature endoscopes and catheters permit direct visualization of bile ducts. They can access bile ducts directly (direct cholangioscopy) or are passed through the working channel of a duodenoscope during ERCP (mother and daughter scopes). The numerous indications for the use of cholangioscopy include evaluation of indeterminate biliary strictures, treatment of difficult bile duct stones, selective cannulation of obstructed bile ducts, and assessment of extent of cholangiocarcinoma. Multiple procedures can be performed during cholangioscopy, targeted biopsies of bile duct lesions can be obtained, and bile duct stones can be fragmented with electrohydraulic or laser lithotripsy probes that are applied directly to the stones. In patients with indeterminate strictures, cholangioscopy may lead to direct inspection of the epithelium to obtain biopsies. The sensitivity of conventional brush cytology and biopsy during ERCP for detection of malignancy in most series ranges from 30% to 50%. In prospective single-center case series, cholangioscopic visualization with or without biopsy was shown to have a sensitivity of 89% to 100% and a specificity of 79% to 96% for detection of biliary malignancy.

Endoscopic Ultrasound

The role of EUS in management of obstructive jaundice has evolved from staging and sampling tumors to accessing bile ducts. When an ERCP fails to cannulate bile ducts because of obstruction or variant anatomy, the biliary access can be achieved with EUS-guided bile duct puncture and cholangiogram. Then, it can be followed by either guidewire advancement for rendezvous ERCP in patients with duodenoscope-accessible papilla or direct drainage in patients with altered anatomy. Once access to the biliary tract is achieved via EUS techniques, the remainder of the procedure is very similar to ERCP. A plastic or a metal stent is left for drainage. In one study, EUS-guided cholangiography and EUS-guided rendezvous ERCP were successful in 97% and 75% of biliary procedures, respectively, that were failed previous standard ERCPs.

BENIGN BILIARY OBSTRUCTION

Choledocholithiasis

Gallstones are common and affect 5% of the population. Approximately 15% to 20% of cases eventually become symptomatic. Among those patients with symptomatic gallstone conditions, 15% have choledocholithiasis, which can result in obstructive jaundice and cholangitis. Choledocholithiasis can be diagnosed in several ways. MRCP has a sensitivity of 90%, similar to ERCP. MRCP has largely replaced

TABLE 1: Causes of obstructive jaundice

Benign	Choledocholithiasis
	Postsurgical stricture
	Pancreatitis
	Primary sclerosing cholangitis
	Primary biliary cirrhosis
	Parasites
Malignant	Pancreatic cancer
	Cholangiocarcinoma
	Ampullary cancer
	Gastric cancer
	Hepatoma
	Metastatic disease

ERCP as the method of choice for diagnosing choledocholithiasis. CT scan and abdominal ultrasound scan have similar sensitivities of 50% with nondilated ducts and 75% with dilated ducts. EUS is much more sensitive than any other modalities for stones that are less than 5 mm.

ERCP is indicated if choledocholithiasis is found on imaging, especially if cholangitis is present. During ERCP, biliary stones are removed with extractor balloon and basket after a biliary sphincterotomy. Baskets, especially lithotripsy baskets, are preferred for large stones (>1 cm). With extraction of the stones with a basket, stones should be removed one at a time, from the distal to proximal bile duct, to avoid impaction of the basket in the ampulla of Vater. With baskets that are compatible with an external lithotripsy system, basket impaction should also be avoided. Sphincteroplasty (balloon dilation of the sphincter) can be done to remove large stones, but only after a biliary sphincterotomy has been performed because it increases the rate of post-ERCP pancreatitis. Mechanical, electrohydraulic, or laser lithotripsies are used to breakdown large stones. The success rate of mechanical lithotripsy is 70% to 80%, and the factors associated with failure are the size of the stone (>30 mm), impaction of the stone at the bile duct, a ratio of stone to bile duct diameter greater than 1, and the type of lithotripter used. Electrohydraulic lithotripsy (EHL), laser-induced shockwave lithotripsy, and extracorporeal shockwave lithotripsy can be used for pulverizing stones. Cholangioscopy has increased the success of electrohydraulic and laser-induced shockwave lithotripsy. EHL can only be used with direct visualization with cholangioscopy to avoid ductal injury. In several retrospective series, clearance of difficult stones that have failed conventional ERCP treatments occurred in 90% to 100% of patients after one or two EHL sessions. The main risk of EHL is perforation, which has an overall risk of less than 1%. This occurs because of extreme elevation of the surface temperature of the stone and surrounding ductal tissues, which is usually caused by prolonged application of EHL. Bleeding can also occur. An alternative treatment is pulsed laser lithotripsy, which has success rates of 83% to 100% in removal of stones and clearing of bile ducts. A plastic stent is often left in situ if the duct is not clear of stones or until interval cholecystectomy is performed.

Postsurgical Complications

Biliary tract complications are an important cause of morbidity and mortality after liver transplants and laparoscopic cholecystectomy. The two main complications are biliary strictures and bile leaks. The incidence rate of these complications is very low (<2%) for postlaparoscopic cholecystectomy, but can reach between 10% and 25% after transplant. Risk factors include placement of T-tubes, acute hepatic artery thrombosis, hepatic artery stenosis, ischemia or reperfusion injury, technical factors during surgery (excessive dissection of periductal tissue during procurement, excessive use of electrocautery for biliary duct bleeding, and tension of the duct anastomosis), small caliber of the bile duct and mismatched size between donor and recipient bile ducts, prolonged cold and warm ischemia times, and primary sclerosing cholangitis. Initial evaluation should begin with Doppler ultrasound scan, followed by MRCP, which has a sensitivity of 96% and a specificity of 94% for diagnosing of postsurgical biliary complications.

Postsurgical Bile Leaks

Iatrogenic injury to the biliary tree after laparoscopic cholecystectomy occurs at a rate of 0.6%. Significant postoperative bile leaks occur in approximately 0.8% to 1.1% of patients. Patients with bile leaks usually present within the first postoperative week, with persistent bile discharge from an operatively placed drain or T-tube tract, symptoms of pain and fever, or abnormal liver function test results. Bile leaks may occur from the cystic stump or from transection of an anomalous duct that most commonly originate from the right hepatic lobe (ducts of Luschka, or subvesical ducts). Bile leak can be confirmed with measurement of bilirubin in the drainage.

Endoscopic cholangiography can delineate the site of the leak in more than 95% of patients. This is usually achieved with an occlusion cholangiogram. After a balloon catheter is inserted and inflated to the size of the duct, contrast is injected. The cholangiographic magnitude of contrast extravasation represents the size of the leak. Endoscopic therapy is successful in about 90% of patients with a postcholecystectomy biliary leak. The goal of endoscopic therapy is to decrease the transpapillary pressure gradient, leading to preferential transpapillary bile flow rather than extravasation at the site of the leak. The larger caliber plastic stent, or a fully covered metal stent used in about 10% of cases, is usually left in place for 4 to 8 weeks. If a percutaneous drain is in place, the drainage should be less than 10 mL per day before removal of the stent. A repeat ERCP at the time of stent removal should be performed to determine whether the leak is still present.

Bile leaks after liver transplant are thought to occur in 2% to 25% of patients. Leakage is thought to occur most commonly from the anastomotic site, from the cystic duct stump, from the surface of the liver (if living donor), or from the T-tube tract. Leaks can be diagnosed from the presence of bile from a drain or, if none are present, from MRCP or ERCP. Great caution should be taken with an occlusion cholangiogram in patients immediately after liver transplant (<7 days) to avoid overfilling and disrupting biliary anastomosis. The presence of a bile leak is an independent risk factor for the development of early or late strictures, and hepatic artery thrombosis, and requires prompt therapy. A biliary sphincterotomy or placement of a plastic stent in the common bile duct is successful in treating 90% to 95% of post–liver transplant bile leaks. Stents are preferred to be left in longer because of delayed healing from immunosuppression. Surgery or a percutaneous transhepatic approach is reserved for patients in whom the endoscopic approach is unsuccessful. Large bilomas that do not communicate with the bile ducts should be treated with percutaneous drainage and antibiotics.

Postsurgical Strictures

Postsurgical strictures are the most common cause of benign biliary strictures. Postlaparoscopic cholecystectomy is the culprit for more than 80% of these. Bile duct strictures also occur between 4% and 16% of cases after liver transplant. Early strictures are usually the result of technical problems with the operation, whereas late strictures are the result of ischemia and vascular insufficiency. Bile leak is an independent risk factor for the development of anastomotic strictures. Strictures are classified as anastomotic or nonanastomotic,

depending on the stricture site. Most anastomotic strictures occur within the first year after liver transplant. The treatment of choice is serial endoscopic dilation and stenting. Response is usually seen by 3 months. However, an 18% rate of recurrence was shown in one study. Serial stenting with increasing diameter is usually done to prevent stent occlusion and cholangitis. Recently, a shift has been seen from the use of multiple plastic stents to fully covered metal stents that have a larger diameter, which reduces the number of reinterventions. Resolution of strictures occurs in 96% of cases; the rest require percutaneous treatment or surgical revision. Nonanastomotic strictures result mainly from ischemia. Less commonly, they can be from recurrence of the underlying disease, such as primary sclerosing cholangitis. Strictures occur anywhere from the hilum to the intrahepatic ducts and cause a beading appearance similar to primary sclerosing cholangitis. Sludge can develop proximal to the stricture and lead to recurrent episodes of cholangitis. Endoscopic treatment is the same, with a sphincterotomy, dilation, and large-caliber stent insertion. Time to response is longer, with a median time of 12 to 16 weeks versus 6 weeks for anastomotic strictures. Resolution of strictures is more problematic because only 50% have resolution and many patients may need retransplantation.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a chronic disorder characterized by inflammation, fibrosis, and strictures of the intrahepatic and extrahepatic biliary tree. Ninety percent of those cases have underlying inflammatory bowel disease (mostly ulcerative colitis). Long-term complications of PSC include cholestasis, cholangitis, stricture formation, and eventually cirrhosis and hepatic failure. A high incidence of cholangiocarcinoma is found among patients with PSC. The diagnosis of PSC is established with the demonstration of characteristic multifocal stricture and dilation of intrahepatic or extrahepatic bile ducts on cholangiography. The biliary strictures may be focal, with normal intervening areas, or diffuse, with involvement of a long segment. Strictures can occur in any part of the biliary tree. MRCP has been proven to have the same sensitivity and specificity as ERCP for diagnosis of PSC.

Up to 60% of patients with PSC have development of a dominant stricture, defined as a stenosis with a diameter of 1.5 mm or less in the common bile duct or 1 mm or less in the hepatic ducts. Studies have shown reduced survival in patients with dominant strictures, and endoscopic therapies to relieve dominant strictures improve survival and slow disease progression. Endoscopic therapies include balloon dilation of the stricture with or without placement of plastic stents across strictures. Cholangioscopy can be used to selectively cannulate stricture bile ducts. Serial dilation is performed with fluoroscopy with high-pressure dilation balloons to match the downstream duct diameter. The patients should receive antibiotics before and after endoscopic therapies. The only definitive cure for PSC is liver transplantation. A small portion of patients have recurrence after the liver transplant.

MALIGNANT OBSTRUCTION

Endoscopic therapies are used in the setting of malignant biliary obstruction, either as a bridge to surgery or, in patients with unresectable disease, for palliation. They are mainly for patients with extrahepatic strictures and have limited impact in intrahepatic obstructions. The most common distal biliary malignant obstruction is from pancreatic cancer. In patients who are deemed potential surgical candidates, placement of distal pancreatic or short expandable fully covered metal stents do not interfere with subsequent surgery. The aim of biliary drainage is to relieve jaundice and prevent complications from cholestasis. Stents are also used in the setting of neoadjuvant therapy for locally advanced disease. Metal stents have been shown to be the treatment of choice.

In patients in whom access to the papilla is not possible, direct access to the bile duct via endoscopic ultrasound–guided puncture can be performed. A metallic or plastic stent is inserted to form either a hepatogastrostomy or a choledochoduodenostomy, depending on the site of puncture. These procedures have an overall success rate of 92% but are limited by complications that include biliary leak, pneumoperitoneum, and infection. Many studies have showed no difference in mortality between palliative surgery and endoscopic drainage groups.

Hilar obstruction may result from cholangiocarcinoma (Klatskin's tumor), gallbladder carcinoma, metastatic cancer, or compression from lymph nodes. Endoscopic biliary drainage is the preferred method for relief of biliary obstruction. When both hepatic ducts are occluded, the goal of endoscopic therapy is to place bilateral stents into the left and right common hepatic ducts. If bilateral stenting cannot be achieved, then unilateral stenting of the most dilated duct is performed. Cholangioscopy can be used to selectively cannulate the obstructive bile duct with a guidewire followed by balloon dilation and stent placement. Plastic biliary stents are commonly used as the initial endoscopic treatment because they are inexpensive and effective and can be easily removed or exchanged. Plastic stents, however, easily develop occlusion from sludge or tumor and require repeat ERCPs for stent exchange. Metal stents were introduced to help alleviate this problem by extending the duration of stent patency. Limitations of metal stents are the cost per procedure.

Endoscopic tumor ablations, such as photodynamic therapy or radiofrequency ablation, are also options for management of malignant biliary obstruction. Prospective randomized controlled trials have shown that photodynamic therapy in combination with stenting resulted in prolonged median survival and significantly improved performance status compared with stenting alone. Recently, endoscopic radiofrequency ablation of cholangiocarcinoma has also been tested as a palliative treatment modality.

The Pancreas

Acute Pancreatitis

Nakul Valsangkar, MD, and
Sarah P. Thayer, MD, PhD

Acute pancreatitis accounts for 300,000 hospitalizations per year in the United States. The cause of 90% of cases can be attributed to alcohol and gallstones. Other causes include hyperlipidemia, hypercalcemia, trauma, heredity, drugs, and iatrogenic complications from procedures such as endoscopic retrograde cholangiopancreatography (ERCP). When a cause cannot be identified, the disease is termed *idiopathic* (Box 1).

The clinical manifestations of pancreatitis can be very broad, from mild to severe. The most common manifestation of acute pancreatitis is mild, with epigastric pain associated with nausea and vomiting, minimal organ dysfunction, and no parenchymal necrosis, and it usually has a self-limiting course. For approximately 15% of patients, however, pancreatitis can be severe and life-threatening. These cases of severe acute pancreatitis (SAP) are associated with organ failure involving the cardiovascular, renal, and/or respiratory systems. SAP is generally divided into two phases. The first phase is associated with the inflammatory response of the host as a result of tissue injury, which lasts approximately 1 week. During this time, the pancreatic edema and multiple-organ failure resolve or advance to peripancreatic ischemia and necrosis. The second phase, which can last weeks to months, is associated with this necrotizing process, and mortality in this case is usually associated with secondary infection.

The initial goal of assessment is to determine the cause, remove any ongoing stimulus that may continue to fuel pancreatitis (drugs, hyperlipidemia, or choledocholithiasis), and identify which patients will progress to SAP. The patient's history should focus on identifying the cause. Directed questions should concern history of alcohol consumption, cholelithiasis, hyperlipidemia, history of prior pancreatitis, and medications. It is important to obtain the ages and number of family members afflicted with AP. During physical examination, it is important to assess vital signs, oxygen saturation, and urine output. Depressed mentation, tachycardia, tachypnea, and low oxygen saturation are concerning signs of SAP. Abdominal examination usually reveals upper abdominal tenderness, particularly in the epigastrium. Affected patients may have peritonitis. Initial laboratory evaluation should include complete blood cell count and measurements of amylase, lipase, liver enzymes (alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, total and direct bilirubin), electrolytes (including ionized calcium), and the ratio of blood urea nitrogen (BUN) to creatinine. If oxygen saturations are found to be low, arterial blood gases should be measured. Ultrasonography should be considered when there is suspicion of choledocholithiasis, inasmuch as therapy is directed at early extraction. Early imaging by computed tomographic (CT) scanning is usually not needed if the diagnosis is clear; however, many physicians obtain a CT scan to exclude other diagnoses because many affected patients present with a toxic appearance, fever, peritonitis, and an elevated white blood cell (WBC) count. The initial management of patients with acute pancreatitis is to establish nothing by mouth (NPO) status and provide ample intravenous fluid hydration and pain control. Prophylactic antibiotics are no longer recommended and are used only in the setting of documented infection. It is important to identify patients who are likely to progress to more severe forms of pancreatitis. Several biochemical and imaging scoring systems have been developed to predict which patients are at greatest risk.

ASSESSMENT OF SEVERITY

Many scoring systems have been used to predict mortality in acute pancreatitis (Table 1). The first of these, Ranson's criteria, initially published in 1974, has been used worldwide as the standard in predicting outcome. This historical score is based on parameters (see Table 1) at hospital admission and at 48 hours to predict the likelihood of progression to SAP and overall mortality. The Ranson's score requires 48 hours of observation, which makes difficult the early identification of patients who are likely to have systemic complications and necrosis. The modified Glasgow or Imrie scoring system, like Ranson's, is based on biochemical factors such as age, WBC count, serum lactate dehydrogenase level, and blood glucose level, but the advantage is that it provides a complete assessment at the time of hospital admission (see Table 1). A significantly more detailed system, the Acute Physiology and Chronic Health Evaluation II (APACHE II) scoring system, has also been used. In spite of the complexity of APACHE II, numerous Web-based calculators make it possible to institute it routinely, such as the one at MDCalc. A published set of criteria is the bedside index for severity in acute pancreatitis (BISAP). Five simple clinical parameters (BUN, impaired mental status, systemic inflammatory response syndrome [SIRS], age, and pleural effusion) are used to obtain the BISAP score and thereby stratify patients within the first 24 hours of hospitalization into distinct groups by degree of risk for in-hospital mortality.

In addition to clinical scoring systems, there are systems based on imaging. Although contrast medium–enhanced computed tomography (CECT) is the diagnostic modality of choice in evaluating pancreatitis, it is best to wait at least 72 hours because early imaging is inaccurate in identifying necrotizing pancreatitis and grossly underestimates the extent of necrosis (Figure 1, *A* and *B*). Diagnostic yield is significantly better if CT scanning is performed at least 72 hours after the initial presentation. Examples of imaging-based systems are the Balthazaar score, the CT Severity Index (CTSI), and the Mortele score (modified CTSI). In the most recently published of these, the 10-point Mortele score, pancreatic inflammation and necrosis are evaluated with extrapancreatic complications. A score greater than

Idiopathic

6 indicates SAP. These and other scoring systems are outlined in Table 1.

The revision of the Atlanta classification provides comprehensive definitions, in which both early clinical and later image-based scoring systems are used to assess acute pancreatitis. In this classification, clinical criteria are used to initially define pancreatitis into three grades of severity: mild pancreatitis, which is not associated with organ failure or with local or systemic complications; moderate pancreatitis, which includes organ failure that resolves in 48 hours or local or systemic complications without persistent organ failure; and SAP, which is characterized by single- or multiple-organ failure that lasts more than 48 hours.

It also uses an image-based classification system to morphologically classify the pancreas; this is usually used during the second phase of the inflammatory process. This classification specifies four types of pancreatic/peripancreatic collections: (1) interstitial edematous pancreatitis, (2) necrotizing pancreatitis, (3) acute peripancreatic fluid collection, and (4) pancreatic pseudocyst. Of all the assessments, no single system has yet been identified as the best overall predictor of disease severity. In general, clinical scoring systems are usually used initially, and radiologic (morphologic) criteria are used during the later phases of acute pancreatitis because these finding can be used to guide treatment.

COMPLICATIONS OF PANCREATITIS

Pancreatic and peripancreatic fluid collections are present in nearly 60% of the patients with acute pancreatitis; a third of these patients have three or more collections. They resolve spontaneously in half of patients, and intervention is usually not required. If a major duct has been disrupted, the fluid collection will probably give rise to a pseudocyst. These fluid collections contain high amylase levels. The management of pseudocysts is discussed elsewhere in this textbook. Of all patients with pancreatitis, 5% to 7% may progress to pancreatic necrosis, in which the mortality rate is 10%. In this necrotic tissue, secondary infection can develop in 40% to 70% of patients, and the mortality rate can be as high as 50% (Figure 2). Vascular complications among all patients with acute pancreatitis include thrombosis of the splenic vein (19%), superior mesenteric vein (14%), and portal vein (13%) and arterial hemorrhage (5%), which arises most commonly from the splenic artery, followed by the gastroduodenal artery.

MANAGEMENT OF PATIENTS WITH ACUTE PANCREATITIS

Supportive Care

Supportive care forms the cornerstone of the management of patients with acute pancreatitis. Patients are initially made NPO to limit pancreatic stimulation. Supportive measures also include volume replacement, maintaining electrolyte balance, and pain control. Patients can deteriorate rapidly, and it is crucial to closely monitor blood pressure, heart rate, BUN level, creatinine concentration, and urine output. Depending on the level of severity, the patient may be managed in a regular hospital room or in an intensive care setting. Several prospective studies have shown that SIRS, defined as alteration in heart rate, temperature, respiratory rate, and WBC, and if present for 48 hours or longer, is a predictor of pancreatic necrosis, multiple-organ failure, and death. On the basis of these clinical and laboratory markers, patients likely to suffer adverse outcomes must be identified early and transferred to an intensive care unit for specialized monitoring and care.

An admission to the intensive care unit should be considered if the patient has an APACHE II score of 8 or higher, a modified Glasgow score higher than 3 at 24 hours, a Ranson's score higher than 3, or C-reactive protein level higher than 150 mg/L 48 hours after admission, evidence of multiple-organ failure, or the presence of pancreatic necrosis.

Volume Resuscitation

Hemodynamic monitoring and fluid replacement are among the most important initial interventions in these patients because of a large volume (≈10 L) of fluid sequestration, and increased vascular permeability in the pancreatic microcirculation. Worsening hemoconcentration 24 hours after hospital admission in these patients has been associated with a higher likelihood of developing pancreatic necrosis and multiple-organ failure. For replacement solutions, crystalloids such as normal saline or Ringer's lactate are preferred over colloids unless specifically indicated. Volume replacement can be titrated to a urine output of 0.5 mL/kg body weight/hour or higher after initial high-volume resuscitation.

Metabolic Imbalance in Acute Pancreatitis

Several electrolyte and metabolic abnormalities are common in acute pancreatitis. These include hyperglycemia, hypertriglyceridemia, hypoalbuminemia, hypocalcemia, and hypomagnesemia. Serum triglyceride levels higher than 1000 mg/dL may indicate underlying type I, IV, or V hyperlipoproteinemia as the cause of acute pancreatitis. Management of such patients entails establishing NPO status, restricting lipids if artificial nutrition is being provided, and administering lipid-lowering medications such as fibric acid derivatives. Plasmapheresis may be needed in some patients with very high levels

TABLE 1: Scoring systems to predict disease severity and overall outcome in acute pancreatitis

Year	System	Notes
1974	Ranson's criteria	Historical score in which parameters at hospital admission and at 48 hours are used to define mortality Parameters at hospital admission: Age >55 WBC count >16,000/mm^3 Blood glucose level >200 mg/dL Serum LDH level >350 IU/L Serum AST >250 IU/L Ranson severity score: ≥3 is an indication of severe acute pancreatitis Parameters at 48 hours: Fall in hematocrit of >10% Fluid sequestration >6 L Hypocalcemia PaO_2 <60 mm Hg Increase in BUN by >5/dL after intravenous fluid hydration Base deficit >4 mmol/L Disadvantage: Can be read only at 48 h
1984	Modified Glasgow (Imrie scoring)	Parameters: Age >55 PaO_2 <60 mm Hg WBC count > 15,000/mm^3 Calcium level <8 mg/dL LDH level >600 IU/L Blood glucose level >10 mmol/L BUN >16 mmol/L Albumin level <3.2 g/L Modified Glasgow severity score: ≥3 is an indication of severe acute pancreatitis
1989	Acute Physiology and Chronic Health Evaluation II (APACHE II)	ICU-based scoring system to calculate morbidity and mortality Parameters/Chronic health points: Age >45 WBC count <3,000 or >14,900/mL Rectal temperature <36°C or >38.4°C MAP <70 or >109 mm Hg HR <70 or >109 mm Hg RR <12 or >24 bpm pH <7.33 or >7.49 Na^+ concentration <130 or >149 mM K^+ concentration <3.5 or >5.4 mM PO_2 <70 or >200 mm Hg Creatinine concentration <0.6/100 mL or >1.4 mg/100 mL Hct <30% or >45.9% GCS = 15-GCS APACHE severity score: ≥8 is an indication of severe acute pancreatitis Cumbersome to use and very complex; however, in comparison with the Ranson's and Glasgow systems, it can be calculated and recalculated daily
2004	Radiologic scoring: modified CT severity index (CTSI)	Based on contrast enhanced CT scan taken after at least 72 hours This score returns a total score based two grades: a *CT grade* (normal pancreas, 0; edematous pancreas, 1; mild extrapancreatic changes with pancreatic edema, 2; severe extrapancreatic changes and one fluid collection, 3; multiple collections, 4), and a *necrotic grade* (no involvement, 0; less than one third of pancreas involved, 2; one third to half involved, 4; more than half involved, 6) Severe pancreatitis indicated by a total score of >6 points

of serum triglycerides. Serum glucose levels should also be intensively monitored. The presence of hyperglycemia is a marker for poor prognosis and predisposes the patient to secondary infections by impeding neutrophil function. Hyperglycemia is treated with insulin as needed. Also present is hypoalbuminemia in association with hypocalcemia. Although the level of total calcium is low, ionized calcium levels are normal. Because total serum calcium measurements are inaccurate in these patients, ionized calcium levels should be monitored and treated if low.

Analgesia

Patients with acute pancreatitis experience debilitating pain. Patient-controlled analgesia pumps are frequently used. Parenteral narcotics are used, such as meperidine, hydromorphone, fentanyl, and morphine, along with the nonnarcotic buprenorphine. Morphine has been reported to cause a spasm of the sphincter of Oddi; although no definitive evidence for this has been found, some clinicians continue to avoid this narcotic. For pain control, patients can gradually

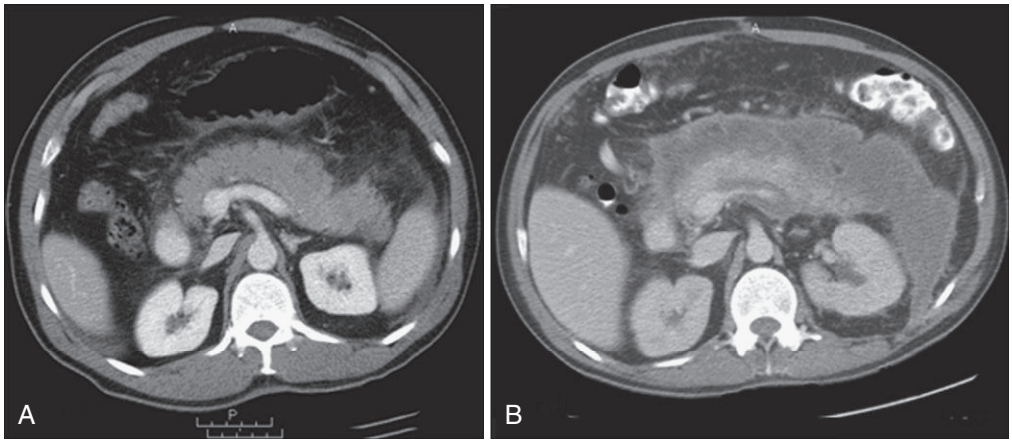

FIGURE 1 Contrast medium–enhanced computed tomographic (CECT) scan. **A,** CECT performed within the first week reveals enhancing pancreas with peripancreatic inflammation and edema with no evidence of necrosis. **B,** Delayed CECT from the same patient shows extensive pancreatic necrosis and perinecrotic fluid collection. These scans illustrate the fact that early imaging may grossly underestimate the extent of the pancreatic necrosis and injury.

be weaned off narcotics and shifted to nonsteroidal antiinflammatory drugs.

Nutrition

In contrast to patients with mild to moderate pancreatitis, in whom withholding enteral intake and bowel rest is one of the mainstays of treatment, patients with SAP require early initiation of nutrition. This has been demonstrated to affect outcome positively. In mild and moderate pancreatitis, patients usually advance to an oral diet within 1 week. In patients with severe pancreatitis, artificial nutrition should be considered early and initiated in the first 48 to 72 hours after hospital admission. For patients with SAP, early initiation of nutrition (<48 hours) is associated with a decreased inflammatory response and has been shown to reduce length of hospital stay, infection (bacteremia, pneumonia, and infected necrosis), multiple-organ failure, need for surgical intervention, and mortality. A randomized controlled trial (International Standard Randomised Controlled Trial Number [ISRCTN] 18170985, "PYTHON"), currently underway, is designed to study whether initiation of very early enteral nutrition (<24 hours) reduces the incidence of infection and overall mortality in patients with SAP.

Enteral nutrition is preferred over total parenteral nutrition (TPN) because it is believed to preserve gut integrity, prevent bacterial translocation, and decrease the incidence of infectious complications of pancreatitis. An additional benefit is that it is more cost effective than TPN. Optimal enteral feeding regimens are rich in medium-chain fatty acids. Formulations enriched with these acids, such as Peptamen AF, are thought to be better tolerated by patients because of their minimal stimulation of the pancreas. In the past, there has been interest in the administration of probiotics in these patients; however, a prospective randomized controlled trial (ISRCTN38327949, "PROPATRIA") has shown patients treated with probiotic prophylaxis to have a higher risk of mortality.

Enteral nutrition can be administered via various routes. Between nasogastric and nasojejunal feeding, nasojejunal tubes are preferred because in theory they provide enteral nutrition but minimally stimulate pancreatic exocrine secretion, and they are tolerated better by patients. However, at least two randomized trials showed no difference between nasogastric and nasojejunal feeding with regard to outcome measures such as time to advancement to oral feedings, C-reactive protein levels, length of hospital stay, and analgesic requirements.

When enteral nutrition is not tolerated by the patient or does not fulfill the nutritional requirements, nutrition must be provided parenterally (TPN). Numerous studies have shown that with TPN, nutritional requirements are easily met with minimal technical and metabolic complications. In patients with severe pancreatitis, complication rates are reduced to one fourth and mortality rates to one third when TPN is initiated within 72 hours of the onset of symptoms. TPN is associated with complications such as hyperglycemia and catheter-related sepsis, however, and for these reasons, it is replaced by enteral feeding as early as tolerable. Finally, TPN may also be combined with low-volume enteral feeding, whereby trophic tube feeds are provided only for the purposes of gut epithelial integrity.

In summary, artificial nutrition is usually needed for patients with SAP. In these patients, the focus must be to provide nutrition by either route (enteral or parenteral) early (<3 days), and this improves overall outcome. As the pancreatitis resolves, attempts must be made to advance the diet back to enteral and then oral feeding.

Antibiotic Prophylaxis

The mortality rate among patients with infected pancreatic necrosis is up to 50%. The use of prophylactic antibiotics to reduce rates of infection and overall mortality has been controversial. However, results of meta-analyses and large multicenter, double-blind, randomized controlled trials suggest that prophylactic antibiotics have no role in the management of these patients. Thus, the use of antibiotics is reserved for patients in whom an infection has been documented.

Endoscopic Retrograde Cholangiopancreatography

ERCP should be considered when choledocholithiasis is suspected. Gallstone obstruction in pancreatitis is suspected when liver enzyme levels are elevated, bilirubin levels are elevated, and the common bile duct is dilated. ERCP is indicated in patients who have acute biliary pancreatitis with cholangitis and retained bile duct stones. Multiple randomized controlled trials have shown that in the subset of patients with severe pancreatitis of biliary origin and ongoing obstruction, there are significant benefits for morbidity and a trend for improved mortality rates when ERCP and biliary sphincterotomy are performed early.

MANAGEMENT OF COMPLICATIONS OF ACUTE PANCREATITIS

Pancreatic and Peripancreatic Fluid Collections

Pancreatitis may be associated with peripancreatic fluid collections in the abdomen in up to 60% of cases. If this is accompanied by signs and symptoms of infection, such as a fever and elevated WBC count that persists beyond 2 weeks, then the fluid may have to be drained and sent for microbiologic examination. If infection is documented, appropriate intravenous antibiotics must be administered. Care must be taken because occasional patients have a complex fluid collection and peripancreatic fluid collection can be diagnosed inappropriately, when in fact these cases represent pancreatic necrosis with perinecrotic fluid collection (see Figure 1, *B*), for which further technical considerations for treatment may be required.

Sterile and Infected Pancreatic Necrosis

Approximately 20% of all patients with pancreatitis develop SAP. Of these, 25% develop necrosis. The necrosis is initially sterile but can be secondarily infected in 40% to 70% of the cases. The mortality rates are 10% to 15% for sterile necrosis and can be as high as 30% to 50% for infected pancreatic necrosis. Pancreatic necrosis can be diagnosed by contrast-enhanced CT scan; the normal CT intensity of the pancreatic parenchyma is 100 to 150 Hounsfield units with intravenous contrast medium, and necrotic pancreas has a significantly lower (<40 Hounsfield units) CT intensity. Because patients with severe pancreatitis clinically appear extremely ill, with fever and an elevated WBC count, it can be challenging to determine whether sterile necrosis has become secondarily infected. CT imaging can be helpful especially when there are obvious signs of infection, such as gas in the necrotic cavity (Figure 3). If there is a question of infected necrosis, however, the patient should undergo CT imaging or ultrasonography-guided percutaneous fine-needle aspiration of the necrosis, followed by Gram stain and culture of the specimen. If the Gram stain is positive, appropriate broad-spectrum intravenous antibiotics should be started. Cultures and sensitivities can be used to narrow antibiotic coverage when available.

FIGURE 3 Contrast medium–enhanced computed tomographic (CECT) scan of the abdomen in a patient with infected necrotizing pancreatitis. The presence of extraluminal gas *(white arrow)* in an area of necrosis is suggestive of infection.

Infection of the pancreatic necrosis is one of the primary indications for intervention. This condition has traditionally been managed with an open necrosectomy along with an adequate drainage procedure. More recently, however, several advances in technique have expanded the potential therapeutic options for débridement. Techniques now include image-guided catheters, endoscopic and laparoscopic drainage, and standard open surgical débridement. Minimally invasive techniques are increasingly used first, with a conservative "step-up" approach, which is now more widely accepted in appropriately selected patients.

In patients with sterile necrosis, the indications for intervention include persistent pain, enteric or biliary obstruction, unresolving signs of SIRS, and persistent unwellness that last for more than 4 weeks. *Persistent unwellness* is a broad term that includes inability to tolerate oral feedings, persistent fever, nausea, vomiting, and hyperamylasemia. Nearly 50% of these patients are ultimately found to have infected necrosis. Infected pancreatic necrosis was traditionally thought to be fatal without mechanical removal of the infected tissue; however, surgeons have tried to avoid surgery and manage initially with percutaneous drainage. The rate of operative mortality for open necrosectomy is 15% for infected necrosis and 4.4% for sterile necrosis.

Regardless of the indications, pancreatic débridement should be delayed until there is a clear demarcation between the devitalized and normal tissues. This delay in intervening allows the necrosis to be organized and makes the intervention technically easier. The technical term currently used for this organized necrosis is *walled-off pancreatic necrosis* (Figure 4). Experience with numerous retrospective studies and at least one controlled trial has shown that waiting for at least 3 to 4 weeks after initial hospital admission is associated with lower rates of mortality than is an intervention carried out in the preceding period. In the only randomized controlled trial in which researchers analyzed the correlation between the timing of pancreatic débridement after onset of symptoms and the outcome, the mortality rates were 58% among patients who underwent early intervention (≤72 hours after onset of symptoms) and 27% among the patients who underwent late intervention (>12 days).

Percutaneous Drainage

Percutaneous drainage may be used to treat complications of pancreatitis. It has been shown to reduce the percentage of patients with necrotizing pancreatitis who need surgery, and it can be used to

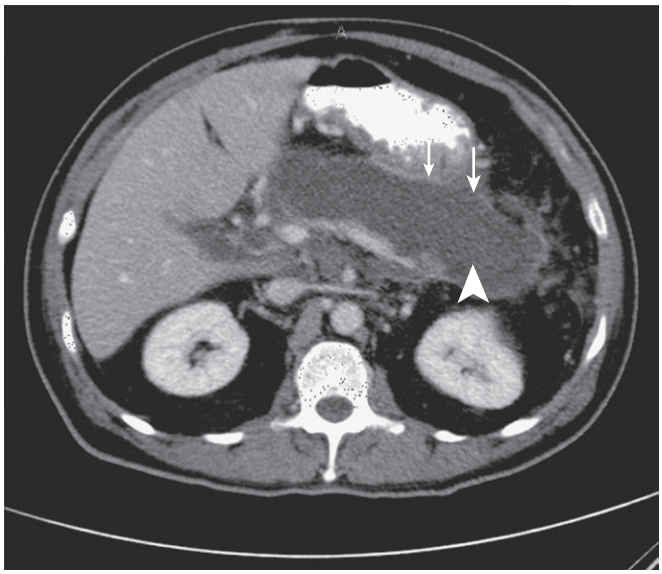

FIGURE 4 Contrast medium–enhanced computed tomographic (CECT) scan of the pancreas demonstrates walled-off pancreatic necrosis. This is a heterogeneous, well-encapsulated *(white arrows)* collection *(white arrowhead)* in the pancreatic and peripancreatic region.

stabilize critically ill patients in the 3-week to 4-week period before definitive surgery. It may be employed as an adjunct to other modalities such as endoscopic débridement. Percutaneous procedures are now part of a broader effort to minimize surgical trauma, and the aim is to reduce the source of infection rather than to evacuate all infected tissue. The "minimally invasive step-up" approach involves, as a first step, percutaneous or endoscopic drainage of infected collections. If there is no clinical response, the next step is minimally invasive retroperitoneal necrosectomy. In a large multiinstitutional randomized controlled trial by the Dutch Pancreatitis Study Group, this minimally invasive step-up approach was compared with open necrosectomy in patients with acute necrotizing pancreatitis (Minimally Invasive Step-Up Approach versus Maximal Necrosectomy in Patients with Acute Necrotising Pancreatitis [PANTER] trial). Preliminary data indicate that among patients with infected necrotizing pancreatitis who underwent the minimally invasive step-up approach, fewer major complications and deaths occurred.

A major drawback of percutaneous drainage is that it is resource intensive. After placement of the drains in the hospital, care includes frequent monitoring of the patient's status and evaluating the efficacy of the drainage. Drains may need to be repositioned or sized upward three or four times. This significantly increases the length of hospital stay. Additional catheters may also be needed. The biggest disadvantages of this technique are that it requires a dedicated and skilled interventional radiology team and that it is not appropriate for all patients. Percutaneous drainage is contraindicated in patients who have a pseudoaneurysm, are actively bleeding, have extensive solid necrosis, or are uncooperative.

Endoscopic Necrosectomy

Because of the high complication rate of open surgical necrosectomy, laparoscopic natural-orifice transluminal endoscopic surgery (NOTES) in the form of endoscopic transgastric or transduodenal necrosectomy offers a safer and minimally invasive technique for an appropriate subset of patients. In this technique, direct endoscopic drainage and necrosectomy are carried out under endoscopic ultrasound guidance.

The advantages of endoscopic transgastric/transduodenal necrosectomy are that it is less invasive, can be used in patients who are poor surgical candidates, and is associated with lower rates of morbidity and mortality. This procedure is most suitable for patients in whom the necrosis involves the lesser sac and in patients with walled-off pancreatic necrosis (WOPN). The disadvantages include a high risk of bleeding, which has been reported to be as high as 30%. Furthermore, some patients—those who have extrapancreatic necrosis, or multiple areas of necrosis that are not walled off, and those in whom the necrosis may extend into the paracolic gutters—are not candidates for this procedure. Patients undergoing endoscopic necrosectomy also have to undergo between two and six procedures for successful treatment, which increases costs significantly.

Endoscopic interventions have been compared directly with surgical interventions. Members of the Dutch pancreatitis study group compared endoscopic transgastric necrosectomy with video-assisted retroperitoneal débridement (VARD) or open necrosectomy for suspected or confirmed infected necrotizing pancreatitis in a randomized controlled trial (Pancreatitis, Endoscopic Transgastric vs. Primary Necrosectomy in Patients With Infected Necrosis [PENGUIN]). Patients were eligible for this trial if they could undergo either type of procedure, on the basis of CT imaging. The results of this study demonstrated that in comparable patients, endoscopic necrosectomy was associated with lower rates of multiple-organ failure, major complications, and mortality.

Videoscopic-Assisted Retroperitoneal Débridement

VARD was originally described as a hybrid between the endoscopic and the open translumbar approaches. In patients with pancreatic necrosis, if infection is suspected or confirmed, a 12F to 14F percutaneous drain is usually placed retroperitoneally. As described previously, a lack of clinical improvement after the placement of the drain leads to the decision of surgical intervention. The VARD surgical procedure involves a 5-cm incision in the left flank. This is followed by necrosectomy, performed with a suction device and grasping forceps under direct visualization, with the preoperative CT images and the previously placed percutaneous drain serving as a guide. After débridement can no longer be performed under direct vision, a long laparoscopic port is placed in the incision, followed by CO_2 inflation of the cavity, and a 0-degree videoscope is introduced. Additional débridement is then performed under videoscopic guidance. After the necrosectomy, irrigation is performed with saline. Two large-bore drains are introduced into the cavity, and continuous lavage is provided with normal saline (10 L/24 hours).

The proponents of this approach suggest that in comparison with pure retroperitoneal endoscopy, the small incision allows a part of the necrosectomy to be carried out under direct visualization with a shorter operative time and fewer numbers of procedures. In comparison with open necrosectomy, VARD is thought to decrease the physiologic stress of surgery to which patients with pancreatic necrosis are exposed.

Laparoscopic Surgical Necrosectomy

Laparoscopic surgical necrosectomy has been used for débridement in various approaches. In the transgastric approach, gastrotomies on the anterior and posterior gastric walls are used to enter the lesser sac. Visible pus is aspirated, and the retroperitoneum is irrigated and lavaged with normal saline. Suction and débridement with nontraumatic forceps are used to perform the necrosectomy. The lesser sac is irrigated after the débridement is complete, and the peritoneal cavity is lavaged before the abdomen is closed. In one series involving laparoscopic pancreatic necrosectomy, the mortality rate among noninfected patients was 10%. A hand-assisted laparoscopic surgical

technique was also described. The surgical approach into the lesser sac was through the transverse mesocolon. The hand was used for enlarging the incision in the transverse mesocolon, while avoiding injury to the middle colic vessels, and the devitalized tissue was débrided by means of gentle finger dissection. After the completion of the débridement, postoperative drainage was provided by closed suction drain. The overall mortality rate was reported to be 11%.

Laparoscopic necrosectomy may be advantageous in carefully selected patients. It offers shorter lengths of stay, earlier postoperative recovery, and earlier return to work than does open surgery. However, laparoscopic necrosectomy has limitations, and patient selection is key to the success of the operation. Depending on the extent of necrosis, only a small subset of patients may be candidates for this approach.

Open Surgical Management of Acute Pancreatitis

Surgical Technique

There are numerous variations in the intraoperative technique and postoperative drainage of patients with acute pancreatitis. Each type of surgical procedure is best suited for a certain case; there are no guidelines or controlled data regarding which surgical procedure must be employed for a given patient. Nevertheless, the preoperative workup and the governing philosophy remain the same.

CECT is used as a guide to determine the location of the necrotic tissue and fluid collections. The incision used for the approach is either midline or subcostal. The lesser sac is approached through the gastrocolic ligament or by the transmesocolic route, depending on the surgeon's preference. In the transmesocolic approach, the preferred entry site into the lesser sac is the avascular region left of the ligament of Treitz (Figure 5, *A*). After the focus of necrosis is exposed, blunt dissection must be carefully performed to remove necrotic tissues that have separated, so as to avoid injury to large vessels in the area. If preoperative imaging suggests fluid collections in the perinephric and paracolic areas, these must also be entered and drained. After dissection, generous irrigation and gentle abrasion with sponge-covered fingertips must be performed. Significant bleeding may occur and must be dealt with via packing or suture ligature as appropriate. During the operation, samples of pancreatic and peripancreatic tissues must also be sent for microbiologic and bacteriologic testing. Methods to provide drainage after necrosectomy are (1) closed packing, (2) open packing, (3) planned staged repeat laparotomies, and (4) continuous lavage of the lesser sac.

Closed Packing

In the technique that is preferred at the Massachusetts General Hospital, the goal is for the initial débridement to be as complete as possible. Every effort is made to find, expose, and débride all foci of necrosis identified on preoperative CECT. The cavities resulting from

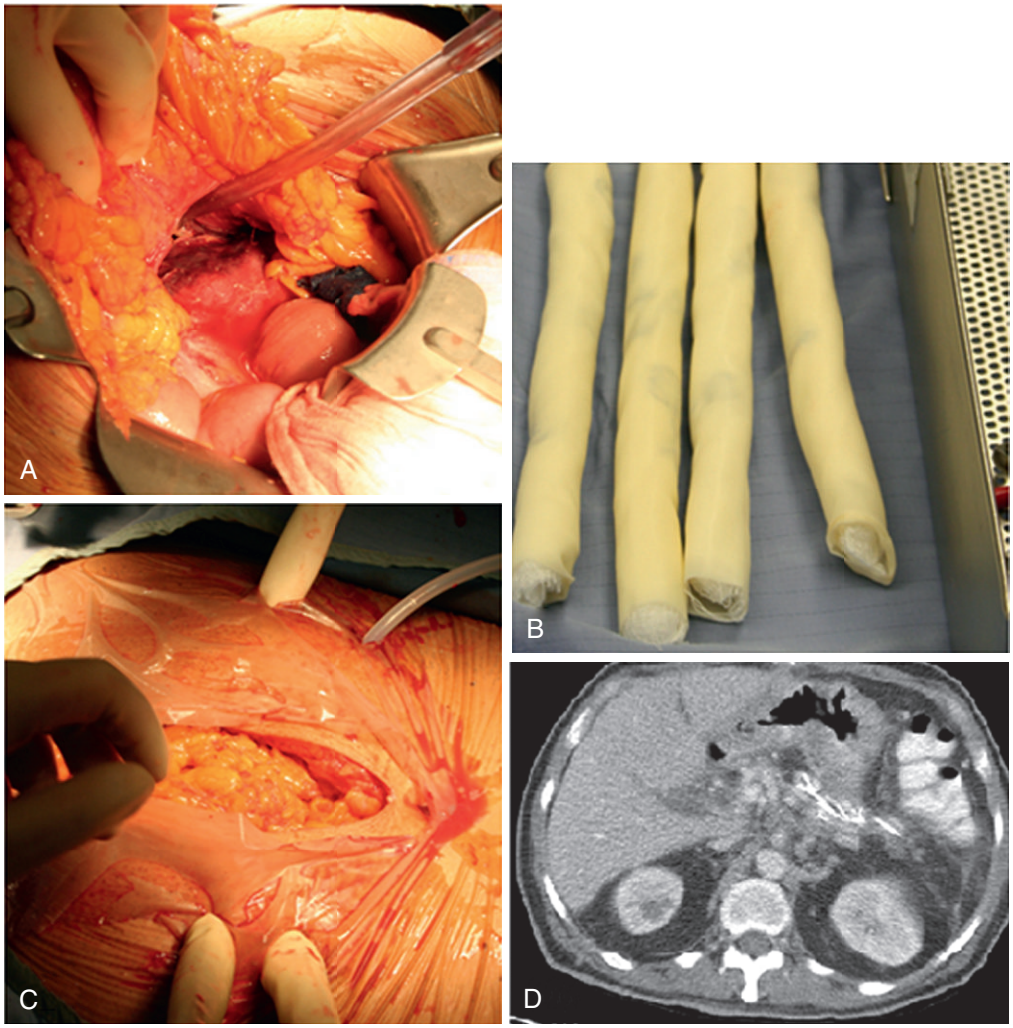

FIGURE 5 Open necrosectomy. **A,** Necrosectomy is performed through the transverse mesocolon. **B,** Multiple stuffed Penrose drains used for closed packing of the necrotic cavity after an open necrosectomy. **C,** The abdomen with stuffed Penrose and closed suction drains in place. **D,** Interval imaging with contrast medium–enhanced computed tomographic (CECT) scan of a patient after pancreatic necrosectomy, demonstrating the presence of the drains in the pancreatic bed and a collapsed necrotic cavity around the drains.

débridement are packed with gauze-stuffed ¾-inch Penrose drains and silicone rubber closed-suction drains (see Figure 5). The gauze-stuffed Penrose drains are removed first to allow the cavities to gradually collapse. The closed-suction drains are removed last, only after the drain output becomes minimal. In studies of this technique for patients with sterile and infected pancreatic necrosis, researchers have reported average postoperative lengths of stay between 27 and 34 days, reoperation rates as low as 15%, and mortality rates as low as 4% to 6%.

Open Packing, Planned Staged Relaparotomies With Repeated Lavage, and Continuous Lavage of Lesser Sac and Retroperitoneum

Certain techniques have been described historically, but these are no longer in widespread use. They are briefly described here. *Open packing* was reserved for patients in whom surgical intervention was necessary early. An overall mortality rate of 73% and procedural morbidity rate of 73% were described for this technique. *Planned staged repeat laparotomies* are associated with significant morbidity. This technique, like open packing, is used primarily when intervention has to be performed early and there is no clear demarcation between healthy and necrotic tissue. According to a published experience of this technique, the overall mortality rate was 17%, major complications included pancreatic fistula (78%) and hemorrhage (26%), and median length of stay in the hospital was 50 days. In addition to staged repeat laparotomies, the problem of leftover infection or necrotic tissue and subsequent intra-abdominal sepsis was previously addressed with continuous lavage of the lesser sac. This technique is not only cumbersome but also associated with increased rates of morbidity and mortality. It is generally accepted that closed packing is superior to open packing and staged repeat laparotomies; it causes less intra-abdominal and systemic trauma to the patient and results in better outcomes.

SUMMARY

Demographics

Pancreatitis causes 300,000 hospital admissions per year. Alcohol and gallstones account for 80% to 90% of all causes. Of all affected patients, 20% progress to SAP. One in four has necrosis, and 40% to 70% acquire infection. The mortality rate among patients with mild pancreatitis is less than 1%, and that among patients with infected necrosis can be as high as 50%.

Severity Assessment

Numerous scoring systems that are based on biochemical and clinical factors may help identify patients likely to develop severe pancreatitis. Imaging-based assessment of severity is usually more helpful during the second phase of pancreatitis.

Intensive Care Unit Admission

It is important to use objective metrics and determine early whether a patient needs to be admitted to the intensive care unit. This results in better outcomes for patients and better utilization of resources.

Supportive Care

Supportive care involves volume replacement, pain control, electrolyte balance, metabolic management, and achievement of euglycemia. No data suggest usefulness of prophylactic antibiotics.

Nutrition

NPO status and bowel rest are adequate for patients with mild pancreatitis. Early initiation of nutrition in patients with moderate and severe pancreatitis improves outcome. Although enteral nutrition is better with regard to gut integrity and has a lower incidence of infectious complications, TPN should be given when needed.

Minimally Invasive Step-Up Approach

In order to minimize the physiologic stress of surgery, the first step in management of infected pancreatic necrosis is percutaneous drainage. A gradual step-up approach is preferred, with minimally invasive and then open necrosectomy utilized successively in patients with no clinical response.

The Management of Gallstone Pancreatitis

Alexandra Briggs, MD, and Stanley W. Ashley, MD

OVERVIEW

Gallstone disease remains one of the most common causes of acute pancreatitis in the United States, accounting for up to 40% to 60% of cases. Although the vast majority of patients have mild or moderate disease, up to 20% have a severe course marked by significant morbidity and mortality. Early determination of disease severity can help guide both medical and surgical management, and prediction systems based on both imaging and clinical data exist to help stratify patients into risk categories. Patients with mild disease should undergo cholecystectomy during the index admission because of a significant risk of recurrent symptoms associated with delayed intervention. In patients considered too high risk for surgical intervention, endoscopic interventions may help prevent recurrent episodes of gallstone pancreatitis. Severe disease requires admission to an ICU and aggressive medical management. In this cohort, some patients may benefit from endoscopic intervention, and cholecystectomy should usually be performed after resolution of the acute episode. The presence of pancreatic fluid collections, pseudocysts, or necrosis can alter the timing of both endoscopic and surgical intervention. This chapter discusses in detail the determination of the severity of disease and both endoscopic and surgical interventions for management.

PRESENTATION AND DIAGNOSIS

Diagnosis of acute pancreatitis according to the Atlanta Classification requires two of the following three criteria: (1) an elevation in the level of serum amylase or lipase to more than three times the upper limit of normal; (2) abdominal pain characteristic of pancreatitis; and (3) characteristic findings of pancreatitis on computed tomographic (CT) scan or other imaging. Typically, patients present with epigastric pain with radiation to the back, which can be accompanied by nausea and vomiting. The severity of the abdominal pain and tenderness on examination can vary widely depending on the extent of disease. Furthermore, in patients with severe disease, early signs of organ failure or systemic inflammatory response syndrome (SIRS) may be apparent even at the time of presentation. A full laboratory panel, including complete blood count (CBC), basic metabolic panel (BMP) with liver function tests (LFTs), and lipase tests, should be obtained. Measurement of serum lipase has been shown to be more sensitive and specific than serum amylase, given that the pancreas is the only source of serum lipase production. In patients with severe symptoms, an arterial blood gas value provides useful information regarding oxygenation and acid-base status. Although CT scan is not required for the workup of patients with acute pancreatitis, it can be helpful in diagnosis and can aid in the prediction of disease severity. Ultrasound scan can also provide useful information as to the etiology of acute pancreatitis with assessment for biliary disease.

Acute pancreatitis can have many potential causes, with alcohol abuse and gallstone disease accounting for most cases in the United States. The diagnosis of gallstone pancreatitis can be made with the confirmation of cholelithiasis, choledocholithiasis or gallbladder sludge with imaging and when other causes have been ruled out. Once a diagnosis has been made, patients should be promptly triaged based on severity of disease to either an inpatient ward or an ICU setting for further treatment.

Determination of Disease Severity

The treatment of gallstone pancreatitis should be guided by the severity of disease, given the disparate courses that the disease can take and the management strategies required. Severe disease occurs in 20% of patients, with significant acid-base disturbances, multiorgan failure, pancreatic necrosis and infection, and an increased mortality rate of up to 30%. Early identification of patients with severe disease allows for prompt intensive treatment and can help predict outcomes and the likelihood of complications. Both clinical and CT scan–based scoring systems exist for predicting severity in acute pancreatitis. A recent study of two clinical and seven CT scan–based scoring systems revealed no difference in the predictive accuracy between the two modalities. No consensus exists as to the best prediction system; however, the clinical scores that can be used in the first 24 hours may provide the most prompt and universally applicable assessment.

The most well-known clinical prediction system is the Ranson score, which is calculated with laboratory values both on admission and after 48 hours. A modified version of the Ranson criteria was developed specifically for biliary pancreatitis, with an initial score greater than 3 predicting severe disease. However, the full predictive value of this system requires the addition of data points 48 hours after admission, at which point the benefits of early identification and management of severe disease may already be lost.

One scoring system that can be used within the first 24 hours of presentation is the Acute Physiology and Chronic Health Evaluation II (APACHE-II) score. This is a complex system calculated with 12 data points that includes laboratory values, age, and mental status and also accounts for significant patient comorbidities. Although published cutoff values for severe pancreatitis vary, an APACHE-II score greater than 5 to 10 can be considered predictive of severe disease. This is a valuable tool, but it does require significant data collection and calculation to obtain.

The development of the Bedside Index for Severity in Acute Pancreatitis (BISAP) score has allowed for the simplified prediction of mortality within the first 24 hours of presentation (Table 1). A score between 0 and 5 is determined with criteria for age, blood urea nitrogen (BUN), presence of pleural effusions on imaging, presence of SIRS, and impaired mental status. BISAP scores of more than 3 correlate with higher rates of patient mortality and increased risk of organ failure, persistent organ failure, and pancreatic necrosis. Multiple validation studies have established the utility of this scoring system, and it may be more easily applied by clinicians given its relative simplicity in comparison with other systems.

Attempts have been made to use individual laboratory tests as predictors in pancreatitis. Although serial hematocrit values have been advocated as a useful marker of hemoconcentration and progression of disease, the sensitivity and specificity of this test has been highly variable in large scale reviews. One recent multicenter study showed that admission BUN value was an accurate marker for predicting mortality, with higher BUN values in nonsurvivors. In addition, it revealed that the odds ratio for mortality increased by 2.2 with each 5 mg/dL increase in BUN level during the first 24 hours. Although debate still exists on the utility of single laboratory studies in predicting disease severity and outcome, these easily measured values can provide additional information for clinicians during treatment.

Multiple scoring systems exist that use findings on CT scan as predictors of disease severity. The CT severity index combines the Balthazar CT scan score, based on the extent of pancreatic inflammation, with a separate point scale for the extent of pancreatic

TABLE 1: Bedside Index for Severity in Acute Pancreatitis (BISAP) score

Blood urea nitrogen (BUN)	>25 mg/dL
Age	>60 y
Impaired mental status	Glasgow Coma Scale (GCS) score <15
Systemic inflammatory response syndrome (SIRS)	Two or more of: Temperature, <36°C or >38°C Respiratory rate, >20 breaths/min; or P_aCO_2, <32 mm Hg Pulse, >90 beats/min White blood cell count, <4000 or >12,000 cells/mm^3 or >10% immature bands
Pleural effusion	Present on imaging

BISAP score ranges from 0 to 5, with 1 point for the presence of each variable within 24 hours of presentation.

TABLE 2: Computed tomographic scan severity index

Pancreatic inflammation		**Points**
Normal pancreas	Grade A	0
Pancreatic enlargement	Grade B	1
Pancreatic with inflammation of peripancreatic fat	Grade C	2
Single peripancreatic fluid collection	Grade D	3
Two or more fluid collections or retroperitoneal air	Grade E	4
Pancreatic necrosis		**Additional points**
None		0
≤30%		2
30%-50%		4
>50%		6

necrosis (Table 2). Severity is subsequently stratified with scores of 0 to 3 for mild disease, 4 to 6 for moderate disease, and 7 to 10 for severe disease. This method has since been modified (Table 3), and the cutoffs adjusted to 0 to 2, 4 to 6, and 8 to 10 for mild, moderate, and severe disease, respectively. The modified system accounts for extrapancreatic complications and also simplifies the stratification of inflammation and necrosis from the initial scoring system. These changes have resulted in improved correlation of severity with clinical parameters such as hospital stay, infection rate, and need for intervention and, unlike the original system, also correlated severity with the development of organ failure. However, not all patients undergo immediate CT scan on presentation; therefore, these systems may not always provide early guidance for patient care.

TABLE 3: Modified computed tomographic scan severity index

	Points
Pancreatic Inflammation	
Normal pancreas	0
Intrinsic pancreatic abnormalities with or without inflammatory changes in peripancreatic fat	2
Pancreatic or peripancreatic fluid collection or peripancreatic fat necrosis	4
Pancreatic Necrosis	
None	0
≤30%	2
>30%	4
Extrapancreatic Complications (One or More)	
Pleural effusion, ascites, vascular complications, parenchymal complications, or gastrointestinal tract involvement	2

Timely determination of disease severity in acute pancreatitis can predict both mortality and complications and facilitate early triage of patients to the best treatment algorithms. Both clinical and CT scan–based scoring systems can be a useful adjunct in patient care, but they still have limitations in their predictive ability. However, careful clinical assessment of the patient on presentation combined with the use of these tools can aid in the appropriate initial course of treatment. Continued and dynamic assessment of patients over the first 24 to 48 hours of treatment can provide additional prognostic information and should guide subsequent therapy.

TREATMENT

Mild Disease

Initial management of mild gallstone pancreatitis involves resuscitation and electrolyte repletion in an inpatient monitored setting. Hydration with intravenous (IV) fluids should be adjusted as needed to maintain urine output (UOP) of 0.5 to 1 mg/kg/h, with boluses given as needed for oliguria or hypotension. Placement of a Foley catheter should be strongly considered for adequate monitoring of UOP and fluid status in patients in whom voids cannot be reliably measured. Electrolyte abnormalities should be corrected and followed with serial laboratory measurements at least daily. In addition, CBC, LFTs, and lipase values should be obtained daily. Additional laboratory tests may be obtained with changes in clinical status. Antibiotic therapy is not indicated in patients with mild disease. Patients should be kept on nothing by mouth (NPO), with serial abdominal examinations performed to follow the degree of abdominal tenderness. If a patient has worsening examination results, hemodynamic instability, or worsening laboratory values or fails to respond to treatment, transfer to the ICU is indicated for more aggressive management.

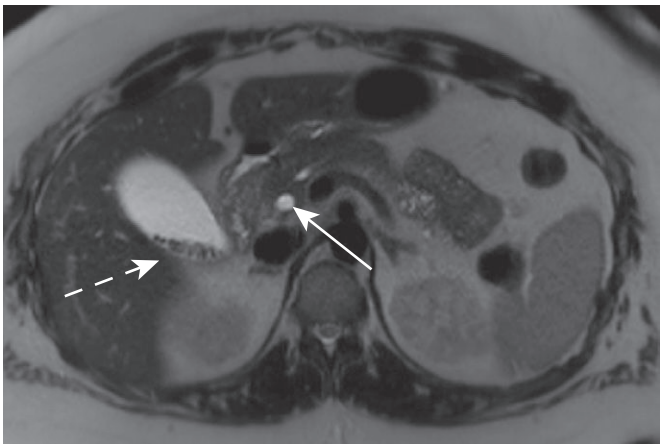

FIGURE 1 Magnetic resonance cholangiopancreatography image shows cholelithiasis *(dashed white arrow)* and a dilated common bile duct *(white arrow)*.

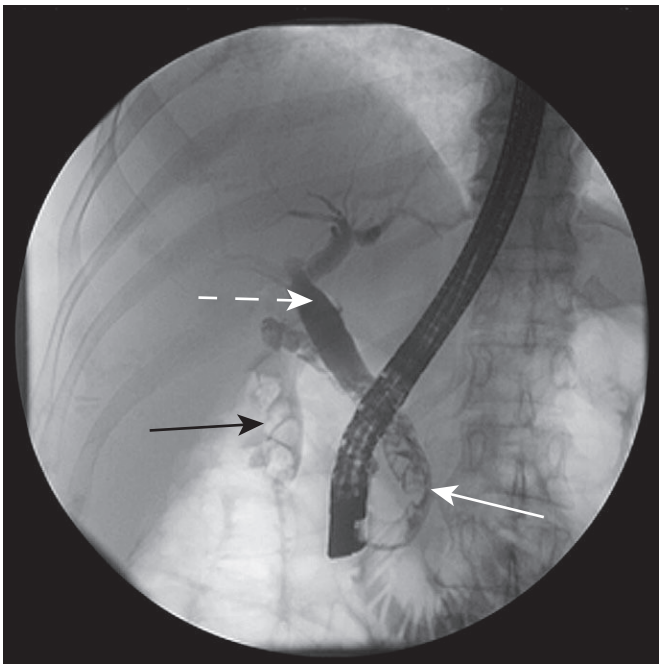

FIGURE 2 Endoscopic retrograde cholangiopancreatography image shows cholelithiasis *(solid black arrow)* and choledocholithiasis *(solid white arrow)* with associated common bile duct dilation *(dashed white arrow)* that requires decompression and stone removal.

Definitive management for mild disease is either laparoscopic or open cholecystectomy during the index hospitalization once the acute symptoms have resolved. Given the well-established advantages of laparoscopy over laparotomy, a minimally invasive approach should be attempted in all suitable cases. Although initially there was much debate regarding the appropriate timing of cholecystectomy, multiple studies have shown an unacceptably high rate of recurrence of both gallstone pancreatitis (as high as 90% in some studies) and other biliary symptoms in patients awaiting interval cholecystectomy after discharge from the hospital. In one systematic review, up to 33% of patients awaiting interval cholecystectomy were readmitted with pancreatitis, biliary colic, or acute cholecystitis. Furthermore, the time to recurrence may be as short as within 2 weeks of discharge for more than one third of patients. Given this evidence, cholecystectomy should be performed during the index admission, once patients are adequately resuscitated and show clinical signs of improvement, including decreased abdominal pain. Both single-institution and nationwide studies in the United States and Europe have shown that compliance with this recommendation remains poor, with many patients discharged from the hospital without cholecystectomy. Steps should be taken to improve adherence to this guideline to prevent disease recurrences and complications.

Choledocholithiasis and Cholangitis

Choledocholithiasis may be suspected in patients with elevated alkaline phosphatase and total bilirubin values on presentation. Although ultrasound scan may reveal an enlarged common bile duct (CBD) or even the presence of CBD stones, its sensitivity is only 40% to 60% for the detection of choledocholithiasis. Magnetic resonance cholangiopancreatography (MRCP) is a more accurate method for the detection of CBD stones and has the advantages of being noninvasive and requiring no nephrotoxic contrast administration. A more invasive but highly sensitive and specific approach is endoscopic ultrasound (EUS). The most invasive approach is endoscopic retrograde cholangiopancreatography (ERCP), but it has the advantage of being both diagnostic and therapeutic (Figures 1 and 2). Stone retrieval can be completed at the time of ERCP, and when indicated, endoscopic sphincterotomy (ES) can also be performed. Approaches to the diagnosis of CBD stones vary among clinicians; there is no established standard for workup of these patients. In patients with mild symptoms, it is reasonable to trend liver function tests and only pursue additional imaging to diagnose CBD stones in those patients with persistently elevated results. If choledocholithiasis is diagnosed before cholecystectomy, ERCP and ES may be performed before surgery, avoiding the need to address the common duct during surgery. If there is failure to retrieve the stones during ERCP, operative bile duct exploration with stone removal can be completed at the time of cholecystectomy. Several studies have suggested that if this can be accomplished laparoscopically, it may be the most cost-effective approach. Intraoperative cholangiography (IOC) can also be performed to confirm the patency of the CBD at the time of cholecystectomy. If filling defects are detected, laparoscopic transcystic duct bile duct exploration or even choledochotomy can be completed to remove visualized stones, but this depends on the skills of the surgeon, which can vary widely. Alternatively, in some cases, postoperative ERCP can be considered for stone retrieval after positive IOC; however, better outcomes have been shown in patients managed via laparoscopic bile duct exploration, and the unusual stone that cannot be removed endoscopically makes many surgeons uncomfortable with this approach.

Although the role of early ERCP in prevention of the evolution of gallstone pancreatitis remains controversial, all patients with evidence of cholangitis on presentation should undergo ERCP and ES. In addition to the characteristic abdominal pain seen on presentation, these patients have fever and jaundice, commonly known as Charcot's triad. More seriously ill patients can exhibit signs of shock and altered mental status in addition to the previous symptoms, a constellation of findings known as Reynold's pentad. Urgent or semi-urgent endoscopic decompression is indicated in most patients with evidence of biliary obstruction on imaging.

Patients at High Risk

In patients with mild disease who cannot safely undergo operative intervention, ERCP/ES can instead be used as a treatment modality. Age alone should not be used as a cutoff for laparoscopic or open cholecystectomy because outcomes in elderly patients without significant comorbidities are acceptable. However, if coexisting medical conditions suggest unacceptable risk to operative intervention in a patient of any age, alternatives should be considered. The use of ERCP and ES has been shown to significantly decrease the likelihood of recurrent biliary events, with published recurrence rates for

gallstone pancreatitis between 0 and 6%, but because of healing of the sphincterotomy, the time interval may be limited; this has not been completely defined. However, although the risk of other biliary complications including colic or acute cholecystitis is lower in these patients than in those undergoing no intervention at all, the recurrence rate remains significant at up to 20%. Cholecystectomy provides the only definitive treatment for gallstone disease, but ERCP/ES can significantly decrease recurrence and is a useful alternative for those patients who cannot safely undergo operative intervention. As with cholecystectomy, this intervention should be completed during the index admission.

Pregnant Patients

Although physiologic changes during pregnancy can predispose women to the formation of gallstones, acute pancreatitis from all causes remains a rare event seen only in every 1 in 1000 to 5000 pregnancies. Initial management of gallstone pancreatitis should be similar to that of nonpregnant patients, with hydration, bowel rest, and careful monitoring. Obstetric consultation should be obtained when appropriate for fetal monitoring. Without definitive intervention during index hospitalization, pregnant patients are also at high risk of symptom recurrence. Laparoscopic cholecystectomy has been shown to be safe during all trimesters of pregnancy and should be pursued in accordance with current guidelines. Placing pregnant patients in the left lateral decubitus position and minimizing the use of reverse Trendelenburg's position can aid in the maintenance of adequate cardiac output, given the aortocaval compression that can occur with a gravid uterus and with insufflation. Additional precautions should be taken to limit the time and extent of insufflation, and entry into the abdomen should be carefully completed to minimize risk of injury to the uterus during the procedure. In patients in whom choledocholithiasis is suspected, MRCP can be safely used to assess the CBD without any radiation exposure to the fetus and to determine whether ERCP is indicated. There have not been large-scale studies of ERCP/ES in pregnancy; however it may be used safely in centers with sufficient experience, with precautions taken to minimize radiation exposure to the fetus. In pregnant patients deemed at high risk for cholecystectomy, ERCP/ES may be a feasible alternative to operative intervention until after delivery.

Severe Disease

Medical Management

Patients with evidence of severe gallstone pancreatitis should be immediately transferred to an ICU for aggressive medical management. Although insertion of a central venous catheter and arterial line are at the discretion of the clinician, they should be placed in critically ill patients for adequate monitoring and to facilitate care. Foley catheters should be inserted in all patients for careful monitoring of urine output. A constant IV fluid maintenance rate should be started, with additional boluses and adjustment as needed. Adequacy of resuscitation can be measured with the careful monitoring of acid-base status and through the maintenance of a mean arterial pressure (MAP) more than 60 mm Hg and urine output of at least 0.5 mg/kg/h. Electrolytes should be closely monitored and repleted because these may become significantly abnormal from both the fluid extravasation secondary to the disease process and the large volume resuscitation. In addition to serial electrolyte monitoring, CBC, LFTs and lipase values should again be followed. In these seriously ill patients, arterial blood gas (ABG) monitoring can provide valuable information regarding resuscitation status and oxygenation.

No role exists for antibiotics in patients with gallstone pancreatitis without proven necrosis. The use of prophylactic antibiotics in patients with necrosis remains controversial, with no clear consensus on whether any reduction results in either morbidity or mortality. Concerns regarding possible fungal infection or antibiotic resistance with the use of prophylactic antibiotics have not been consistently proven, and there is no established role for the use of prophylactic antifungal therapy. A recent Cochrane review of antibiotic use in patients with acute pancreatitis and CT scan evidence of necrosis showed no statistically significant difference in mortality, pancreatic necrosis infection rates, or overall infection rates. However, an association was found between imipenem use specifically and a significant reduction in pancreatic infection rate, with a relative risk of 0.34 (confidence interval, 0.13 to 0.84.) Given these data, imipenem may be considered for use in patients with pancreatic necrosis; however, no adequately powered studies to date have provided definitive evidence of benefit. Antibiotics are indicated if cholangitis is a concern.

The role of nutrition in patients with severe pancreatitis has also been the subject of multiple studies. When possible, enteral administration is preferred to parenteral nutrition because it has been shown to decrease infection rates, organ failure, and operative interventions. Although the data are limited, mortality and length of hospital stay may also be lower in patients receiving enteral nutrition. No definitive evidence exists for whether gastric or jejunal feeding is the best route of enteral administration, although many have postulated that jejunal feeding is preferred to minimize pancreatic stimulation. At this time, there is also no current evidence to differentiate any specific type of diet or supplementation as preferable. If there is evidence of gastrointestinal complications such as severe ileus that preclude enteral feeding, parenteral nutrition should be initiated instead, given the overall benefits of providing nutrition in critically ill patients in a highly catabolic state.

Intervention in Severe Pancreatitis

Most patients in whom severe gallstone pancreatitis develops also require cholecystectomy for definitive management. However, in contrast to mild disease, intervention should be delayed until the acute episode has resolved and inflammation has decreased. Although little data exist, anecdotal experience suggests that the risk of recurrent pancreatitis in a patient with severe necrosis is low. In addition, patients with development of complications such as pseudocysts and fluid collections during the acute episode can be followed and reevaluated before interval cholecystectomy. In some cases, these may resolve spontaneously without additional intervention. However, if pseudocysts or collections are persistent, these can be addressed at the same time as the interval cholecystectomy.

The role of ERCP/ES in patients with severe pancreatitis remains a topic of significant debate. As previously mentioned, ERCP/ES should be performed urgently in patients with cholangitis. However, in patients without biliary obstruction and cholangitis, there may be no benefit to early endoscopic intervention. A recent Cochrane review showed no difference in complications or mortality between patients with gallstone pancreatitis managed medically versus those undergoing early ERCP. Although this review included patients with all levels of disease severity, no clear evidence shows that disease severity has any influence on ERCP outcomes.

Management of Pancreatic Necrosis

Patients with severe pancreatitis are at risk of development of infected pancreatic necrosis, which is associated with significant mortality as a result of sepsis and multiorgan failure (Figure 3). Differentiation between sterile and infected pancreatic necrosis is important because multiple studies have shown that a conservative approach to the management of sterile pancreatic necrosis can be successful. Repeat CT imaging in patients with systemic signs of infection such as fever and leukocytosis can be a useful tool in establishing the presence and extent of necrosis. If infected necrosis is suspected, fine-needle aspiration (FNA) can be used to establish this diagnosis. However, this could also introduce infection to a previously sterile collection.

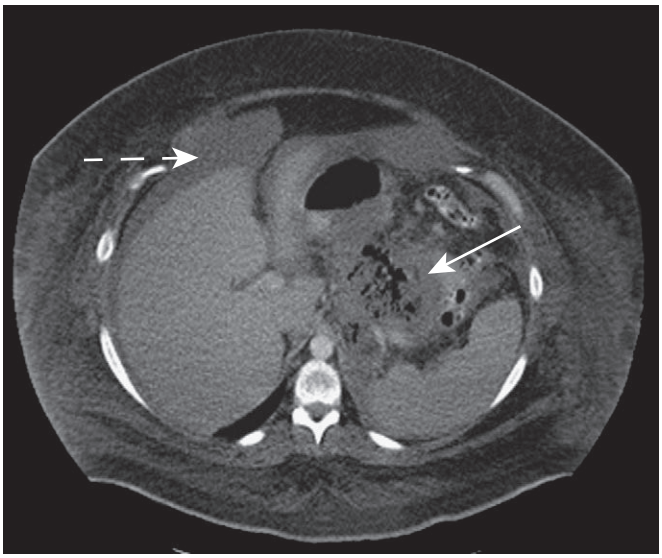

FIGURE 3 Computed tomographic scan image shows significant pancreatic necrosis *(white arrow)* and ascites *(dashed white arrow)*.

The approach to patients with infected pancreatic necrosis has changed significantly with the use of percutaneous, endoscopic, and minimally invasive interventions. Prior studies have revealed that percutaneous drainage can be an effective first approach to infected necrosis, with 35% of patients in one randomized controlled trial requiring only this intervention without the need for more invasive procedures. Less-invasive approaches are associated with decreased complication rates when compared with open necrosectomy. A recent randomized controlled trial of 22 patients compared endoscopic transgastric necrosectomy with surgical necronectomy and showed decreased serum levels of the inflammatory marker interleukin-6 (IL-6) and a decrease in a clinical composite endpoint composed of major complications and death. Multiple groups have now proposed a step-up approach to infected necrosis, starting with percutaneous drainage and then moving towards endoscopic or minimally invasive approaches as indicated. When feasible, these approaches should be considered in all patients with infected necrosis prior to open necrosectomy.

Pancreas Divisum and Other Variants of Dominant Dorsal Duct Anatomy

Robert Evans Heithaus Jr., MD, and Steven B. Goldin, MD, PhD

INTRODUCTION

Pancreas divisum refers to a variety of pancreatic ductal anatomic variations. Although commonly thought of in the context of pancreatitis, pancreas divisum is not a disease. "Normal" pancreatic ductal anatomy is present in approximately 80% of individuals. In people with normal anatomy, most pancreatic enzyme secretions (approximately 2 L/d) enter the duodenum via the ampulla of Vater or major papilla. People with pancreas divisum have a dominant dorsal duct that is responsible for draining most pancreatic enzyme secretions via the minor pancreatic duct or duct of Santorini. This condition occurs in up to 20% of the population, 95% of whom never have medical problems related to the ductal anatomy. Approximately 5% of those with pancreas divisum have pancreatitis develop as a result of the variant anatomy, which may be coupled to other predisposing factors. Understanding how pancreas divisum predisposes to pancreatitis requires knowledge of the embryologic development of the pancreas. This knowledge allows the clinician to appropriately evaluate and treat individuals with pancreatitis as a result of variant anatomy.

PANCREATIC EMBRYOLOGIC DEVELOPMENT

At approximately 30 days' gestation, the endodermal lining of the duodenum forms separate ventral and dorsal pancreatic buds (Figure 1). As the duodenum changes in shape and size to form its C-shaped curve, the ventral pancreatic bud migrates clockwise into a location inferior to the dorsal pancreatic bud (see Figure 1). By the 6th week of gestation, the dorsal and ventral pancreatic buds are contiguous with each other; and by the 8th week, they fuse. The ventral pancreatic bud becomes the inferior portion of the head (also known as the uncinate process), and the dorsal bud forms the remaining portion of the head, body, and tail of the pancreas (Figure 2). The main pancreatic duct (duct of Wirsung) is formed by the fusion of the distal portion of the dorsal pancreatic duct with the entire ventral pancreatic duct. The main pancreatic duct then typically joins with the common bile duct to form a common channel that enters the duodenum at the major papilla (ampulla of Vater). The distal portion of the dorsal pancreatic duct (near the duodenum) may persist as the accessory pancreatic duct (duct of Santorini) or may be totally obliterated (Figure 3, *A* and *B*).

A number of variations in pancreatic ductal anatomy may occur during development. Pancreas divisum occurs when the ventral and dorsal ductal systems do not fuse completely. This condition happens

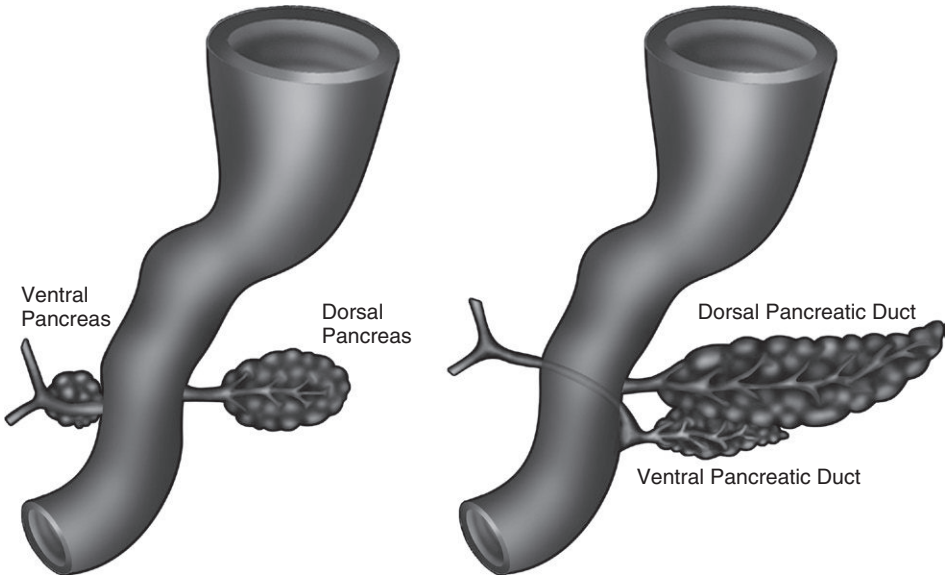

FIGURE 1 Dorsal and ventral pancreatic buds before migration *(left)* and after migration *(right). (Lawrence PF:* Essentials of general surgery, *ed 5, Philadelphia, 2012, Lippincott Williams & Wilkins. Illustrations by Matthew Campbell.)*

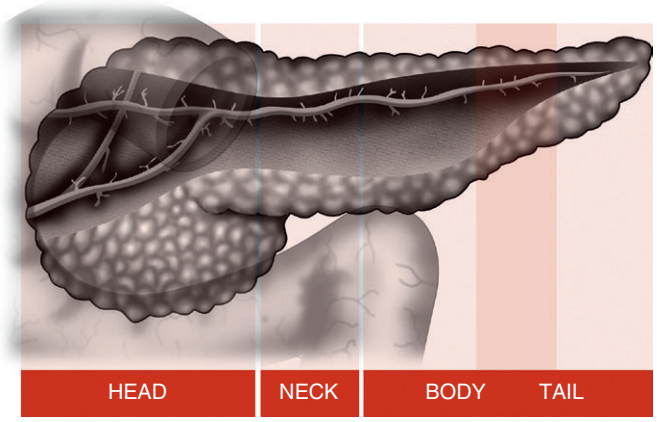

FIGURE 2 Divisions of the pancreas. *(Lawrence PF:* Essentials of general surgery, *ed 5, Philadelphia, 2012, Lippincott Williams & Wilkins. Illustrations by Matthew Campbell.)*

in up to 20% of the population. The classically described pancreas divisum has separate noncommunicating dorsal and ventral ducts. This classic variant occurs in up to 5% of the population (Figure 3, *C*). Other variations include an absent duct of Wirsung (Figure 3, *D*) and a filamentous communication between the ventral and dorsal ductal systems (Figure 3, *E*), which are seen in 4% and 10% of the population, respectively. All of these variants are typically lumped together under the heading of pancreas divisum because the dorsal duct that drains through the minor papilla is responsible for draining the majority of the pancreatic enzyme secretions into the duodenum.

CLINICAL SIGNIFICANCE

Pancreatitis is hypothesized to occur in those with ductal systems that are not able to adequately drain the pancreatic secretions from the gland into the duodenum. This occurs in only a small percentage of the 20% of individuals with some type of incomplete fusion, but the exact incidence rate of pancreatitis in this group is unknown. In most cases, the diameter of the major pancreatic duct ranges from 1.5 to 2 mm in the tail and 3 to 4 mm in the head of the gland. The diameter of the minor duct is usually smaller, and when the minor duct is responsible for draining most of the gland (as in people with pancreas divisum), the potential for problems exists. Three primary pathologic conditions are associated with pancreas divisum: acute pancreatitis, chronic pancreatitis, and a pancreatic pain syndrome (midepigastric pain with radiation to the back). Although Goenei has shown pancreas divisum to be a predisposing factor in chronic and acute recurrent pancreatitis, most patients with pancreas divisum and pancreatitis have pancreatitis that is not the result of pancreas divisum. Remember that pancreas divisum may or may not be the cause of pancreatitis in any specific patient. Therefore, even if pancreas divisum is present, a careful investigation for other causes of pancreatitis is imperative. If no other cause for the patient's pancreatitis can be found, the diagnosis of pancreatitis from pancreas divisum should be entertained.

New research has shown an association between some genetic abnormalities and pancreas divisum. Bertin has recently shown that mutations in the cystic fibrosis transmembrane conductance regulator gene (CFTR), the serine protease inhibitor Kazal type 1 gene (SPINK1), and the cationic trypsinogen gene (PRSS1) are associated with both chronic pancreatitis and acute recurrent pancreatitis. In Bertin's study, pancreas divisum was found in 47% of patients with CFTR gene mutations. Another study by Choudari reported that 22% of patients with pancreatitis and pancreas divisum had CFTR mutations or polymorphisms. These genetic alterations likely result in increased viscosity of the pancreatic fluid, which may clog smaller ductal systems and predispose these individuals to pancreatitis. Although not completely understood, a multifactorial model is likely to evolve to explain how pancreatitis occurs in individuals with pancreas divisum that includes both anatomic changes and a variety of individual predisposing genetic factors.

DIAGNOSTIC STRATEGIES

Patients with acute bouts of recurrent pancreatitis, chronic pancreatitis, or pancreatic pain often undergo extensive evaluation to determine the etiology of their disease. The list of potential causes of pancreatitis is extensive, and every effort should be made to identify the cause. Biliary tract disease in patients without macroscopic cholelithiasis should also be considered. Ultrasound scan may not always detect sludge, small stones, and debris within the biliary system or gallbladder that can cause pancreatitis. Microscopic crystals in bile

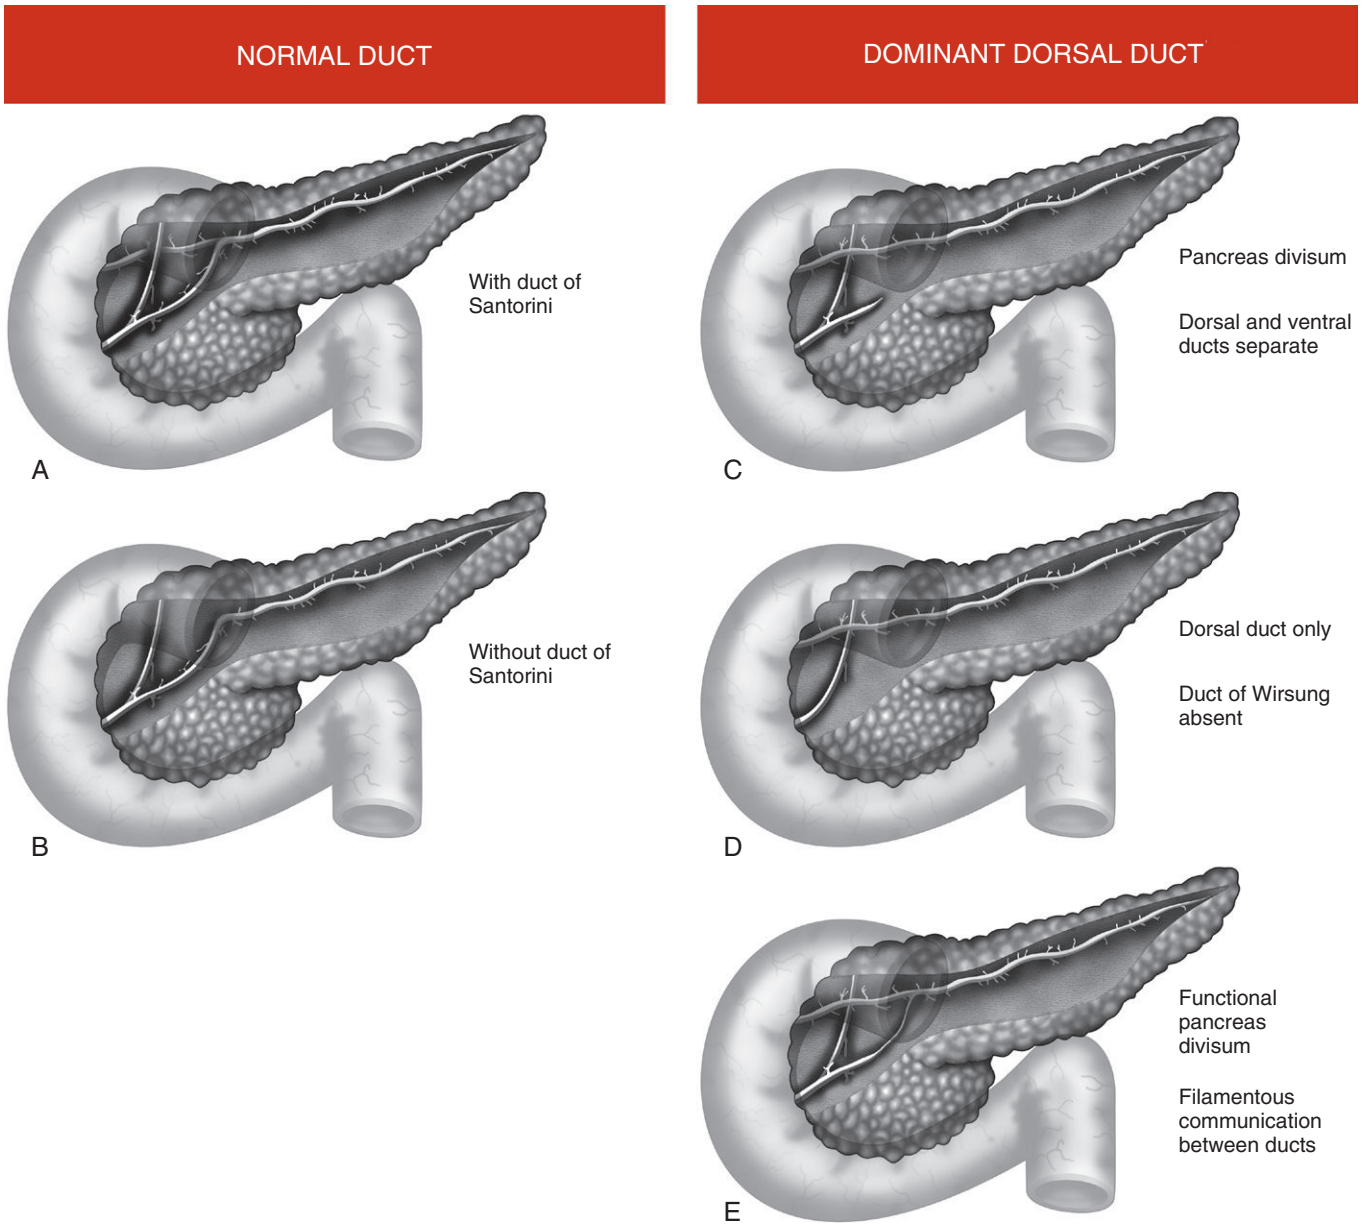

FIGURE 3 **A** to **E,** Variations in pancreatic ductal anatomy. *(Lawrence PF:* Essentials of general surgery, *ed 5, Philadelphia, 2012, Lippincott Williams & Wilkins. Illustrations by Matthew Campbell.)*

have been identified in up to 85% of patients with idiopathic pancreatitis. Cholecystectomy is usually curative and can usually be completed during the same hospital admission if the episode of pancreatitis is not severe.

Numerous imaging modalities are available to aid the clinician. Ultrasound scan is probably the best diagnostic test for identification of gallstones. Endoscopic retrograde cholangiopancreatography (ERCP) is still considered the gold standard in diagnosing pancreas divisum. When an obvious cause for pancreatitis is missing, the ventral and dorsal ductile systems should be evaluated with imaging studies, and their respective papillae should be checked for stenosis. Pancreatic ductal manometry can be done but is difficult and beyond the expertise of many centers. Cannulation of the dorsal duct also causes complications in up to 8% of patients. The post-ERCP induced pancreatitis risk is less if only the major papilla is cannulated. Endoscopic ultrasound is another imaging technique that can also aid in the diagnosis of pancreas divisum through direct evaluation of the pancreatic parenchyma and the ductal response to increased pancreatic enzyme secretion after intravenous (IV) secretin injection. Warshaw and colleagues have also shown the effectiveness of endoscopic ultrasound and secretin injection for evaluation of the papilla for a functional stenosis.

Multirow detector computed tomographic (CT) scan is also an effective means for evaluation of the pancreatic parenchyma and ductal anatomy. Asayama and associates showed that CT scan can reliably detect pancreas divisum in patients with Balthazar grade A acute pancreatitis (i.e., pancreatitis with no enlargement or inflammation involving the pancreas and peripancreatic fat seen on imaging). Magnetic resonance cholangiopancreatography (MRCP) may also be used in the evaluation of pancreatic ductile anatomy and does not subject the patient to ionizing radiation (Figure 4). Secretin stimulation can also be used with the MRCP and has been shown to increase the diagnostic yield of the test through enhanced visualization of the pancreatic ductal branches. One study by Ortega and colleagues compared endoscopic ultrasound scan (EUS) and MRCP and showed EUS to be superior in establishing a possible biliary

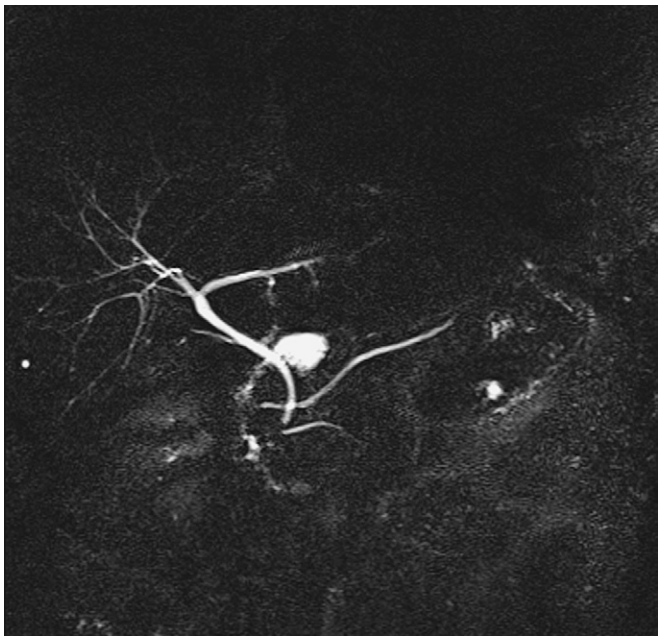

FIGURE 4 Magnetic resonance cholangiopancreatography shows pancreas divisum. *(Townsend, CM:* Sabiston textbook of surgery: the biologic basis of modern surgical practice, *ed 19, Philadelphia, 2012, Saunders.)*

etiology of pancreatitis in patients who had not undergone prior cholecystectomy; however, in patients whose gallbladder was surgically absent, MRCP seemed to be better.

TREATMENT

Treatment of patients with pancreatitis depends on identification of the etiology of the attack in the individual and then on focused intervention aimed at that etiologic agent. If pancreas divisum is a probable cause, both endoscopic and surgical treatment options exist. Unfortunately, only a handful of randomized controlled trials for endoscopic therapy have been performed, and none have been undertaken for surgical therapy. Also, no study has compared surgical with endoscopic treatment. Therefore, current treatment algorithms are based on a small number of retrospective studies.

Endoscopic Therapy

Endoscopic strategies include balloon dilation of the papilla, papillotomy, stent insertion, and endoscopic botulinum toxin injection into the papillae. These procedures can be extremely difficult to carry out because the minor papilla is often difficult to identify and hard to cannulate. These procedures have had limited success, are very operator dependent, and are dependent on various patient factors, including the type of pancreatitis and type of patient symptoms.

Balloon dilation by itself was associated with a high rate of postprocedure pancreatitis and has been largely abandoned. Pancreatic ductal stenting has also been used to treat a stenosis at the papilla, but the long-term success and the potential long-term problems that may accompany pancreatic ductal stenting are not fully known. Lans and associates, in a very small randomized controlled trial, showed that stenting might be superior to no intervention. Heyries and colleagues evaluated 24 patients who underwent sphincterotomy alone versus sphincterotomy plus stenting. The median duration of stenting was 8 months, and the median number of stent placements that required an ERCP procedure was three. Patients were followed for a minimum of 2 years. Thirty-eight percent of participants experienced complications (44% of those with stenting vs 25% of those without). Complications included acute pancreatitis, acute cholecystitis, hemorrhage, stent migration, stent obstruction, and stenosis of the sphincterotomy. The authors concluded that both methods of treatment decreased the incidence rate of acute pancreatitis but the relief of chronic pain was less obvious. Another study for evaluation of the efficacy of minor pancreatic ductal stenting included 25 patients with pancreas divisum. Twenty-three of the 25 patients with stenting did not have further bouts of recurrent pancreatitis, but they did experience stent occlusion rates of 40.7%. After stent removal, 76% of the patients remained asymptomatic during a mean follow-up period of 24 months. Although these studies have shown promise, the long-term complications of pancreatic ductal stenting persist and include acquired chronic ductal changes, such as pruning and ectasia. Smith and colleagues have observed that more than 80% of patients have ductal changes consistent with chronic pancreatitis soon after insertion of a polyethylene stent. The significance of these changes is still unknown, as is their potential impact on later surgical intervention.

Besides endoscopic stenting, other endoscopic techniques have been used. Wehrmann and associates have reported a technique to inject botulinum toxin into the minor papilla. This treatment idea is based on techniques used to treat sphincter of Oddi dysfunction. Success with this technique has been reported in a nonrandomized group of five patients. Two of these patients relapsed within 1 year and subsequently underwent needle-knife sphincterotomy with relief of symptoms. One patient did not respond to therapy, and one patient required a second botulinum toxin injection Further studies need to be done to elucidate whether this procedure should be offered to patients with pancreatitis from pancreas divisum.

Patient or disease factors may also play a role in determining who obtains benefit from an endoscopic procedure. A small amount of data suggests that differences in response to endoscopic therapy might be based on the type of pancreatitis or pain a patient experiences. Borak and colleagues observed better responses to endoscopic therapy in older patients than in younger patients (median age, 58 years vs 46.5 years) and worse outcomes in patients with chronic pancreatitis treated endoscopically compared with those with acute recurrent pancreatitis or patients with pancreatic type pain. Similarly, a meta-analysis conducted by Liao and associates reviewed the response to surgery and to endoscopic therapy based on the type of pancreatitis or pain patients exhibited. The pooled overall response rate to endoscopic therapy and surgery were similar (69.4% vs 74.9%, respectively), suggesting that both treatment methods are effective in most patients. They also noted a better response in patients with acute recurrent pancreatitis compared with those with chronic pancreatitis or pancreatic pain.

Surgical Therapy

Transduodenal sphincteroplasty forms the cornerstone of surgical therapy for pancreas divisum. Other potential operative procedures include the Partington-Rochelle procedure (pancreaticojejunostomy), pancreaticoduodenectomy, and the Beger and Frey procedures. Most patients treated surgically have had failed previous endoscopic interventions because the majority of patients have been evaluated by a gastroenterologist before referral for surgery. In addition, the appeal of an endoscopic procedure is greater compared with one that requires a celiotomy.

Patient selection is essential when predicting operative success. A strong indication for surgical intervention includes endoscopic failure to cannulate the minor papilla via ERCP. When dorsal duct cannulation can be accomplished, patients that benefit from stenting of the pancreatic duct for a minimum of 3 months before surgery are more likely to have successful operative procedures.

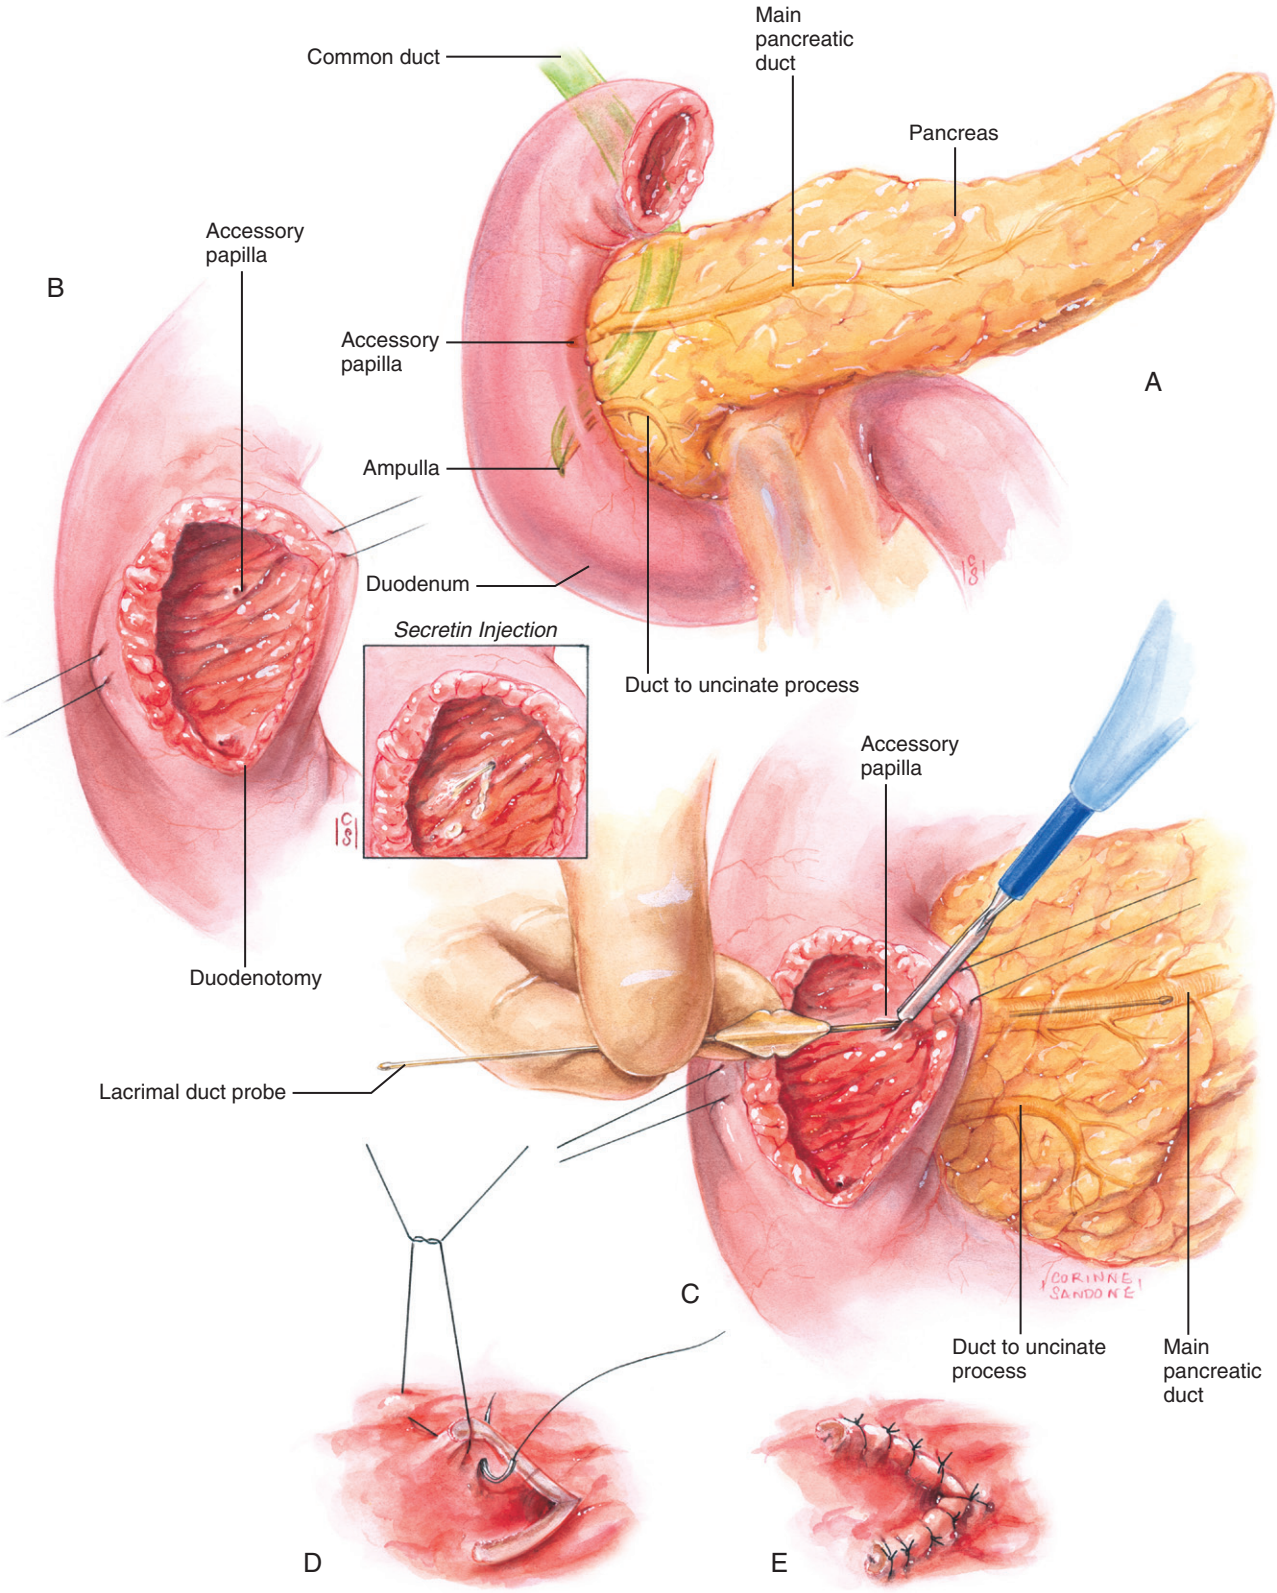

FIGURE 5 Dorsal duct sphincterotomy. **A,** Pictorial anatomy shows ampulla and accessory papilla in relation to duodenum and pancreas; **B,** longitudinal duodenotomy exposes accessory papilla; **C,** the dorsal duct is cannulated with a fine lacrimal probe, and the papilla is incised; and **D** and **E,** fine (5-0) absorbable sutures are placed in an interrupted fashion to approximate the mucosa from the duct to that of the duodenum. *(Used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol 2, Shelton, Conn, 2012, PMPH-USA.)*

Surgery can offer relief of symptoms with rates similar to those seen with endoscopic therapy. Morgan and associates retrospectively reviewed the outcome after transduodenal sphincteroplasty and showed that pain improved in 62% of patients. Patients who had a prior history of gastric surgery and had not undergone endoscopic sphincterotomy had better outcomes compared with those who had previous endoscopic interventions. Similar to endoscopic studies, younger patients with chronic pancreatitis had poorer outcomes.

Surgical Technique

Dorsal duct sphincterotomy is undertaken through a midline or right subcostal incision. A cholecystectomy should be done if the gallbladder is still present. A biliary Fogarty catheter may be inserted through the cystic duct to aid in the identification of the ampulla (Figure 5, *A*). This is often unnecessary because the papilla can usually be identified with careful palpation of the pancreaticoduodenal groove. Kocher's maneuver is done, and the pancreas is exposed to allow for visual inspection and palpation. A generous duodenotomy is made longitudinally opposite the ampulla of Vater (Figure 5, *B*). Exposure may be facilitated by placing stay sutures in the duodenum at either end of the incision. Palpation approximately 1 to 2 cm proximally and 0.5 cm anteriorly to the ampulla of Vater reveals the minor papilla. The papilla typically feels like a firm, tiny nodule. Intravenous secretin can be given at this time to help identify the minor duct by directly observing the outflow of pancreatic secretions. Secretin also helps ease cannulation through ductal dilation. Fine lacrimal probes are then carefully introduced into the dorsal pancreatic duct (Figure 5, *C*). Care should be taken to prevent traumatic cannulation because this can result in bleeding and hematoma formation. Minor trauma to this area can also make cannulation of the duct very difficult. Hence, atraumatic identification is very important because once this area has been traumatized, cannulation of the duct may be impossible. If indicated, a small catheter such as a 5F pediatric feeding tube can be inserted, and 2 to 3 mL of water-soluble contrast can be injected into the dorsal duct for further imaging.

After cannulation of the minor papillae, fine absorbable sutures (5-0 vicryl) should be placed in the duct 2 mm apart. The duct should be cut between the sutures until the diameter of the stoma is equal to the diameter of the minor duct. Absorbable 5-0 sutures are then placed in an interrupted fashion to approximate the mucosa from the duodenum and the duct (Figure 5, *D* and *E*). After sphincteroplasty, cannulation of the duct with a 3-mm or larger dilator usually indicates success.

The duodenotomy may be closed in a variety of manners with either one or two layers. The authors' preference is to use two layers with an inner layer of 3-0 vicryl placed in a Connell manner reinforced with a layer of 3-0 silk Lembert sutures. The duodenotomy may be closed longitudinally or transversely. Some surgeons advocate a sphincteroplasty of the sphincter of Oddi; however, if the patient's problems stem from stenosis of the dorsal duct, then this portion of the procedure is not indicated.

CONCLUSION

Pancreas divisum is seen in up to 20% of the population. To produce illness, other factors besides the anatomic variation seen with pancreas divisum are probably required. Treatment for patients symptomatic for pancreas divisum may be done either endoscopically or surgically. No randomized studies comparing endoscopic with surgical treatment exist. Success of any procedure is largely based on patient selection. Patients with pancreatic pain generally have worse outcomes than those with recurrent bouts of acute pancreatitis. Patients with chronic pancreatitis also seem to fair worse than those with pancreatic type pain. Patients with stenosis of the minor papilla and a soft pancreas without evidence of chronic pancreatitis usually have better outcomes with a good, fair, and poor response to therapy seen in 59%, 11% and 30%, respectively. In other studies, a good or fair outcome was seen in 85% of patients with documented stenosis at the papilla. Treatment depends on the ductal anatomy. Patients with chronic pancreatitis and a dilated pancreatic duct should undergo a pancreaticojejunostomy. Patients who have restenosis after surgical sphincteroplasty have success after revision only 50% of the time, and pancreatic head resection should be considered. Ultimately, the relief of outflow obstruction without restenosis generally results in successful symptom relief in most patients, which implies that surgical intervention is a definitive method of treatment in nearly all patients with pancreas divisum experiencing acute recurrent bouts of pancreatitis. Until a multicenter randomized control trial comparing surgery and endoscopic therapy is conducted, the treatment strategies surrounding this condition will continue to be debated.

Pancreatic Necrosis

Jordan R. Stern, MD, and Jeffrey B. Matthews, MD, FACS

INTRODUCTION

Most patients who experience an attack of acute pancreatitis follow a benign course and recover without significant long-term sequelae. However, for the approximately 20% who do have complications, the outcome can be devastating. The most feared complication is the development of pancreatic necrosis, estimated to occur in 10% to 25% of all cases of acute pancreatitis and, in historic series, carrying a harrowing 10% to 20% mortality rate. Mortality in necrotizing pancreatitis is bimodal in temporal distribution. Early deaths, occurring within days of onset, are generally attributable to an exuberant systemic inflammatory response and the development of multisystem organ failure. Late deaths occur weeks later, typically in the setting of infection and sepsis. Infected pancreatic necrosis is associated with up to a threefold increase in mortality over sterile necrosis and has traditionally been considered an indication for urgent surgical intervention. However, operative débridement of necrotic pancreatic tissue carries a high mortality rate, and complications including abscess or pseudocyst formation, hemorrhage, bowel injury, pancreatic fistula, and late pancreatic exocrine and endocrine insufficiency are frequent. More recently, evidence has emerged that suggests that extended nonoperative management strategies are safe; this approach is now generally favored, even in the setting of infection. In those patients who cannot avoid surgical intervention, a multimodal approach including minimally invasive surgical techniques has become the preferred clinical strategy in many experienced centers. This chapter describes both the nonoperative and the operative management of pancreatic necrosis and outlines a strategy to optimize patient outcomes.

DEFINITIONS AND DIAGNOSIS

Considerable confusion has occurred over the nomenclature used to describe complications of severe acute pancreatitis. Terms such as necrosis, fluid collection, abscess, and pseudocyst are often used interchangeably. A more precise framework and definition of terms that distinguishes among these entities and facilitates communication between clinicians was developed at a multidisciplinary consensus conference in Atlanta in 1992. The Atlanta classification is outlined in Table 1.

Computed tomographic (CT) scan is particularly useful in establishing the presence of necrotizing pancreatitis and other peripancreatic complications (Figure 1). Administration of intravenous contrast is generally necessary to make the diagnosis. Criteria for the diagnosis of pancreatic necrosis are diffuse or focal areas of nonenhancement that involve greater than 30% of the pancreas or measure 3 cm in maximal dimension. Areas that contain gas should raise the suspicion of the presence of infected necrosis. Magnetic resonance imaging (MRI) may also be used, and the combination of T1-weighted and T2-weighted sequences in combination with magnetic resonance cholangiopancreatography (MRCP) can be of particular use in defining the extent of necrosis and assessing the bile ducts for anatomy and the presence of stones. MRI is particularly useful to distinguish fluid from solid collections of necrotic tissue, a distinct advantage over CT scan. Radiologically guided tissue sampling for bacterial culture is occasionally useful to distinguish between infected and sterile necrosis. This practice was originally based on prevailing surgical dogma of immediate operative intervention in infected necrosis. Despite theoretic concerns for conversion of sterile necrosis to infected necrosis via instrumentation, rates of secondary infection are extremely low and image-guided needle aspiration should still be considered a safe and useful diagnostic tool. However, because initial nonoperative management is now generally favored regardless of infection status, this practice is no longer routine.

ROLE OF PROPHYLACTIC ANTIBIOTICS

Given the higher mortality rate for infected pancreatic necrosis, much attention has been paid to the potential benefit of prophylactic antibiotics to prevent secondary infection of initially sterile necrosis. Although the theoretic rationale is compelling, the supporting evidence is conflicting and concerns have been raised regarding the possible selection for resistant bacteria and the potential for the emergence of fungal infection. Given the potential concerns and lack of evidence to support their use, prophylactic antibiotic use should not be routine in clinical practice. Probiotic (rather than antibiotic) prophylaxis has been suggested as an alternative approach to the prevention of infection in pancreatic necrosis by maintaining normal gut flora, but recent evidence has unexpectedly shown an increased mortality in those patients undergoing probiotic therapy.

TIMING OF SURGICAL INTERVENTION

In the past, surgical intervention was generally undertaken early in the course of severe necrotizing acute pancreatitis, typically within a few days of onset. Early operation, particularly in cases of infected necrosis, was assumed to improve the otherwise dismal prognosis. However, a number of studies suggested that intervention within the first 48 to 72 hours was associated with particularly high mortality, and the International Association of Pancreatology (IAP) guidelines of 2002 recommended against surgical intervention within the first 14 days of onset of the illness unless there were specific overriding indications. Subsequent studies have provided evidence that mortality remains high even within the first 14 to 21 days of presentation but can be reduced to less than about 8% when operation is delayed beyond 28 to 30 days. One prospective, randomized trial that examined early versus late necronectomy was closed early because of high mortality in the early operative group. The benefit from delayed operation seems to come from the improved demarcation between normal and necrotic tissue over time, to the point where dissection can be less extensive, the risk of hemorrhage and injury to surrounding organs can be reduced, and unnecessary removal of otherwise viable pancreatic tissue can be limited. Given these findings, whenever possible, definitive surgical therapy should be delayed and patients managed nonoperatively for at least 28 days. As an added benefit, this practice obviates the need for surgery in a number of patients, especially those with sterile necrosis.

THERAPEUTIC INTERVENTION FOR PANCREATIC NECROSIS

Surgical intervention should be delayed whenever possible. However, the clinical scenario may dictate operation or other forms of intervention at earlier time points, particularly in patients who appear to have infected necrosis. In general, a clinical picture consistent with infection such as persistent fevers, tachycardia, adynamic ileus, and continued or progressive multisystem organ failure should be taken as sufficient evidence of infection even in the absence of confirmation with fine-needle aspirate and culture. A patient with failure to respond to supportive therapy, manifested by progressive multiorgan

TABLE 1: Atlanta classification for acute pancreatitis

Clinical entity	Definition	Clinical manifestation	Pathologic findings	Notes
Acute Pancreatitis	Acute inflammatory process, with variable involvement of other regional tissues or remote organ systems	Rapid onset with variable abdominal findings Often associated with emesis, fever, tachycardia, leukocytosis, and elevated pancreatic enzymes	Ranges from interstitial edema to macroscopic necrosis and hemorrhage See subsequent	Clinical diagnosis only
Severe Acute Pancreatitis	Associated with organ failure or local complications, such as necrosis, abscess, or pseudocyst	Increased abdominal tenderness and distention, hypoactive or absent bowel sounds, ≥ 3 Ranson criteria or ≥ 8 APACHE points with organ failure	Most often associated with necrosis, but also may occur with severe interstitial edema	Rapid onset, delayed progression from mild pancreatitis is rare
Mild Acute Pancreatitis	Minimal organ dysfunction and an uneventful recovery; lacking criteria for severe acute pancreatitis	Abdominal pain and tenderness but less severe Responsive to fluid resuscitation, usually within 48-72 h	Interstitial edema, with or without small areas of focal necrosis or peripancreatic fat necrosis	~75% of patients with acute pancreatitis have mild disease and an uncomplicated course
Acute Fluid Collection	Occur early in the course of acute pancreatitis, located in or near the pancreas, always lack a wall of granulation or fibrous tissue	Common in patients with severe disease (30%-50%), and usually discovered with imaging studies	No defined wall, precise fluid composition is unknown, and presence of bacteria is variable	Represents an early form of pseudocyst, but most regress and do not develop further
Pancreatic Necrosis	Diffuse or focal areas of nonviable pancreatic parenchyma, typically associated with peripancreatic fat necrosis	Severe pancreatitis with zones of nonenhanced (<50 Hounsfield units) parenchyma ≥ 3 cm or involving ≥ 30% of the pancreas on CT scan	Interstitial fat necrosis with vessel damage affecting acinar, islet, and ductal cells	Subclassified as infected and sterile pancreatic necrosis
Acute Pseudocyst	Collection of pancreatic juice enclosed by a wall of fibrous or granulation tissue, which arises as a consequence of acute pancreatitis, pancreatic trauma, or chronic pancreatitis	Occasionally palpable but most often develops several weeks after an episode of acute pancreatitis and discovered on repeat imaging	Well-defined wall of fibrous or granulation tissue present, may contain bacteria but does not contain pus	Develops at least 4 wk after attack and has defined wall, otherwise termed acute fluid collection (as described previously)
Pancreatic Abscess	Circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas, containing little or no pancreatic necrosis, which arises as a consequence of acute pancreatitis or pancreatic trauma	Clinical picture usually that of systemic infection	Well-defined wall with presence of pus in the cavity and culture-positive aspiration for bacteria or fungi	Develops at least 4 wk after attack, and differentiated from infected pancreatic necrosis by lack of necrosis and presence of pus

This clinically based system of definitions was developed at the International Symposium on Acute Pancreatitis in Atlanta, in September 1992. It was created to standardize definitions among clinicians.

APACHE, Acute Physiology and Chronic Health Evaluation; *CT,* computed tomographic.

Table reproduced from Stern JR, Matthews JB: Pancreatic necrosectomy,* Adv Surg *45:155–176, 2011, Elsevier Science.*

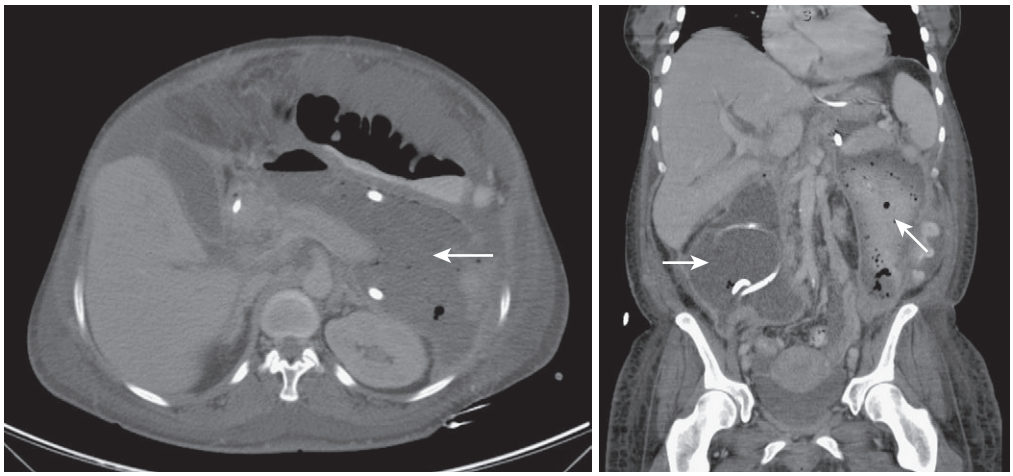

FIGURE 1 Computed tomographic (CT) scan of pancreatic necrosis. CT scan was performed with intravenous contrast on a 45-year-old woman with history of necrotizing pancreatitis. Axial and coronal images show extensive retroperitoneal collections containing air and fluid in addition to solid necrotic tissue *(white arrows)*. A percutaneous drainage catheter is seen within the right-sided collection.

dysfunction and failure or other signs of clinical deterioration, should be considered a candidate for therapeutic intervention. The general principles of traditional "open" pancreatic necronectomy include complete débridement of necrotic tissue and wide drainage of infected compartments. However, in selected instances, temporization with percutaneous or endoscopic approaches may allow formal débridement to be deferred until a safer window of time.

Percutaneous Drainage

Primary intervention on patients with severe complications of acute pancreatitis may include image-guided drainage performed by interventional radiologists (see Figure 1). Large pseudocysts and abscesses containing little solid necrosis may be particularly amenable to percutaneous drainage, and this may circumvent the need for later surgical intervention in some patients altogether. Drains may be exchanged and upsized as needed. More commonly, though, percutaneous drainage is not definitive therapy but is instead used to gain source control to stabilize patients for delayed surgical intervention. In cases with a significant solid necrotic component, percutaneous drains may be inadequate to drain thick debris through even large-bore pigtail catheters. Nevertheless, occasionally, the combination of percutaneous drainage and prolonged antibiotic therapy may lead to complete resolution of such collections without the need for formal operative débridement, in apparent violation of long-held surgical dogma.

Endoluminal Drainage

Endoscopy has been used for some time in the management of pancreatic pseudocysts. Adequate definitive drainage may be accomplished through placement of transgastric, or occasionally transduodenal, drains into walled-off peripancreatic fluid collections abutting the stomach or duodenum. With advances in technology and endoscopic skill, drainage of more complex, heterogeneous collections extending into the retroperitoneal peripancreatic, pararenal, and paracolic spaces may be achieved. Pancreatic débridement with this approach is in essence a form of natural orifice transluminal endoscopic surgery (NOTES). An endoscope is passed through the mouth and into the stomach, where extrinsic compression from the necrotic cavity is indentified. Usually, endoscopic ultrasound scan is used to further characterize the space, the extent of solid versus fluid debris, and the presence of nearby vascular structures such as dilated or variceal short gastric veins. Entrance to the cavity is gained with electrocautery through the posterior stomach or medial duodenum wall, and then the opening is enlarged to allow the endoscope to be passed directly into the cavity. Correct positioning is often confirmed with fluoroscopy (Figure 2, *A*). Endoscopic forceps can be used to remove solid material, followed by copious irrigation (Figure 2, *B*). Nasocystic catheters can be left in the cavity for irrigation, or double pigtail catheters (often multiple) can be left between the lumen of the stomach or duodenum and the cavity to allow for continued drainage through a controlled internal fistula.

Open Pancreatic Necronectomy

Open necronectomy with drain placement and continual postoperative lavage is effective to remove necrotic and infected tissues and has long been considered the standard against which newer approaches to infected necrosis should be judged. Mortality rates as high as 50% have been reported depending on the timing of intervention and patient selection, and the risks of bowel injury, postoperative fistula, recurrent abscess, and wound complications are considerable. Nonetheless, in modern series, the morbidity and mortality of open necronectomy are far lower when intervention is delayed and when it is performed in experienced centers. It remains an excellent, tried-and-true option in these patients.

A midline laparotomy or left-sided subcostal incision is used to gain peritoneal access, depending on radiologic findings of the extent of the necrosis and extension into retroperitoneal spaces. Blunt dissection is used to elevate the omentum, stomach, and transverse colon and mesocolon away from the inflammation and necrosis within the lesser sac, pancreatic body, and tail. On entering the involved peripancreatic spaces, significant amounts of fluid or necrotic tissue with extensive loculations are often encountered. Careful efforts to preserve the integrity of the transverse mesocolon are worthwhile, to avoid devascularization of the colon and to prevent internal adhesions, herniation, or fistulization of the small bowel. Access to the pancreatic head and uncinate process is gained via the lesser sac through Kocher's maneuver and extensive mobilization of the duodenum as possible. Necrotic tissue is often able to be finger-dissected away from the retroperitoneal vasculature and from viable pancreatic tissue, but clear definition of tissue planes is often impossible. The area posterior to the superior mesenteric vessels should be carefully and gently débrided and drained as well. Normal-appearing pancreas should be left undisturbed if possible, even at the expense of leaving a small amount of necrotic tissue behind. Depending on preoperative imaging, the pararenal spaces and paracolic gutters should be thoroughly explored for evidence of necrotic tracking. Once débridement is complete, attention should be turned to irrigation and establishment of adequate external drainage. Previously

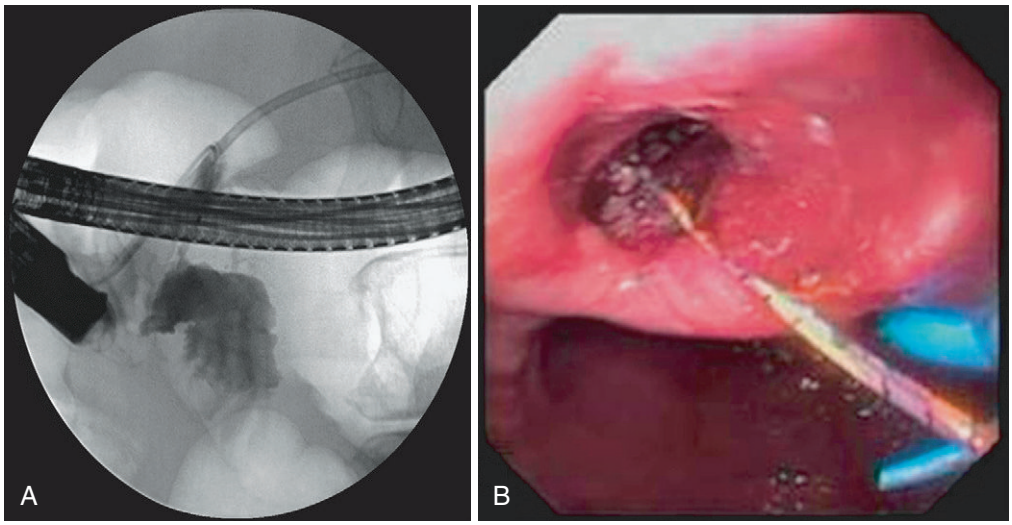

FIGURE 2 Endoscopic necronectomy. **A,** After the posterior gastrostomy is made with electrocautery, fluoroscopy is used to verify correct placement of the endoscope in the necrotic cavity. **B,** Endoscopic instruments are used to remove necrotic tissue through the opening in the stomach wall. *(Images courtesy of Irving Waxman, MD, Department of Gastroenterology, The University of Chicago Hospitals.)*

placed percutaneous catheters may be repositioned or exchanged. Additional catheters should be large bore (at least 28F) and should contain multiple large drainage holes to allow semisolid material to pass through. Ideally, the choice of surgical drainage catheter should allow for later exchange if necessary. Single-lumen closed-suction catheters can provide adequate drainage, and multiple-lumen catheters allow for continuous postoperative lavage with saline solution or peritoneal dialysis fluid if desired. The goal should be to achieve complete and thorough débridement at the time of initial operation. Planned reexploration every 48 to 72 hours is probably not necessary unless there has been significant hemorrhage or a question of viability of intestinal segments that may have been compromised by operative injury or mesenteric inflammation (particularly the transverse colon). Drains and packing should only be removed after a minimum of 7 days, allowing for the slow collapse of the necrotic cavity and resolution of pancreatic fistula.

Videoscopic Surgical Techniques

Several minimally invasive surgical alternatives to open necronectomy have evolved for the treatment of pancreatic necrosis, with both laparoscopic (transperitoneal) and intracavitary (retroperitoneal) approaches. Laparoscopic pancreatic necronectomy is analogous to the open technique, achieving the same goals of débridement and drainage. A larger incision can be used for a hand port to aid dissection, gain access to deeper loculations and compartments, and control bleeding if so desired by the operating surgeon. Drainage catheters are again left in the emptied cavities. Avoidance of full laparotomy while still achieving adequate débridement and drainage may be important in critically ill patients with compromised respiratory status, provided that they can tolerate pneumoperitoneum. Repeat laparoscopic intervention is simpler and safer than repeat laparotomy, and wound complications such as infection and hernia formation are less common. A retroperitoneal approach has variably been termed intracavitary or percutaneous necronectomy, or increasingly commonly, video-assisted retroperitoneal débridement (VARD) (Figure 3). VARD is touted to achieve lower operative mortality than open necronectomy and lower overall morbidity, postoperative organ failure, and need for intensive care unit (ICU) management. This approach is conceptually appealing, in that it avoids contamination of virgin spaces (most notably the peritoneal cavity), theoretically containing the infection with natural biologic compartment barriers and reducing the systemic inflammatory response, which can ultimately lead to multiple organ dysfunction and death.

Step-Up Approach

Because of the high morbidity and mortality of definitive surgical therapy for pancreatic necrosis, and the need to delay such interventions for a minimum of 4 weeks, a stepwise approach to these patients has been suggested. On presentation, patients with acute necrotizing pancreatitis often display signs of the systemic inflammatory response syndrome and sepsis, and timely implementation of supportive therapy in the ICU is paramount. After initial stabilization, attention should be turned to gaining source control and evacuating necrotic tissue and infected fluid collections. This can be achieved initially with percutaneous or endoscopic drain placement, which may improve patient stability and lead to clinical convalescence. Drainage procedures can achieve sufficient temporization such that definitive therapy can be delayed for the requisite time period as inflammation subsides and the necrosis becomes more organized. Perhaps even more importantly, drainage can obviate the need for necronectomy in approximately 35% of patients. For patients who do have organized necrosis that is not amenable to complete evacuation with percutaneous or endoscopic drains, definitive necronectomy should be undertaken first with minimally invasive approaches. On the basis of imaging and location of necrosis, and surgeon expertise with each technique, either VARD (retroperitoneal) or laparoscopic necronectomy can be performed at this time. This approach, with a progression of interventions with increasing invasiveness, led to decreased overall complications and death when compared with open necronectomy in a randomized trial.

SUMMARY

Pancreatic necrosis is a source of significant morbidity and mortality, and patients with this disease are often acutely and severely ill. Initial management should prioritize aggressive fluid resuscitation and supportive care in the intensive care unit. Prophylactic antibiotic therapy is no longer routinely used, but empiric therapy should be considered in patients who show signs of systemic infection (fever, leukocytosis) or with evidence of infection on imaging studies. Patients should be imaged with either infused CT scan or MRI to evaluate the location and extent of necrosis and associated fluid collections or abscesses, and temporizing percutaneous drainage procedures can be accordingly planned. Drains should be upsized if indicated with repeat imaging. With the "step-up" approach, in approximately one third of patients, percutaneous drainage alone suffices, and they recover without need for additional intervention. In patients with organized infected necrosis, either traditional open necronectomy, VARD, or

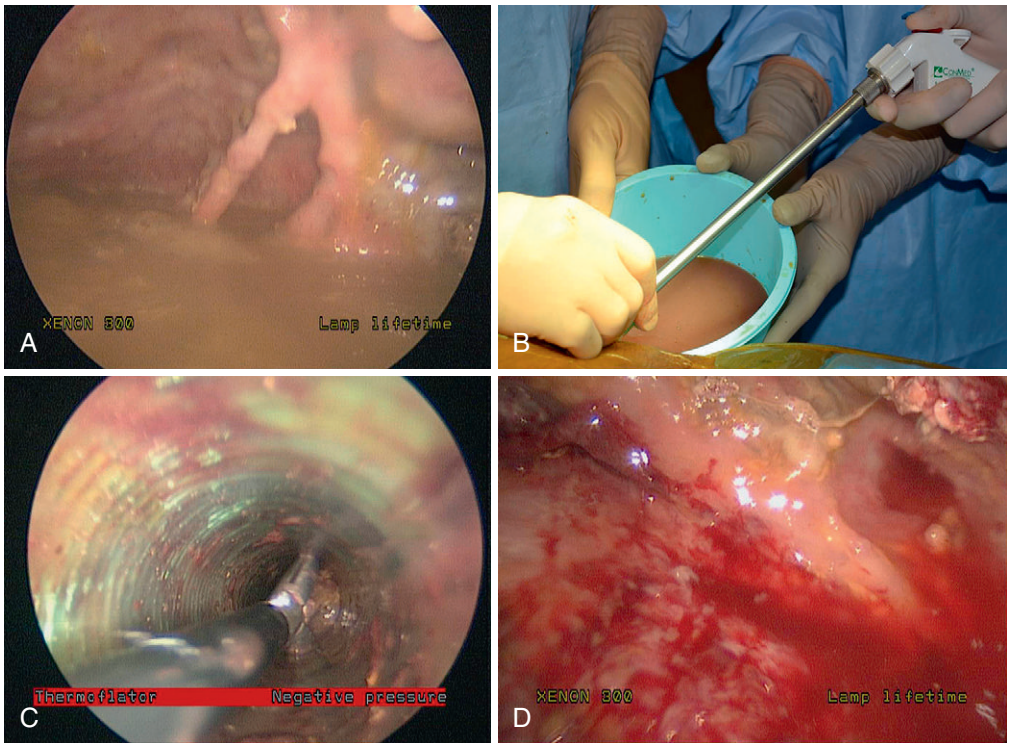

FIGURE 3 Video-assisted retroperitoneal débridement. The necrotic cavity is entered by following the tract of percutaneous drains, and a large amount of brown liquid and floating debris is encountered **(A)**, which is drained with a laparoscopic suction-irrigation device **(B).** Solid material can be removed with graspers and other traditional laparoscopic instruments **(C)**. After débridement, healthy tissue is seen along the wall of the cavity **(D)**.

laparoscopic necronectomy should be performed after a minimum of 28 days to allow inflammation to subside and tissue planes to develop between necrosis and the remaining normal pancreas and underlying vasculature. The goals of débridement should be to completely evacuate all necrotic tissue and unroof any cavities throughout the retroperitoneal space and to leave large-bore drainage catheters to allow for continued drainage and irrigation. The step-up approach may represent a new standard of care in experienced centers, although open necronectomy continues to be a valid and acceptable approach.

THE MANAGEMENT OF PANCREATIC PSEUDOCYST

Katherine A. Morgan, MD, and David B. Adams, MD, FACS

"The fascination that pseudocysts hold for surgeons is beyond comprehension."

Robert Zollinger, MD

OVERVIEW

The pancreatic pseudocyst is a collection of pancreatic secretions contained within a fibrous sac comprised of chronic inflammatory cells and fibroblasts in and adjacent to the pancreas contained by surrounding structures. Why a fibrous sac filled with pancreatic fluid is the source of so much interest, speculation, and emotion amongst surgeons and gastroenterologists is indeed hard to understand. Do we debate so vigorously about bilomas, urinomas, or other abdominal collections of visceral secretions? Perhaps it is because the pancreatic pseudocyst represents a sleeping tiger, which though frequently harmless, still can rise up unexpectedly and attack with its enzymatic claws into adjacent visceral and vascular structures and cause life-threatening complications. Another part of the debate and

puzzlement about pancreatic pseudocysts is related to confusion about pancreatic pseudocyst definition and nomenclature.

The Atlanta classification, developed in 1992, was a pioneering effort in describing and defining morphologic entities in acute pancreatitis. Since then, a working group has been revising this system to incorporate more modern experience into the terminology. In the latest version of this system, pancreatitis is divided into acute interstitial edematous pancreatitis (IEP) and necrotizing pancreatitis (NP), based on the presence of pancreatic tissue necrosis. The fluid collections associated with these two "types" of pancreatitis are also differentiated. Early (<4 weeks into the disease course) peripancreatic fluid collections in IEP are referred to as acute peripancreatic fluid collections (APFC), whereas in NP, they are referred to as postnecrotic peripancreatic fluid collections (PNPFC). Late (>4 weeks) fluid collections in IEP are called pancreatic pseudocysts, and in NP, they are called walled-off pancreatic necrosis (WOPN). These latter two entities are the subject of this chapter.

Acute pancreatitis represents a broad spectrum of disease. Although the disease course may smolder, typically an initial inciting event results in organ injury, which sets into play the evolving clinical course. The early phase of disease is marked by the inflammatory mediators from damaged pancreatic tissue, resulting in variable degrees of systemic inflammatory response. The later phase is determined by the morphology of organ injury, specifically with regard to tissue ischemia and necrosis. The outcome of this later phase is often impacted by local or systemic infection.

Peripancreatic fluid collections can occur in both the early and the late phases of disease. They presumably occur from injury to or ischemia of the main pancreatic duct or a side branch duct, although some, particularly early on, may be the result of third-space edema fluid. Peripancreatic fluid collections represent a heterogeneous entity. Definition of peripancreatic fluid collections is essential in determination of clinical decision making.

PATHOPHYSIOLOGY

Pancreatic pseudocysts develop as a consequence of pancreatic duct disruption and can occur in the setting of acute pancreatitis, chronic pancreatitis, or pancreatic trauma. In acute pancreatitis, ischemia, inflammation, and increased pressure may play a role in ductal injury. In chronic pancreatitis, ductal pathology from postinflammatory fibrosis can lead to ductal compromise. With duct disruption, pancreatic exocrine fluid leaks and pools. The pancreatic enzyme-rich fluid incites an inflammatory response with fibroblast-mediated extracellular matrix formation and the development of a fibrous capsule. Pseudocysts are defined microscopically by this inflammatory fibrous lining, which lacks an epithelial layer. The fluid content of walled-off pancreatic necrosis may develop from a similar pathophysiology, although in the presence of necrosis, or it may be the result of liquefaction necrosis of pancreatic or peripancreatic tissue after severe acute pancreatitis.

The natural history of the pseudocyst is determined by the resultant state of the underlying pancreatic duct. The duct injury may heal on its own, or a persistent fistula or ductal stricture may develop, which impedes resolution of the pseudocyst.

PRESENTATION

A pseudocyst may commonly present as persistent or worsening abdominal or back pain, bloating, early satiety, nausea, vomiting, or failure to thrive after a significant bout of pancreatitis or pancreatic trauma. A pseudocyst in the head of the pancreas can cause biliary obstruction with jaundice or duodenal obstruction with intolerance of oral diet. Mechanical compression from a pseudocyst or the associated inflammatory reaction can result in mesenteric venous thrombosis with variceal bleeding or ascites. The inflammatory pseudocyst can erode into surrounding structures, including the small bowel or colon, to develop an enteric fistula. The pseudocyst can also erode into surrounding vessels (including the splenic artery, gastroduodenal artery, and superior mesenteric artery) to cause a pseudoaneurysm and potentially life-threatening hemorrhage. In addition, the cyst may rupture into the peritoneal cavity to result in pancreatic ascites or the thoracic cavity to result in a pleuropancreatic fistula. Finally, a pseudocyst may be asymptomatic and discovered incidentally on imaging.

DIAGNOSTIC EVALUATION

The goals of the diagnostic evaluation of the pancreatic pseudocyst include defining the disease process at hand, determining the need for intervention, and assessing the options for therapy. Distinguishing a pseudocyst or WOPN from a cystic neoplasm is an essential first step in this diagnostic process. Often history alone can make this determination, but radiography should be consistent with this distinction. Radiography is also effective in differentiating a pseudocyst from WOPN with the presence of necrosis. This important distinction has significant implications in the need for and approach to intervention. Finally, the evaluation of the anatomy of the underlying pancreatic duct and its relationship to the pancreatic pseudocyst is vital to clinical decision making.

Contrast-enhanced computed tomographic (CE-CT) scan is the modality of choice for the frontline evaluation of a pancreatic pseudocyst in the modern era. On CE-CT scan, a pseudocyst appears as a uniform, rounded, fluid-filled mass with a thickened, hyperdense capsule that may take on the morphology of the surrounding structures (Figure 1, *A*). WOPN is marked by associated necrosis, most often visualized as heterogeneity of the cyst fluid with solid matter and particulate debris (Figure 2, *A*). Pseudocysts most commonly occur in the lesser sac, although they may occur in the paracolic gutters, at the base of the mesentery, anterior to the stomach, or even more remotely from the pancreas deep in the retroperitoneum. CE-CT scan allows for the assessment of the pancreatic pseudocyst and its relationship to surrounding structures. It may show evidence of hyperdense material within the cyst, raising concern for hemorrhage from an associated pseudoaneurysm. It may show air within the pseudocyst, indicating infection or the presence of a fistula with the gastrointestinal tract. CE-CT scan can show evidence of pancreatic parenchymal atrophy or calcifications suggestive of underlying chronic pancreatitis. It can also show abnormalities of the underlying pancreatic duct or biliary system, although with less sensitivity and detail than magnetic resonance.

Magnetic resonance cholangiopancreatography with secretin stimulation (ssMRCP) is also a useful modality for the evaluation of a pancreatic pseudocyst (Figure 1, *B*). It can show more detailed morphology of cystic structures, improving the differentiation of the pseudocyst from neoplasm and detecting solid debris in WOPN, distinguishing it from the simple fluid of a pseudocyst (Figure 2, *B*). In addition, ssMRCP can help to delineate the anatomy of the pancreatic duct and its relationship to the pseudocyst.

Endoscopic retrograde cholangiopancreatography (ERCP) is used less commonly as a diagnostic tool in the modern era given the chance for inciting a bout of pancreatitis or for introducing enteric organisms into the pseudocyst or WOPN with the potential for infection. ERCP is well used therapeutically, however, in pseudocysts with a connection to the main pancreatic duct that may be amenable to endoscopic stenting or sphincterotomy for resolution.

Endoscopic ultrasound (EUS) may be useful in the evaluation of the pseudocyst, particularly in distinguishing it from a pancreatic cystic neoplasm. EUS examination can elucidate cyst morphology, including solid nodules or septations, and cyst relationship to the pancreatic duct and identify the presence of pancreatitis in the surrounding pancreatic parenchyma. EUS-guided fine-needle aspiration of fluid can also be helpful. High amylase fluid indicates the cyst is

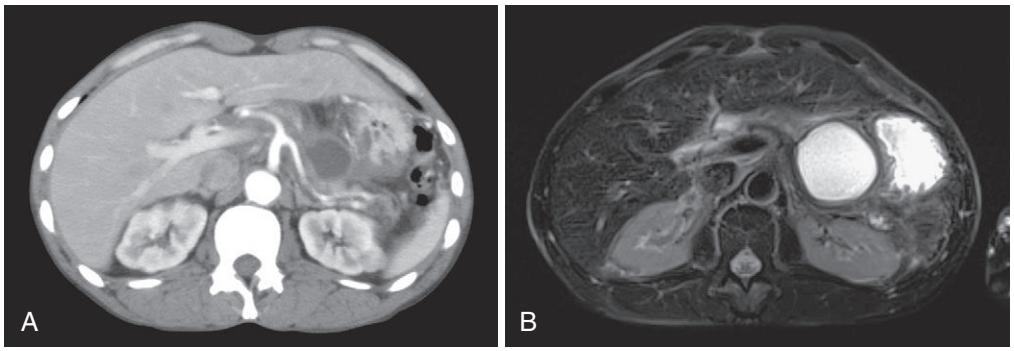

FIGURE 1 A pancreatic pseudocyst is well visualized with contrast-enhanced computed tomographic scan **(A)** as a simple fluid-filled structure with a hyperdense fibrous capsule in the body of the pancreas and with magnetic resonance **(B)** on T2-weighted imaging as a round, homogeneously enhancing lesion.

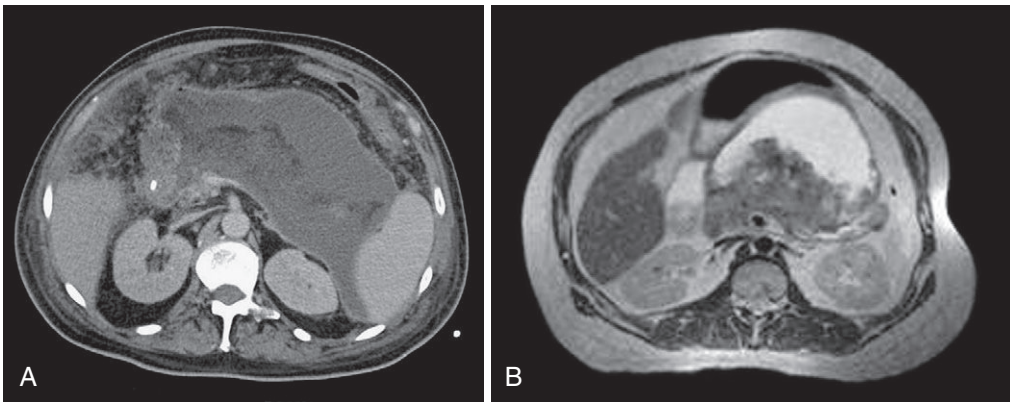

FIGURE 2 Walled-off pancreatic necrosis is shown on contrast-enhanced computed tomographic scan **(A)** as a peripancreatic fluid collection containing heterogeneous material representing solid necrotic debris and with magnetic resonance **(B)** on T2-weighted imaging as a rounded enhancing fluid-filled collection containing nonenhancing solid necrosis.

or has been in communication with the pancreatic duct. Cyst fluid high in carcinoembryonic antigen suggests the presence of a mucinous neoplasm. EUS can also be useful in the therapeutic management of pseudocysts in endoscopic cystoenterostomy.

MANAGEMENT

Pseudocysts (After Acute Interstitial Edematous Pancreatitis)

The natural history of pseudocysts in most cases involves spontaneous resolution over time. In persistent cases, however, intervention may be indicated. Historically, a pseudocyst greater than 6 cm or persistent over time (greater than 6 weeks) was considered to warrant intervention. Modern experience, however, has shown that watchful waiting is appropriate, particularly in small asymptomatic pseudocysts.

There are many reasons not to undertake operative internal drainage of a pseudocyst. The patient may be acutely and chronically unwell and a poor operative risk. The diagnosis may be incorrect despite evaluation with modern imaging studies. The collection may not be a pseudocyst as the acute fluid collection seen early in acute pancreatitis, the so-called pseudo-pseudocyst, does not need operative drainage. A sterile postnecrotic fluid collection or the pancreatic sequestrum may not need drainage. Beware of the cystic neoplasm. Many patients with mucinous cystic neoplasms have undergone cystogastrostomy with perilous outcomes. Most important is to remember that cyst internal drainage procedures do not correct an underlying pancreatic ductal disorder, and the cystoenteric or cystogastric anastomosis may not be effective long-term drainage of an obstructed pancreatic duct. A pancreatic pseudocyst that does not communicate with the main pancreatic duct can be eradicated with a number of minimally invasive techniques.

Symptomatic pseudocysts that cause pain, obstruction (biliary, enteric, mesenteric venous), hemorrhage, or perforation (enteric fistula, pancreatic ascites, pleuropancreatic fistula) warrant intervention. Delineation of the anatomy with MRCP or ERCP is the first step in management. A pseudocyst in connection with the main pancreatic duct and with otherwise normal pancreatic duct anatomy can often be well treated with ERCP-guided sphincterotomy or transpapillary stent placement, altering the pressure differential across the ampulla and allowing for preferential drainage of the pseudocyst into the duodenum with resolution of the pancreatic duct disruption.

A pseudocyst without communication to the pancreatic duct or that has failed transpapillary endoscopic management can often be managed then with drainage. Endoscopic cystogastrostomy or duodenostomy involves placing a stent with endoscopic guidance through the back wall of the stomach or duodenum into a closely opposed retrogastric pseudocyst. Both open and laparoscopic surgical approaches to cystogastrostomy and duodenostomy are also well used, with the advantage of a larger anastomosis for a more durable drainage effect and better control of hemostasis. For all cystogastrostomies and cystoduodenostomies, the stomach or duodenum must be densely adherent to the pseudocyst, or the posterior enterotomy is at risk for postoperative leak and sepsis. In this procedure, an anterior gastrotomy is performed for access to the posterior gastric wall. The flat, firm, bulging surface on the back of the gastric wall represents the underlying pseudocyst. A posterior gastrotomy is then made with cautery (or another energy device for hemostasis). A cyst wall biopsy is included to rule out a cystic neoplasm and the cystoenteric anastomosis is oversewn to ensure hemostasis. The anterior gastrotomy is sewn or stapled securely closed. Open and laparoscopic Roux-en-Y cystoenterostomies are also used for drainage of the pseudocyst that is not well adherent to the stomach into a jejunal limb, with a similar technique.

In cases with the underlying pancreatic duct pathology visualized on preoperative MRCP or ERCP (stricture, obstruction), drainage alone may result in long-term failure of the operation with pseudocyst recurrence. If the pancreatic duct pathology is in the body or tail of the pancreas, distal pancreatectomy is a better, more durable operation than a cystoenterostomy.

Walled-Off Pancreatic Necrosis (After Acute Necrotizing Pancreatitis)

Walled-off pancreatic necrosis in many cases resolves spontaneously over time. In patients with evidence of infected necrosis, either by aspiration and culture or by visualized air within the collection on cross-sectional imaging, drainage or débridement is indicated. In the patient with sterile necrosis who is persistently unwell, marked by pain or nutritional failure with continued disease burden, intervention is also warranted.

The multiple approaches to the treatment of WOPN include the classic open necronectomy, the transgastric approach (either open, laparoscopic, or endoscopic), percutaneous drainage, and the retroperitoneal approach (open or videoscopic). The choice of approach is dependent on the anatomy and distribution of the necrosis, other patient-related factors (body mass index [BMI], surgical history, comorbidities), and importantly, surgeon experience and preference.

Similar to the pancreatic pseudocyst, the initial step in planning intervention in WOPN is to define the underlying pancreatic ductal anatomy with MRCP (or ERCP). Failure to address pancreatic ductal pathology may lead to primary operative failure and recurrent problems.

Open necrosectomy remains the mainstay of management of pancreatic necrosis. In this approach, the lesser sac is entered and gentle blunt débridement undertaken. The placement of large catheters for postoperative drainage and lavage is a classic component of this technique. Laparotomy allows for access to the entire peritoneal cavity for optimal débridement and safe accomplishment of hemostasis. In addition, concomitant cholecystectomy and enteral feeding access are easily obtained.

Open necrosectomy is always a good approach to pancreatic necrosis, even in this modern era. It is particularly suited for the patient with a large, diffuse disease burden, including both paracolic gutters and the root of the mesentery, which are not easily reached with less invasive techniques.

Transgastric necrosectomy emerges from the experience with transgastric drainage of pseudocysts. This technique can be accomplished in an open fashion or laparoscopically. An anterior gastrotomy is performed to gain access to the posterior gastric wall. The site of the WOPN is identified as a firm bulge in the wall of the stomach. The cavity is then entered with cautery or other energy sources (i.e., ultrasonic shears). This posterior gastrotomy is best made in a generous fashion to allow for thorough inspection and débridement of the necrosis cavity. The posterior gastrotomy and cavity wall opening are then secured together for hemostasis with a running absorbable suture. The anterior gastrotomy is closed either with a running suture or with a stapler. The endoscopic approach entails an endoscopically created posterior gastrotomy into the necrosum, often with the use of cautery and pneumatic dilation. Débridement is undertaken with endoscopic instrumentation and can be time and resource intensive.

The transgastric approach is well suited for the patient with disease burden primarily limited to the lesser sac and with a posterior mass effect on the gastric wall. An advantage of the transgastric approach includes the potential creation of a pancreatogastric fistula in cases of a disconnected left pancreatic remnant, potentially avoiding the need for distal pancreatectomy or fistula-enterostomy down the road.

In selected patients with pancreatic necrosis, image-guided percutaneous drainage can be an effective means of therapy. Percutaneous drains have the obvious advantage of avoiding the insult of surgical or even endoscopic intervention. Percutaneous drains serve to drain any liquid component of the necrosum but do not serve well to remove solid necrotic tissue. Several studies have shown significant percentages of patients with WOPN with response to percutaneous drainage alone without surgery (15% to 45%). At a minimum, percutaneous drainage can provide temporization for an ill patient early in the course of necrosis to allow for physiologic recovery and a delayed débridement. Drains are also an essential component of the retroperitoneal approach to pancreatic débridement.

The retroperitoneal approach to pancreatic débridement has been described with an open technique but is more commonly applied with laparoscopic guidance. It has been referred to as videoscopic-assisted retroperitoneal débridement (VARD) by the group in Seattle and as the step-up approach by the Dutch. This technique involves placing percutaneous catheters, typically in the left flank, as an initial attempt at drainage. In those patients with continued solid disease burden, the catheter track is then used as a guide into the necrosis cavity through the left flank into the lesser sac. The laparoscope is used for visualization, and laparoscopic instruments are used for the débridement. A large-bore catheter is left behind for postoperative irrigation and drainage. The retroperitoneal approach is best suited for patients with WOPN that extends into the left paracolic gutter. It can have limited effectiveness with disease burden at the base of the mesentery or into the right paracolic gutter.

Disconnected Left Pancreatic Remnant

In severe cases of acute pancreatitis, significant parenchymal inflammation and necrosis may result in obliteration of the main pancreatic duct, typically at the neck of the pancreas, resulting in a disconnected left pancreatic remnant. This viable body and tail tissue continues to have exocrine production, which does not have an avenue for drainage. The result is a midbody pseudocyst or persistent pancreatic fistula if a drain is in place (Figure 3). Patients with this problem may present several months after the resolution of severe pancreatitis with the signs and symptoms of a pseudocyst and are well treated with resection of the tail remnant. If there is a significantly large segment of disconnected pancreas, a cyst enterostomy can be undertaken to preserve pancreatic endocrine function. Alternatively, a distal pancreatectomy with islet autotransplantation is an option. If this anatomy is apparent at the time of initial débridement, the patient can undergo combined open distal pancreatectomy and débridement if they are physiologically fit for this potentially morbid operation. Alternatively, a transgastric débridement approach may be considered to allow for the creation of a pancreatogastric fistula and the internal drainage of this remnant.

Pseudocysts Associated With Chronic Pancreatitis

In the setting of chronic pancreatitis, delineation of the underlying pancreatic ductal anatomy is essential to the proper management of the pseudocyst. Unaddressed obstruction from stricture or stone is likely to result in long-term management failure. Endoscopic intervention with stenting or stricture dilation is a good initial approach, particularly in patients with small duct disease involving the pancreatic head. In small duct disease with a stricture in the body or tail, left-sided resection may be appropriate. In the setting of dilated duct pancreatitis, a drainage procedure consisting of a lateral pancreaticojejunostomy is a good option.

CONCLUSION

Peripancreatic fluid collections are heterogeneous. Most are benign and resolve spontaneously. Some, however, are complex, with significant potential for morbidity, and can be vexing in management. Proper categorization can aid in clinical decision making, as

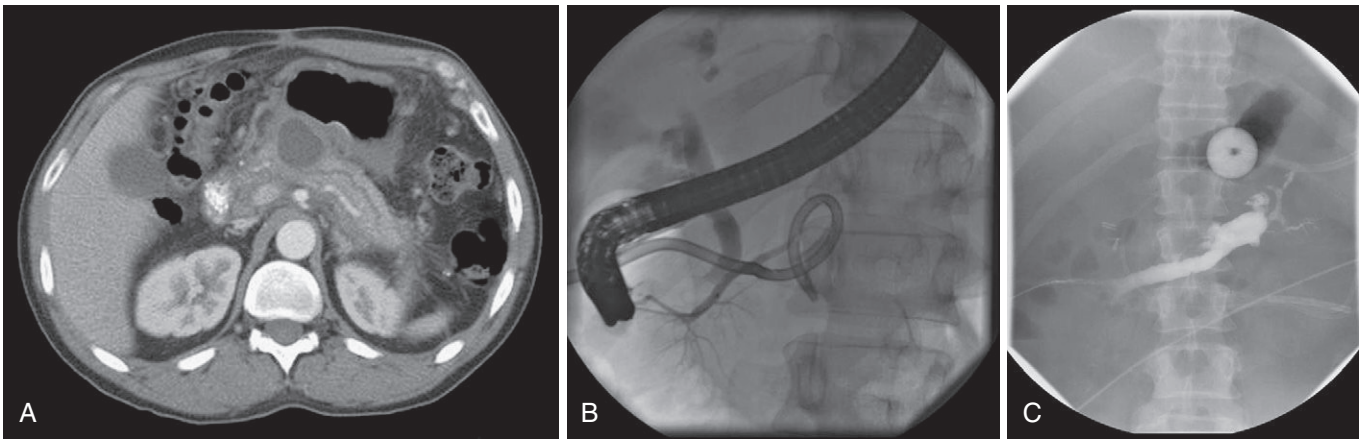

FIGURE 3 A disconnected left pancreatic remnant occurs after necrosis in the neck of the pancreas with resultant obliteration of the main pancreatic duct. The disrupted pancreatic duct from the viable left pancreas, now not in continuity, leaks and results in a midbody pseudocyst. This condition is visualized on contrast enhanced computed tomographic scan **(A)**. It is shown by an abrupt cut-off of the pancreatic duct at the neck on endoscopic retrograde pancreatography **(B)** and by a drain track fistulagram filling only a small tail remnant **(C)**.

can determination of the underlying pancreatic ductal anatomy. Symptomatic pseudocysts can be drained, but the underlying pancreatic duct pathology should be considered and may warrant a distal resection. Infected pancreatic necrosis and sterile necrosis with persistent illness require drainage or débridement. There are multiple effective approaches to pancreatic débridement in the modern era.

Pancreatic Ductal Disruptions Leading to Pancreatic Fistula, Pancreatic Ascites, or Pancreatic Pleural Effusion

Graham W. Donald, MD, and O. Joseph Hines, MD

INTRODUCTION

Pancreatic ductal disruptions represent a challenging clinical problem for the surgeon. The etiology, diagnoses, complications, treatments, and outcomes of ductal disruptions are highly variable. These are the result of or directed at the correction of one overarching problem—namely, leakage of caustic pancreatic enzymes outside of the ductal system into the pancreatic parenchyma or the peripancreatic space (pseudocysts, pancreatic necrosis, peripancreatic fluid collections) into other bodily cavities (pancreatic ascites, pancreatic pleural fistula) or externally through the skin (pancreaticocutaneous fistula).

Management of ductal disruption and the conditions that result require collaboration with multiple specialties, including gastroenterology, radiology, and surgery. Furthermore, current treatment strategies are evolving with special consideration for timing after the inciting event for intervention. Certainly when surgical intervention is being considered, the patient should be medically optimized and nutritionally replete, and the condition and ductal anatomy should be thoroughly defined.

ETIOLOGY AND COMPLICATIONS

Pancreatic ductal disruption can occur in the setting of pancreatic disease (acute and chronic pancreatitis), postoperatively after pancreatic surgery (e.g., pancreaticoduodenectomy, distal pancreatectomy, débridement for necrosis), or after trauma.

Ductal disruption occurring after an episode of acute pancreatitis or in the setting of chronic pancreatitis results in a variety of complications. *Peripancreatic fluid collections* refer to the presence of fluid around the pancreas with or without a semisolid debris component. The amount of fluid is likely a reflection of the caliber of the duct injured during the inflammatory process (minor peripheral ductule versus main pancreatic duct). *Pancreatic pseudocysts* are fluid collections that, unlike peripancreatic fluid collections, are classically described as having a thick wall that is lacking an epithelial lining and require several weeks to form.

Leakage of fluid beyond the confines of the pancreas or peripancreatic space—what can be called an internal pancreatic fistula—also occurs in cases of ductal disruption and usually in conjunction with the aforementioned problems (fluid collections, pseudocysts, necrosis). They also present unique problems, outlined below, requiring particular intervention related to anatomic considerations.

Pancreaticocutaneous Fistulae

Pancreaticocutaneous fistulae can occur, albeit rarely, in a spontaneous fashion after pancreatitis because there are no natural pathways from within the abdominal cavity to the skin. More commonly, these occur after drainage procedures for fluid collections or as a result of a drain placed at the time of surgery for operative débridement or resection.

Postoperative Fistulae

Pancreatic resection resulting in a pancreatic fistula or "leak" (i.e., iatrogenic ductal disruption) occurs in between 10% and 15% of pancreaticoduodenectomies and in around 20% to 30% of middle and distal pancreatectomies. After pancreaticoduodenectomy, pancreatic fistula is the result of a disruption of the anastomosis between the pancreatic remnant and the jejunum or stomach, and it can often be predicted based on the consistency of the pancreas and the diameter of the main pancreatic duct. It is well documented that the resection of a normal or soft pancreas has a much higher rate of fistula than resection of a firm or fibrotic pancreas and that a main duct of less than 3 mm increases the chance of postoperative fistula.

Pancreatic Ascites

Pancreatic ascites refers to enzyme-rich pancreatic fluid accumulated within the peritoneal cavity (Figure 1), and it often occurs with rupture of a pseudocyst in the face of a disrupted duct. The presence of pancreatic ascites may not be clear in a patient with ethanol-induced pancreatitis because these patients may have cirrhosis and some degree of ascites due to elevated portal vein pressures. Pancreatic ascites can also occur after splenectomy, distal pancreatectomy, or left nephrectomy wherein the tail of the pancreas has been damaged and the pancreatic fluid that leaks is not contained.

Pancreatic Pleural Fistulae

Pancreatic pleural fistulas can result in a pleural effusion or fluid within the mediastinum due to tracking of pancreatic juices from a fluid collection or pseudocyst in the abdominal cavity, usually through the foramina of the diaphragm and into the chest cavity. A rare clinical entity, it is infrequently associated with an acute episode of pancreatitis. More often, pancreatic pleural fistulae arise in the setting of chronic pancreatitis or in patients with recurrent attacks of acute pancreatitis with a history of alcohol abuse.

FIGURE 1 Abdominal computed tomographic (CT) scan demonstrating pancreatic ascites with fluid around the liver and a fluid collection within the pancreas.

Trauma-Induced Ductal Disruption

A final etiology of ductal disruption is trauma. These injuries are associated with a high mortality rate and with blunt deceleration injury, oftentimes in patients who were wearing seatbelts when in a motor vehicle accident. Clinicians should therefore have a high index of suspicion for pancreatic injury in patients who are victims of this type of injury. These disruptions classically occur in the midbody of the pancreas where it traverses the spinal column, and it can lead to extravasation of the enzyme-rich fluid, resulting in a pseudocyst, a peripancreatic fluid collection, or any of the anomalous fistulous collections between the ductal system and bodily cavities heretofore mentioned.

CLINICAL PRESENTATION AND DIAGNOSIS

Pancreaticocutaneous/Postoperative Fistula

This clinical condition occurs when a drain placed percutaneously or surgically does not cease to drain enzyme-rich fluid. After pancreaticoduodenectomy, a leak is typically diagnosed if a surgical drain near the pancreaticoenteric anastomosis is draining greater than 30 mL/day of enzyme-rich fluid, with an amylase concentration of greater than three times the normal limit of serum amylase and after the fifth postoperative day. However, because of the wide variation in definitions of postoperative pancreatic fistula across the literature, an international study group (Bassi C, et al., 2005) recently established an all-inclusive definition of drain output of any measurable volume on or after postoperative day 3 with an amylase greater than three times the serum amylase level. The clinician should have a high index of suspicion for fistulae when a postoperative patient has any of the following: failure to convalesce in a normal fashion, nausea or vomiting, persistent fevers or unexplained sepsis, malnutrition or failure to thrive, or prolonged abdominal pain.

Pancreatic Ascites

Patients with pancreatic ascites typically complain of abdominal discomfort, and history and physical exam reveal weight loss, likely due to malnutrition in the setting of malabsorption. Examination reveals abdominal distention or fluid wave without tenderness.

Pancreatic Pleural Fistulae

Patients with a pancreatic pleural fistula may demonstrate dyspnea or cough, or show physical exam signs consistent with pleural effusion, such as decreased or absent breath sounds, decreased fremitus, and dullness to percussion. Radiograph may show fluid in the chest (Figure 2).

In all of these cases, failure to improve after the inciting event (pancreatitis, operation, or trauma) should prompt a computed tomographic (CT) scan to access for fluid collections (Figure 3). If the diagnosis is still unclear regarding the origin of fluid, the collection can be aspirated and tested for pancreatic amylase. Although there has been some discussion regarding the role of fluid analysis and the risk of introducing infection into a previously sterile collection, the likelihood of this is minimal. Aspiration of the pleural effusion may be both diagnostic and therapeutic, with the introduction of a tube thoracostomy.

Diagnostic Evaluation

CT is the most appropriate initial study when investigating suspected pancreatic ductal disruption. Optimal visualization of the pancreas is obtained with a pancreatic protocol CT, which involves images captured with a multidetector row helical scanner in three phases (arterial, late arterial, and venous) using thin slices. Sometimes oral contrast can be added to improve the quality of the image. Furthermore, CT guidance offers the ability to intervene percutaneously should any fluid collections or abscesses be apparent. In the case of pancreatic fistula, percutaneous drainage is essentially creating an iatrogenic, controlled pancreaticocutaneous fistula.

Endoscopic retrograde cholangiopancreatography (ERCP) is not recommended in the early period when ductal disruptions are suspected. The reasons are that first, ERCP carries with it a not insignificant risk of postprocedure pancreatitis that may exacerbate the inciting condition, and second, the risk of introducing infection via instrumentation may not outweigh the benefit of early characterization of ductal anatomy. Most importantly, however, is the fact that most of the conditions of pancreatic ductal disruption described above will resolve spontaneously over the course of a few weeks with conservative therapy alone. There is some literature advocating for ERCP because it has both diagnostic and therapeutic capabilities in the form of transpapillary stenting for persistent pancreatic fistula or for chronic pain associated with chronic pancreatitis. ERCP should instead be reserved for the chronic complication of a nonresolved ductal disruption with inadequate drainage into the gastrointestinal tract (see the "Management and Treatment" section). While classification systems for ductal disruption have been proposed, it is our opinion that the most important categorization of ductal anatomy is the distinction of whether or not the fluid collections that persist are in communication with the main duct and whether or not the duct is completely disrupted—that is, so-called *disconnected duct syndrome*—because definitive operative intervention is often necessary in these cases.

A safer and less invasive alternative to ERCP if CT scan images are equivocal is magnetic resonance cholangiopancreatography (MRCP). MRCP can delineate ductal anatomy (particularly of the main pancreatic duct), identify the majority of disruptions and fistulae without the need to instrument the duct, assess the need for ERCP or a step-up in therapy, be used in the setting of failed ERCP duct cannulation, or be used to monitor progression of a disruption over time without the need for repeat ERCP. Many institutions utilize MRCP to investigate persistent suspected ductal disruptions or ongoing fistulae prior to ERCP. Drawbacks of MRCP include possible lower spatial resolution of the ductal anatomy when compared to ERCP because MRCP depends on endogenous liquid within the duct for visualization, while ERCP takes advantage of the injection of dye as a contrast material. Secretin administration can stimulate pancreatic secretion and increase the sensitivity of MRCP.

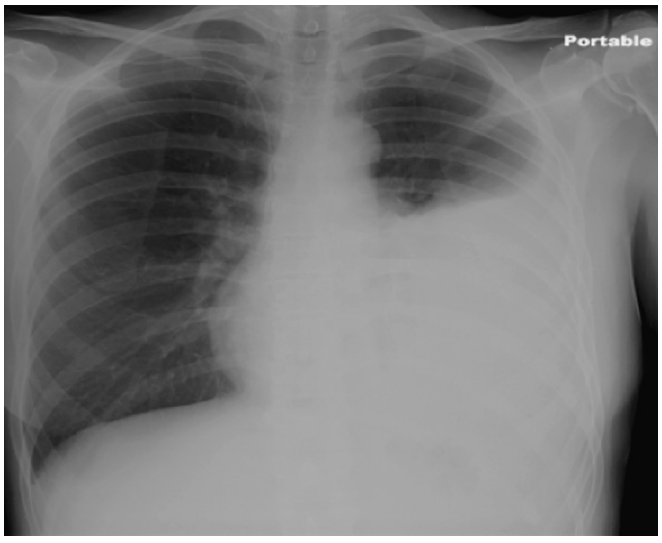

FIGURE 2 Chest x-ray demonstrating a left-sided pleural effusion secondary to a pancreaticopleural fistula.

MANAGEMENT AND TREATMENT

While the problem of pancreatic ductal disruption can lead to a variety of complications as previously mentioned, the management of this problem is largely dependent on the acuity or chronicity of the clinical problem. Early management in the acute phases in a majority of cases is conservative, because these disruptions and the anomalous fluid collections often resolve. Nasojejunal feeding or total parenteral nutrition to decrease pancreatic activity during the acute phase of pancreatitis that comes with oral or prepyloric alimentation, along with percutaneous management of fluid collections under CT or ultrasound guidance, are staples of early therapy. Repeat interval imaging at 4 to 6 weeks is obtained to assess the state of fluid collections as they respond to these interventions.

In cases where fluid collections and fistulas do not improve after being given adequate time to resolve or if patients' symptoms worsen, both of which indicate ongoing, large-caliber ductal disruption or superimposed infection, intervention is required and defined based on the inciting event and the condition to be addressed. Two of these—pseudocyst and postoperative leak—are unique clinical circumstances and will be addressed first.

Pseudocyst

As with necrosis, management of pseudocysts involves several specialties, each with varying degrees of invasiveness. Where traditionally operation was the gold standard intervention for mature pseudocysts with resolution in 90% to 95% of cases, percutaneous and endoscopic techniques to manage these problems are quickly gaining ground in terms of utilization. Percutaneous intervention is limited to simple drainage and carries the risk of an external fistula caused by an external drain and a higher recurrence rate. Endoscopic treatments involve transgastric and, rarely, transduodenal drainage. An additional modality that experienced endoscopists can employ is the placement of transpapillary stents during ERCP, which are small-caliber plastic catheters that traverse the sphincter of Oddi. Pancreatic fluid can then drain through the path of least resistance into the duodenum. This technique is most successful when there is radiographic evidence on ERCP or CT scan of connection between the main pancreatic duct and the pseudocyst.

Operative intervention includes cystogastrostomy or roux-en-Y cystojejunostomy, with postoperative hemorrhage and sepsis being more common after cystogastrostomy. Cystogastrostomy should be performed when the cyst is in close proximity or adherent to the posterior aspect of the stomach. After anterior gastrostomy, the pseudocyst is located with needle aspiration and drained into the stomach by excising a circle of the gastric wall into the cyst or by using a linear or circular stapler. If a portion of the gastric wall is excised, the cut edge of the stomach should be sewn with a running, locking absorbable suture to prevent postoperative hemorrhage. The anterior stomach is then closed in two layers. If the cyst is not near the stomach, a side-to-side cystojejunostomy should be performed and often positioned through the left transverse mesocolon.

Postoperative Pancreatic Fistulae/ Pancreaticocutaneous Fistulae

We previously discussed the association of pancreatic texture and main duct diameter in the development of postoperative pancreatic fistula after pancreaticoduodenectomy. Other risk factors include the underlying disease, with pancreatic fistula more likely in cases of

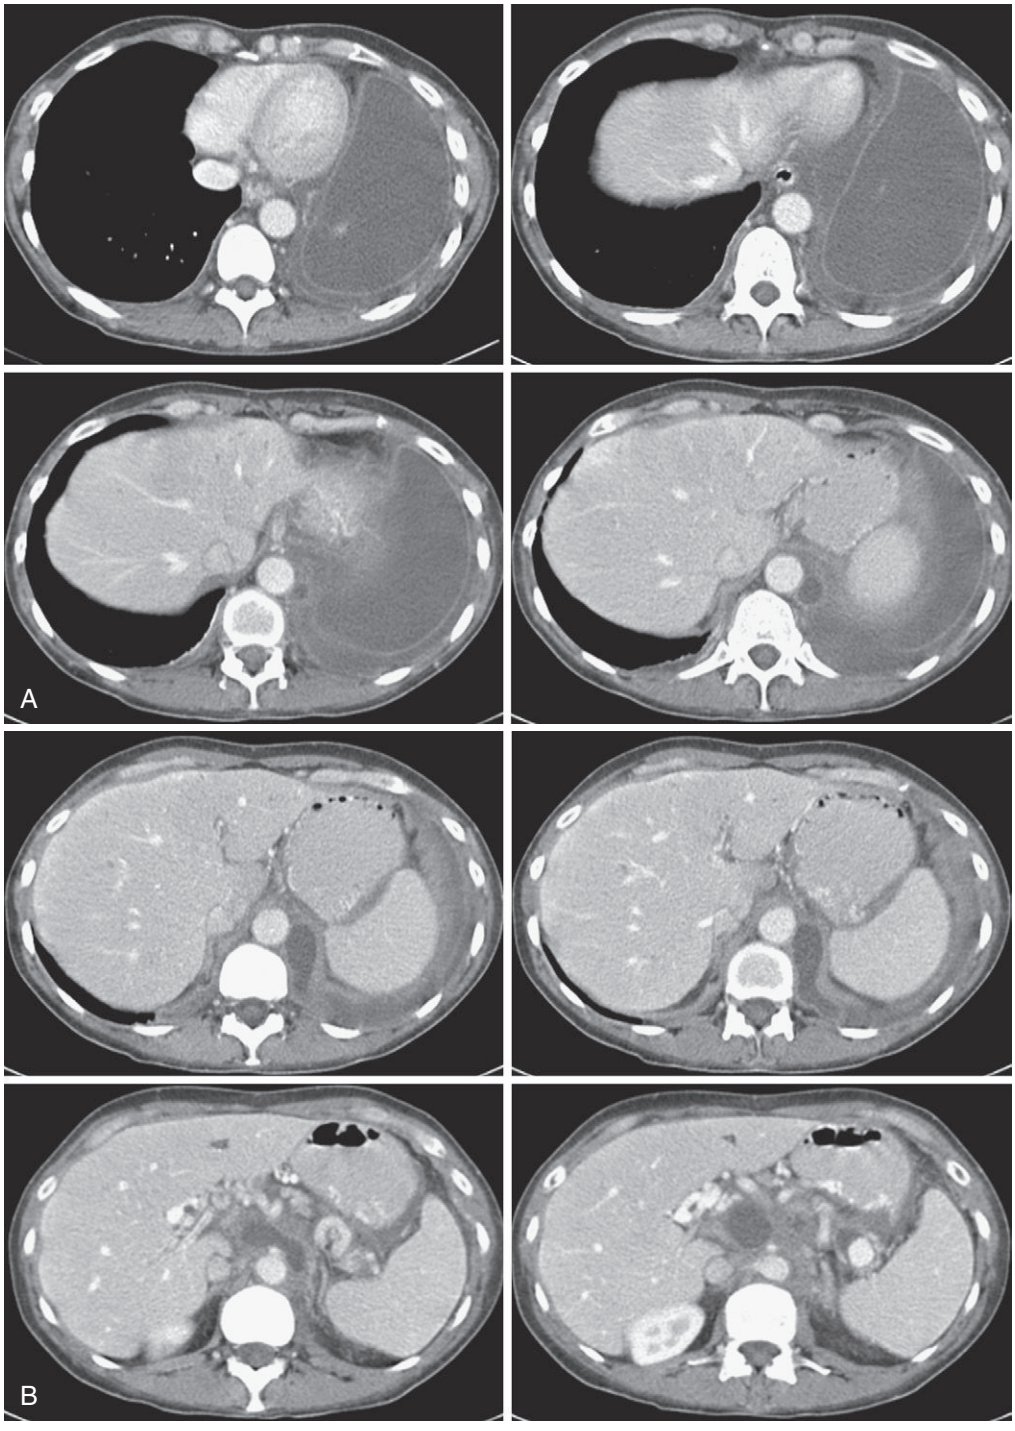

FIGURE 3 Computed tomographic (CT) scans showing a large pleural effusion **(A)**. There is a pancreatic pseudocyst communicating with this effusion **(B)**.

Continued

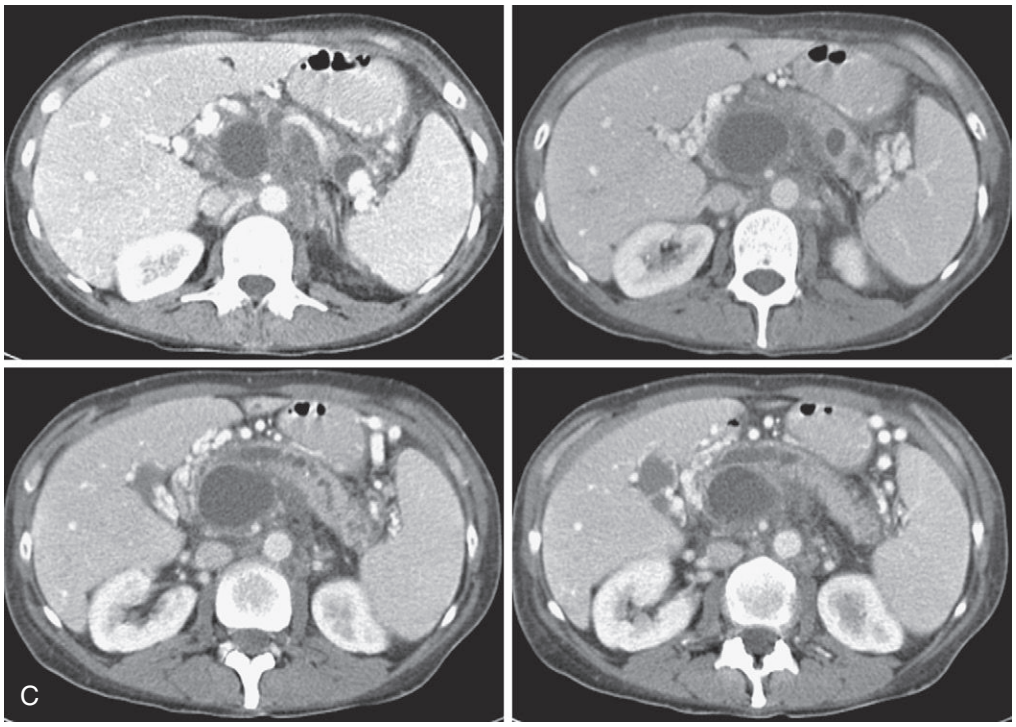

FIGURE 3, cont'd The final panel demonstrates chronic pancreatitis and a dilated pancreatic duct, as well as splenic vein thrombosis, a splenic artery aneurysm, and left-sided portal hypertension **(C)**.

benign cystic neoplasms and periampullary tumors and less likely in adenocarcinoma. Much research has been directed toward preventive measures to decrease the risk of these leaks developing.

Prophylactic somatostatin analogues have been widely studied. While individual studies show marginal benefit in reducing the rate of postoperative fistula after pancreaticoduodenectomy or distal pancreatectomy with administration of these analogues, subsequent meta-analyses of randomized controlled trials show no benefit. This is a testament to the heterogeneity of the studies, including differences in administration of the drug, the analogue used, and the definition of pancreatic fistula. A somatostatin analogue would, however, be useful in the case of high-output fistulae to control the volume and possibly lead to faster closure.

In regards to intraoperative measures, application of fibrin glue intraoperatively has garnered interest in the literature. Studies describing the use of fibrin glue on the pancreatic stump or circumferentially around the anastomosis after pancreaticoduodenectomy have varied results, overall showing no difference in fistula rates.

Methods of pancreatic reconstruction for pancreaticojejunostomy after pancreatic head resection include end-to-side duct-to-mucosa anastomosis or invagination of the pancreatic remnant. Results have shown, including one randomized controlled trial, that there is a significantly lower rate of fistula formation in the invagination group. In addition, some have advocated that a pancreaticogastrostomy may decrease postoperative leak. Validation studies are needed.

Prophylactic pancreatic duct stenting intraoperatively during pancreaticoduodenectomy theoretically decompresses the pancreatic duct and directs the flow of the enzyme-rich fluid into the enteric limb. As with the previous preventive strategies, this modality has mixed results in terms of decreasing fistula rate, and its role is not clear.

Once the diagnosis of a persistent pancreatic leak after resection is made, efforts should be directed at ensuring the patient is stable. Intravenous fluids should be administered liberally because these patients can suffer significant pancreatic fluid loss. Antibiotics should be empirically started for any patient with persistent fevers or an elevated white blood cell count. The management then depends on the nature of the initial operation (i.e., pancreatic head resection vs distal pancreatectomy vs enucleation, etc.). In the case of pancreatic fistula after pancreatic head resection, nearly 95% of fistula will resolve with conservative management alone—namely, prolonged tube drainage, which can be managed in the outpatient setting as long as the patient is eating and without fever.

In the case of an enucleation or distal pancreatectomy or in cases of débridement, MRCP or ERCP should be carried out to define the nature of the ductal disruption. It is at this point that transpapillary stents can be placed with the intent that stenting a downstream portion of the pancreatic duct will cause the enzyme-rich fluid to travel the path of least resistance into the intestine. Figure 4 demonstrates the successful stenting across a ductal disruption after enucleation of an insulinoma.

If a patient has a fever in the setting of a pancreatic fistula, a CT scan should be obtained to look for an intra-abdominal fluid collection, which could be drained during the same scan. If a patient has persistent fistula for several weeks after discharge, a fistulogram should be obtained and the original drain replaced with a red rubber catheter. At this point, nearly all fistulae close within 1 or 2 days because the rubber incites an inflammatory response, closing the fistula tract.

Late reoperation for persistent pancreatic fistula after a resection is thus rarely needed, but it would entail creating an anastomosis between a Roux limb to the fistula tract. At the time of laparotomy, the fistulojejunostomy is performed by first identifying the fistula tract. The tract is then traced toward and as close to the pancreas as safely possible and then sewn to a Roux limb of jejunum in an end-to-side fashion.

Early reoperation for pancreatic fistula is also rarely required but may be necessary in cases of hemorrhage caused by erosion of the fistula into an artery (a so-called "herald bleed") or for abscesses or fluid collections not amenable to percutaneous drainage. Reoperation consists of wide drainage of any fluid collections with drains left in place. In the case of hemorrhage, bleeding can be initially addressed by embolization through interventional radiology techniques.

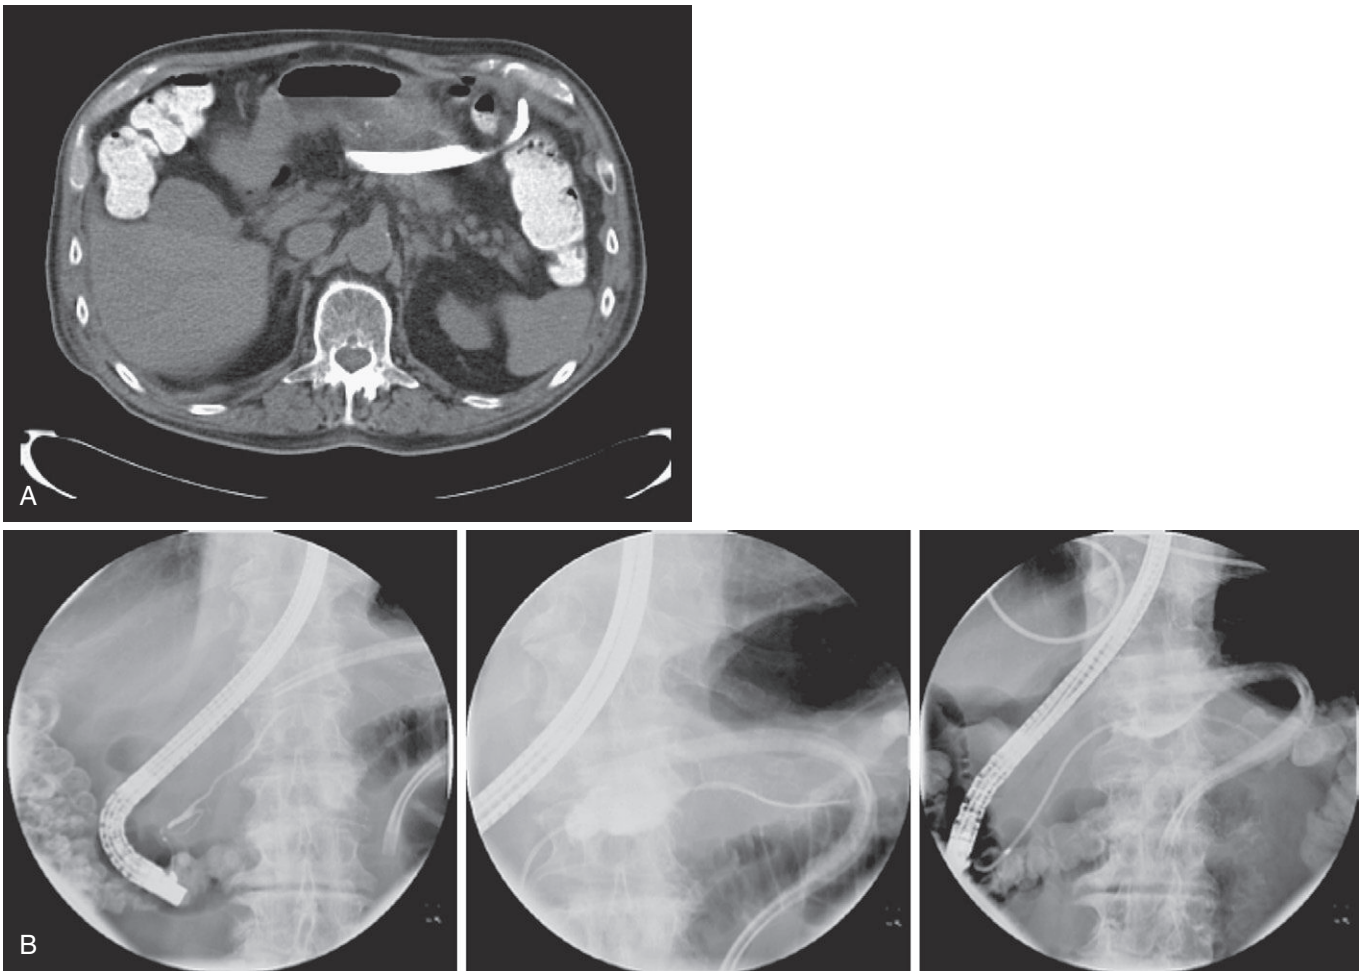

FIGURE 4 Pancreatic duct disruption at the pancreatic neck after an enucleation of an insulinoma followed by ERCP (demonstrating leak) **(A)** and placement of a long 5 French 15 cm pancreatic duct stent across the leak **(B)**.

Pancreatic Pleural Fistulae

Traditionally, pancreatic pleural fistulae are subjected to a nonoperative treatment trial for several weeks prior to any attempt at operative correction of the underlying ductal disruption. As with other pancreatic fistula, nonoperative treatment includes bowel rest and nutritional support. These patients may require repeated large-volume thoracentesis or tube thoracostomy. Medical management includes administration of antisecretagogues, including octreotide. If these fail to resolve the fistula, an interventional strategy may be attempted with ERCP and main duct stenting.

Conservative strategies, however, have low success rates in the case of pancreatic pleural fistula (with fistula resolution approximately only one third of the time), as well as high rates of recurrence and morbidity. We propose that appropriate patients be considered early on for surgical intervention with a Roux-en-Y limb pancreaticojejunostomy to the base of the fistula (Figure 5). In our experience, a majority of these patients will require no further therapy and will be subject to significantly shorter treatment duration.

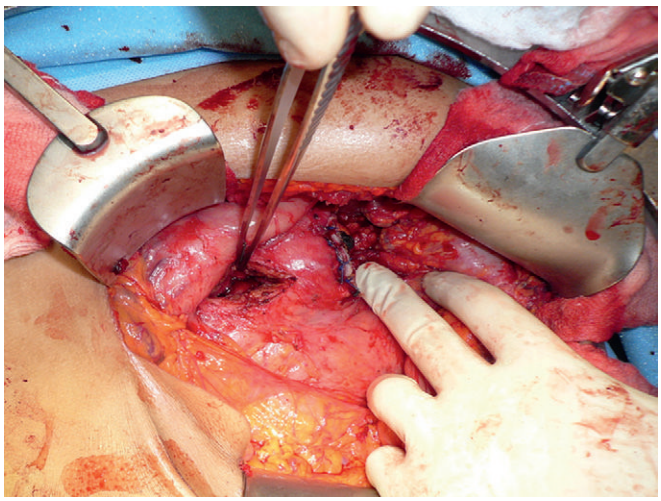

FIGURE 5 Exposed main pancreatic duct in the patient in Figure 3. A Roux-en-Y pancreaticojejunostomy was performed to control a pancreaticopleural fistula after a distal pancreatectomy, a splenectomy, and an excision of a splenic artery aneurysm.

Pancreatic Ascites

Initial management of pancreatic ascites entails nonsurgical, conservative strategies of nutritional support (nasojejunal feedings or total parenteral nutrition); antisecretagogues to diminish pancreatic secretions; and repeat, large-volume paracentesis. Salvage surgery is reserved for those cases that did not resolve in 6 weeks. Operative

management depends on the ductal anatomy. If the pancreatic ascites is due to a ductal disruption (defined by imaging or ERCP) without a pseudocyst, internal drainage into a Roux-en-Y limb is the operation of choice. If the ductal disruption is in the tail of the pancreas and the proximal duct is normal, distal pancreatectomy and oversewing of the remnant can be performed. If a ruptured pseudocyst is present, surgical therapy should be in the form of cystogastrostomy or Roux-en-Y cystojejunostomy.

It should be noted, however, that endoscopic therapy is becoming more advanced. Experienced endoscopists may be able to bridge a disruption with a stent via ERCP, with simultaneous endoscopic drainage of fluid collections or percutaneous drainage, thus precluding the need for surgery.

CONCLUSION

Overall, ductal disruption leading to pancreatic fistula, whether that be a thoracopancreatic, intra-abdominal (pancreatic ascites) or pancreaticocutaneous, the mainstay of therapy is ensuring first and foremost that the patient is receiving adequate nutritional support. Beyond that, the modalities of medical management, interventional procedures (radiologic and endoscopic), and surgery should all be considered. The optimal strategy or combination of strategies has changed considerably over recent years with advances in technique and is dependent on the etiology of the ductal disruption, the nature of the disruption, the overall condition of the patient, and access to resources.

The Management of Chronic Pancreatitis

Timothy R. Donahue, MD, and
Howard A. Reber, MD

INTRODUCTION

Most patients with chronic pancreatitis seek medical care because of the pain that is commonly associated with the disease. This chapter reviews briefly the diagnosis, medical management, and endoscopic treatment of pain in these patients. A more detailed discussion of the surgical management and the operations for pain relief is provided, including the Peustow, Frey, and Beger procedures and pancreaticoduodenectomy.

DEFINITION AND TYPES OF CHRONIC PANCREATITIS

Chronic pancreatitis is characterized by progressive inflammatory changes in the pancreas that result in permanent structural damage. The inflammation is usually associated with epigastric abdominal pain, which is the most common presenting symptom. Nevertheless 5% to 10% of patients remain pain-free. The structural damage can result in impairment of endocrine and exocrine function. Patients may develop type I diabetes mellitus and fat malabsorption. Chronic pancreatitis contrasts with acute pancreatitis, which is an acute inflammatory response to pancreatic injury that often does not progress and is usually reversible. The two conditions may overlap, and patients with chronic pancreatitis can have intermittent episodes of acute inflammation. However the histopathologic features of the gland with chronic pancreatitis (acinar and islet atrophy, and chronic inflammation with fibrosis) do not return to normal when the episodes resolve. Less commonly, repeated episodes of acute pancreatitis can lead to chronic pancreatitis when they cause structural damage in the pancreas, such as ductal strictures or disruptions, or pseudocysts.

Due to the chronic inflammation, patients with chronic pancreatitis are at risk for pancreatic cancer. It has been shown that oncogenic KRAS mutations coupled with inflammation can lead to malignant transformation. Approximately 4% of patients with chronic pancreatitis develop pancreatic cancer in their lifetime.

Chronic pancreatitis has many causes. Alcohol abuse is the most common cause, particularly in the Western world, where it is the cause of 60% of cases. Caustic environmental insults also have been implicated. Certain anatomic changes that obstruct the pancreatic ducts also may lead to chronic pancreatitis. These include ductal strictures and disruptions, pseudocysts, stones, periampullary tumors, pancreas divisum, or mechanical and structural changes of the pancreatic duct sphincter. Chronic pancreatitis due to ductal obstruction is less likely to be associated with ductal calcification, which is more common in alcoholic chronic pancreatitis.

There are a number of genetic causes of chronic pancreatitis. These include mutations in the cystic fibrosis transmembrane receptor (CFTR), trypsin inhibitor (SPINK1), and trypsin-1 gene (PRSS-1).

Many less common causes complete the list. Autoimmune pancreatitis occurs in a small number of patients. It is usually associated with elevated serum levels of IgG4. Active flares can be relieved with systemic steroids. However, chronic and progressive inflammation can lead to the development of chronic pancreatitis. Tropical pancreatitis, another unusual cause, is rare in the Western world. Unfortunately, the exact cause of the disease often cannot be determined, and patients are diagnosed with "idiopathic" chronic pancreatitis in up to 30% of cases.

DIAGNOSIS AND SEVERITY CLASSIFICATION

The diagnosis of chronic pancreatitis can be difficult because other conditions may produce similar symptoms. If one is suspicious of the diagnosis, it is important to send these patients to a medical professional with experience in the management of pancreatic diseases. With disease progression, most patients experience abdominal pain; exocrine and endocrine dysfunction usually occur later. The pain is multifactorial; this may be due in part to increased intraductal and parenchymal pressure of the pancreas, which leads to ischemia of the gland. An increase in the number and sensitivity of intrapancreatic pain sensors also occurs. Exocrine function usually declines before endocrine function, but clinical evidence of insufficiency may not become evident for many years after the histopathologic changes begin. When exocrine function is impaired significantly, patients may no longer have elevations of pancreatic enzymes in the serum during episodes of acute inflammation.

Many imaging tests can be used to diagnose and "stage" chronic pancreatitis. On abdominal plain films, intraductal calcifications can be seen in 30% to 50% of patients. These are pathognomonic for the disease and are thought to be due to increased protein concentration in the pancreatic juice, which leads to concretions and proteinaceous plugs that eventually calcify (Figure 1).

Computed tomographic (CT) scan or magnetic resonance imaging (MRI)/magnetic resonance cholangiopancreatography (MRCP) are commonly used and are quite accurate for diagnosis. In most cases, there is characteristic beading of the main pancreatic duct with side branch ectasia (Figure 2) or ductal dilation. Endoscopic retrograde cholangiopancreatography (ERCP) is an invasive test that is now only occasionally used for diagnostic purposes. More often, it has a therapeutic role to manage ductal stones and strictures. The Cambridge Classification System (Table 1) was based on ERCP findings and used to divide patients into three categories according to the extent of the ductal changes. These correlate with pancreatic functional impairment. The categories include Cambridge I: equivocal; Cambridge II: mild to moderate; and Cambridge III: considerable changes (Figure 3). This classification can still be used today based on the ductal features evident from noninvasive imaging. Endoscopic ultrasound (EUS) is the highest-resolution test to visualize the pancreatic parenchyma and ducts, and it has been used to detect some of the earliest changes of chronic pancreatitis. EUS in the setting of more advanced chronic pancreatitis is used to obtain pancreatic tissue (fine needle aspiration) to differentiate chronic pancreatitis and pancreatic cancer. Cancer should always be excluded first in patients about to undergo endoscopic or surgical therapy.

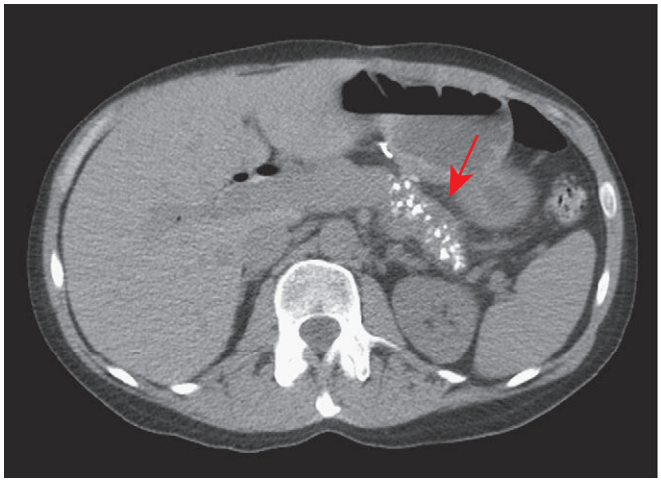

FIGURE 1 CT scan of a patient with chronic pancreatitis. Cross-sectional imaging without intravenous contrast of the body and tail of the pancreas reveals numerous calcifications within the pancreatic ductal system *(red arrow)*.

MEDICAL MANAGEMENT

Patients with chronic pancreatitis are best managed at specialized centers because they often require experts from multiple disciplines such as radiology, gastroenterology, and surgery to coordinate their care.

In addition to pain control, a prime objective of patient management is to minimize the insults to the pancreas, which may slow the progressive inflammatory changes. Alcoholic patients with chronic pancreatitis should be strongly encouraged to stop all alcohol intake. While cigarette smoking has not been implicated as a cause of chronic pancreatitis, it can accelerate the disease. Smokers should be advised to stop smoking. Oral pancreatic enzymes that inhibit cholecystokinin (CCK) release have been used to decrease the frequency of acute attacks of inflammation, but their efficacy is doubted by most.

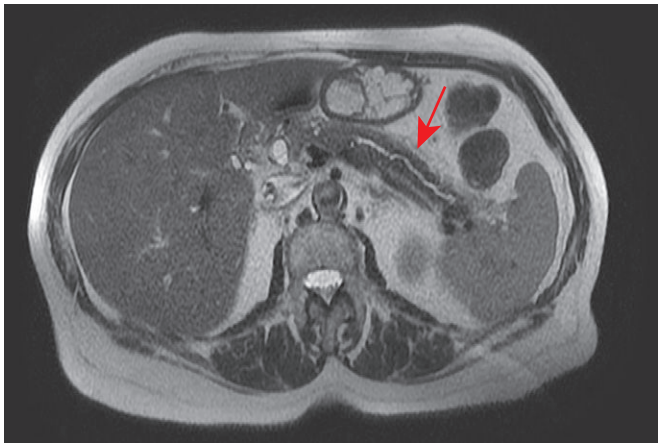

FIGURE 2 Abdominal MRI in a patient with chronic pancreatitis. T2 weighted images of an abdominal MRI with gadolinium contrast in a patient with chronic pancreatitis. The red arrow points to the pancreatic duct in the body/tail of the pancreas, which is moderately dilated and tortuous, both radiographic signs of chronic pancreatitis.

TABLE 1: Cambridge classification of image severity for chronic pancreatitis

Cambridge class	Main pancreatic duct	Abnormal side branches
Normal	Normal	0
Equivocal	Normal	<3
Mild	Normal	>3
Moderate	Abnormal	>3
Marked	Abnormal*	>3

*Main pancreatic duct (MPD) terminates prematurely (abrupt, tapering, irregular), multiple MPD strictures, MPD dilated >10 mm, ductal filling defects (stones), intrapancreatic or extrapancreatic "cavities" are observed, or contiguous organ involvement (stenoses of common bile duct or duodenum, arterial venous fistula).

Modified from Axon ATR, Classen M, Cotton PB, et al: Pancreatography in chronic pancreatitis: international definitions, Gut *25:1107–1112, 1984.*

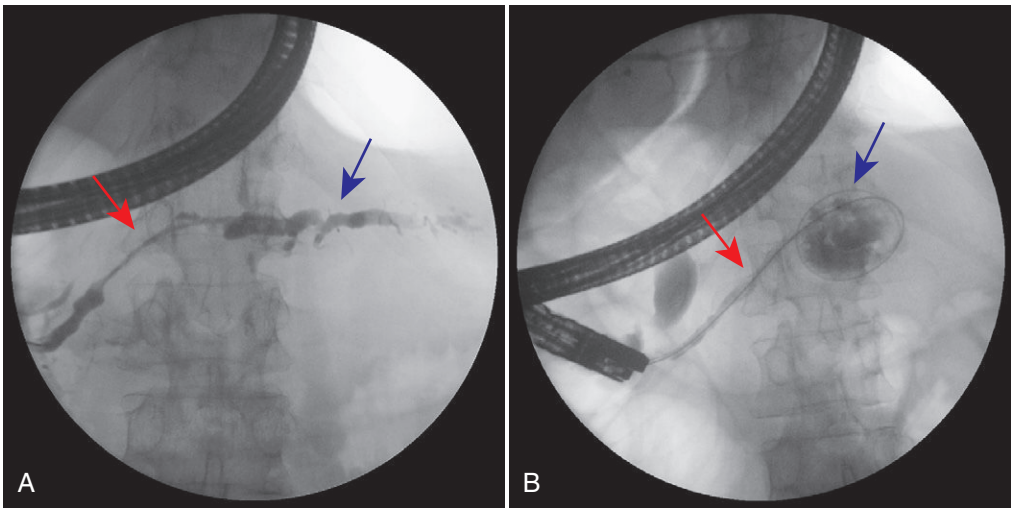

FIGURE 3 ERCP images in patients with Cambridge III chronic pancreatitis. **A,** Red arrow reveals a long pancreatic duct stricture with upstream ductal irregularity *(blue arrow)*. **B,** Long pancreatic duct stricture *(red arrow)* with an upstream ductal disruption. The patient in **(B)** presented with pancreatic ascites.

Proponents also believe that they will slow the progression of disease and improve chronic pain and acute exacerbations. We are skeptical. Of course, pancreatic enzyme supplements should be administered to patients with fat malabsorption manifested as diarrhea and steatorrhea. They should receive at least 30,000 IU of lipase with each meal and also be given medications to reduce gastric acid secretion, which can denature the non-enteric-coated enzymes and eliminate their activity. Most patients with chronic pancreatitis require analgesics for pain relief. Nonopioid medications should be used whenever possible. Referral to a pain specialist may be of value.

ENDOTHERAPY

By the time a patient has been referred for a surgical evaluation, most have been evaluated by a gastroenterologist, and many with strictures and dilated ducts have undergone some form of endoscopic intervention designed to relieve their pain. This usually takes the form of stricture dilation with or without stone removal, followed by the placement of a pancreatic duct stent. While strictures often can be dilated and stented effectively with endoscopic techniques, clearing the duct of stones is more challenging. Problems include difficulty with access to the stones because of stricture(s), adherence of the stone to the duct wall, and large size of the stone that precludes its removal. Fragmentation of the stone with endoscopic or extracorporal shock wave lithotripsy has been used with some success. The extracorporal approach is more frequently used in Europe compared to the United States. Multiple procedures may be required before a satisfactory result is obtained; often complete clearance is not possible.

Pain relief after endoscopic treatment is more likely in patients who have pancreatic duct strictures without stones. Stricture resolution may occur in one third of cases, and two thirds of patients experience improvement of pain. Most failures are due to recurrence of stricture after stents are removed, and there has been an unfortunate tendency for such patients to be managed with stents over long periods of time. Instead, such patients should be strongly considered for surgery. The results are worse for patients with pancreatic duct stones. In most series, at least one half of patients progress to surgery. Cahen and colleagues (Cahen D, et al., 2011) (Figure 4) recently reported in a randomized trial with 5-year follow-up that chronic pancreatitis patients with a dilated pancreatic duct who went straight to surgery had less hospitalizations and repeat procedures and better long-term pain relief. Based on these results, those authors recommend that surgical therapy should be strongly considered at the outset and endotherapy reserved for those with multiple comorbidities who cannot tolerate the operation. We agree.

SURGICAL TREATMENT

Pain is the most common indication for surgery, but other reasons include biliary or duodenal obstruction or concern for cancer, usually in the head of the pancreas. Here we consider surgery for pain relief. Consideration of surgery requires an assessment of the significance of the pain for the individual patient, which is highly subjective; a determination of the type of surgical procedure that might be appropriate; and an evaluation of the ability of the patient to deal with any long-term morbidity that the operation itself might produce (e.g., diabetes or exocrine insufficiency).

In general, an operation may be indicated in patients whose pain interferes with the quality of their lives. For example, the attacks of pain may require frequent hospitalizations that interfere with school or employment. The patient may be unable to function productively because of the depression that often accompanies the chronic pain state. Nutrition may be impaired because oral intake is limited by the pain that eating produces. The patient may be addicted to narcotics.

The etiology of pain is not well understood, but it is probably multifactorial. Two pathogenic theories direct different surgical treatments. The first hypothesis relates the pain in chronic pancreatitis to the high pressure within the pancreatic ducts and the pancreatic parenchyma, which results in a compartment syndrome and gland ischemia. This is the rationale for *drainage* procedures in patients with dilated main pancreatic ducts. The second hypothesis relates the pain to the release of neurotransmitters in an "inflammatory mass" most often situated in the pancreatic head. This is the rationale for *resections* of the pancreatic head.

Most discussions about the choice of operation are centered on performing a resection versus a drainage procedure, or a combination of the two, and are influenced by the diameter of the main pancreatic duct and the size of the head of the pancreas. Normal duct diameters are 4 mm in the head, 3 mm in the body, and 2 mm in the tail of the pancreas. A pancreatic duct diameter greater than 7 mm in the body of the pancreas suggests that a pancreatic duct drainage procedure (lateral pancreaticojejunostomy or Puestow procedure)

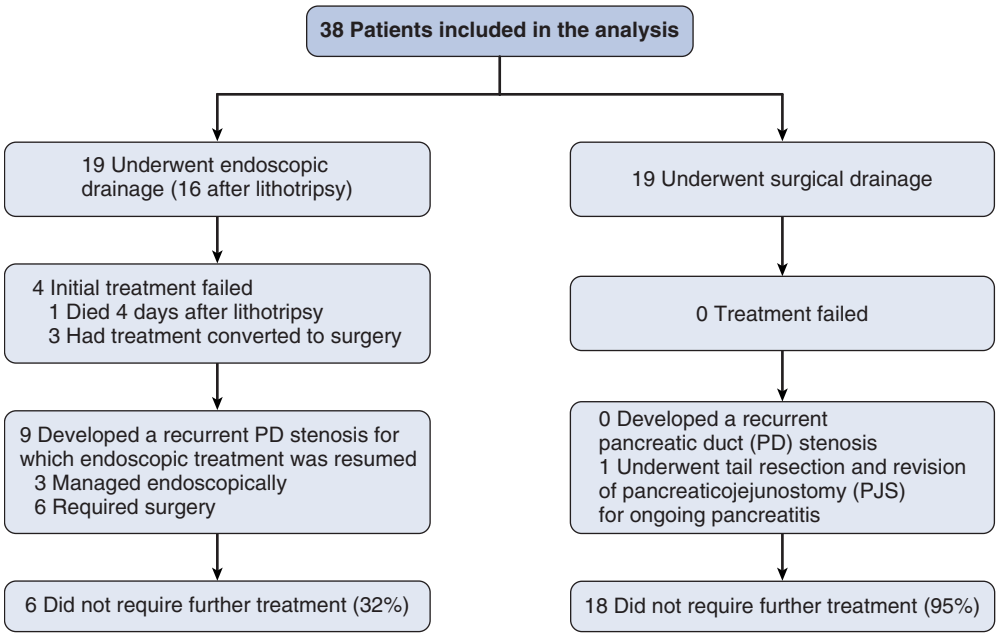

FIGURE 4 Randomized trial of endoscopic versus surgical therapy for patients with chronic pancreatitis and main pancreatic duct dilation. Ninety-five percent of patients who underwent surgical drainage did not require further treatment. In contrast, only 32% who had endoscopic therapy did not require further treatment. These results suggest that surgical therapy may be a more appropriate initial therapy. *(From Cahen DL, Gouma DJ, Laramee P: Long-term outcomes of endoscopic vs surgical drainage of the pancreatic duct in patients with chronic pancreatitis,* Gastroenterology *141:1690–1695, 2011.)*

would likely relieve pain. Indeed, prompt pain relief occurs in 80% to 85% of such patients, and endocrine and exocrine function are usually spared because no pancreatic parenchyma is removed. But because pain may recur in up to 50% of cases within 5 years, this operation is not ideal. If the pancreatic head exceeds 4 cm in its anterior-posterior diameter, some form of head resection should be considered. Most commonly, either a standard Whipple resection (pancreaticoduodenectomy) or its pylorus-preserving variant is done, which provides permanent pain relief in 85% to 90% of patients. However, because exocrine and endocrine insufficiencies occur in approximately 50% of cases, there may be reluctance to do the operation in certain patients who are judged to be incapable of managing these problems. A total pancreatectomy is sometimes considered, often in patients in whom multiple previous lesser operations have been done without pain relief. Of course, this guarantees endocrine and exocrine insufficiency, and the resulting diabetes may be brittle and difficult to manage. For this reason, this operation has been done only rarely. With improvements in the results of auto islet transplantation, this may be a more attractive alternative in the future.

If the duct and the head of the pancreas are both enlarged, often the best choice is an operation that combines drainage of the dilated duct along with a more limited resection of the pancreatic head and preservation of the duodenum, in an effort to minimize the risk of endocrine and exocrine insufficiency. Two procedures are available to achieve these goals: the so-called Beger procedure and the Frey operation. Randomized trials comparing the two procedures have shown equivalent permanent pain relief in 85% to 90% of patients and no endocrine or exocrine insufficiency precipitated by the surgery.

SURGICAL DRAINAGE AND RESECTION TECHNIQUES

Pancreaticoduodenectomy (Whipple Operation)

The Whipple operation (pancreaticoduodenectomy, pylorus-preserving pancreaticoduodenectomy) (Figure 5) is done most commonly for

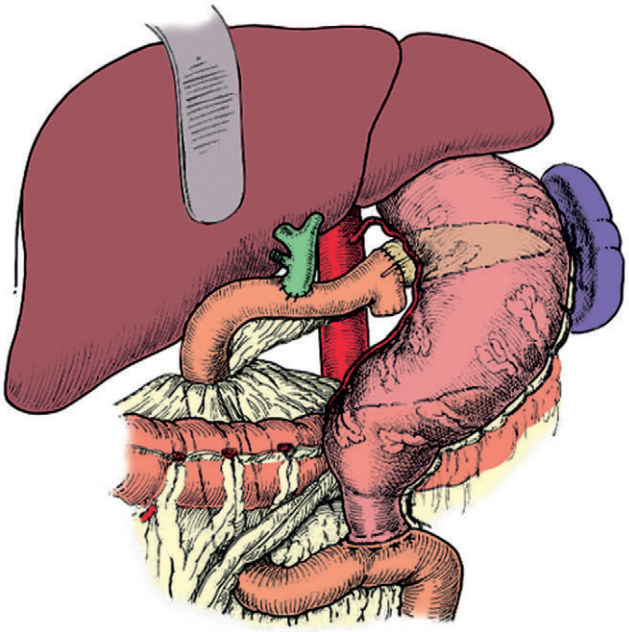

FIGURE 5 After pylorus-preserving pancreaticoduodenectomy (PPPD), reconstruction of the pancreatic duct and bile duct are in a retrocolic fashion. The pancreaticojejunostomy can be made in a side-to-side fashion if a chain-of-lakes ductal pattern exists in the pancreatic remnant. The end-to-side duodenojejunostomy is in an antecolic position to isolate the duodenal anastomosis from the pancreatic anastomosis and minimize delayed gastric emptying if the pancreatic anastomosis should leak. *(From Traverso LW: The surgical management of chronic pancreatitis: the Whipple procedure. In Cameron JL, editor:* Advances in surgery, *vol 32, St Louis, 1999, Mosby, p 33.)*

malignant or premalignant lesions in the head of the pancreas, but the technique for resection in patients with chronic pancreatitis is identical. However, in this latter group, repeated episodes of inflammation are common, so adherence of the peripancreatic tissues to various tributaries of the portal vein is frequent, and there may be some element of portal venous hypertension from venous compression in the head of the pancreas. Thus, operative blood loss is on average a bit higher than when the operation is being done for malignant disease. Pancreatic fistulae are uncommon because of the firm nature of the pancreas. In patients with chronic pancreatitis, a pancreaticoduodenectomy should *always* be done if there is also concern for the presence of cancer in the head of the pancreas, which may be difficult to diagnose with certainty in this setting. Otherwise, if the presence of cancer is not a concern, the choice for a Whipple resection is usually made on the basis of individual surgeon preference and consideration of the factors already discussed.

Lateral Pancreaticojejunostomy (Puestow Procedure)

The Puestow procedure is a lateral pancreaticojejunostomy between the main pancreatic duct and a Roux-en-Y limb of jejunum (Figure 6). The lesser sac is entered and the pancreas is exposed. The duodenum and head of the pancreas are mobilized (Kocher maneuver), and the gastroduodenal artery is ligated as it courses on the head of the pancreas at the point where it emerges from under the duodenum. The pancreatic duct is located by inserting a needle through the parenchyma on the anterior surface of the gland. The duct is then opened longitudinally by incising through the parenchyma. The duct must be opened over a long distance that begins in the head (even closer to the duodenum than shown in Figure 6) and through the entire length of the body and into the tail. Stones and concretions are removed from the duct lumen, and a retrocolic roux limb of jejunum is then anastomosed to the pancreatic duct in one or two layers. Although we routinely leave a closed suction drain along the anastomosis, fistulas are rare because the firm parenchyma holds sutures well.

Duodenum-Preserving Pancreatic Head Resection (Beger Procedure)

In Germany in 1972, Hans Beger performed a duodenum-preserving pancreatic head resection, or DPPHR, in patients with an inflammatory mass in the head of the pancreas. Many of these patients also had an enlarged pancreatic duct (Figure 7). The operation removes the inflammatory mass but maintains the viability of the duodenum and intrapancreatic common bile duct by preserving the posterior branch of the gastroduodenal artery. The neck of the pancreas is divided, and all but a small amount of pancreatic tissue along the medial aspect of the duodenum is removed. Reconstruction consists of an end-to-end pancreaticojejunostomy to the distal pancreas and pancreaticojejunostomy to the remnant of pancreatic tissue on the inner aspect of the duodenum. If the pancreatic duct is also dilated, it is longitudinally opened and a pancreaticojejunostomy is done to the body/tail portion of the pancreas.

Local Resection of the Head of the Pancreas With Lateral Pancreaticojejunostomy (Frey Procedure)

Charles Frey described a local resection of the head of the pancreas with lateral pancreaticojejunostomy in 1985. This is similar to the DPPHR, and it combines the pancreatic head resection with a duct drainage procedure, while preserving duodenal continuity (Figures 8 and 9). This operation is also indicated in patients with an enlarged inflammatory mass in the pancreatic head, and it preserves endocrine and exocrine function. The operation differs from the DPPHR in that the neck of the pancreas is not transected. Thus, inflammatory adherence to the superior mesenteric and portal veins, which may result in troublesome bleeding during the Beger operation, is not a problem. For that reason, many surgeons prefer it. The Frey procedure is more frequently performed in the United States, while the Beger procedure is more commonly done in Europe.

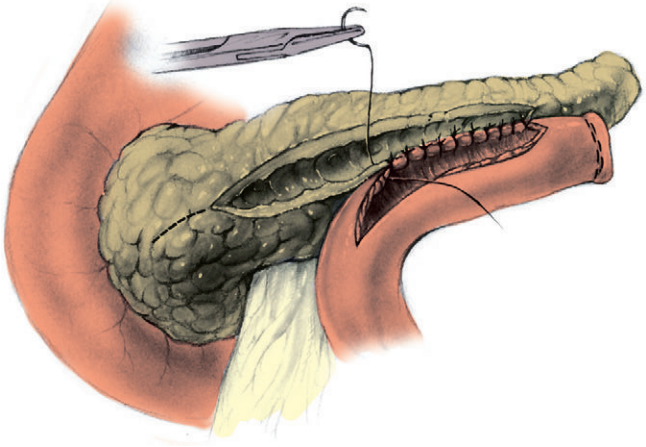

FIGURE 6 The Puestow procedure (lateral pancreaticojejunostomy) is depicted. Note the end of the limb is positioned toward the tail of the pancreas. If the Puestow procedure fails to relieve pain in long-term follow-up and a head resection is required, this position of the jejunal limb allows for the preservation of the pancreatic anastomosis and also allows addition of the biliary connection to the jejunal limb. *(Reprinted from Pancreaticojejunostomy [Puestow] for chronic pancreatitis. In Scott-Conner CEH, editor:* Chassin's operative strategy in general surgery: an expositive atlas, *ed 3, New York, 2002, Springer-Verlag. With kind permission of Springer Science+Business Media.)*

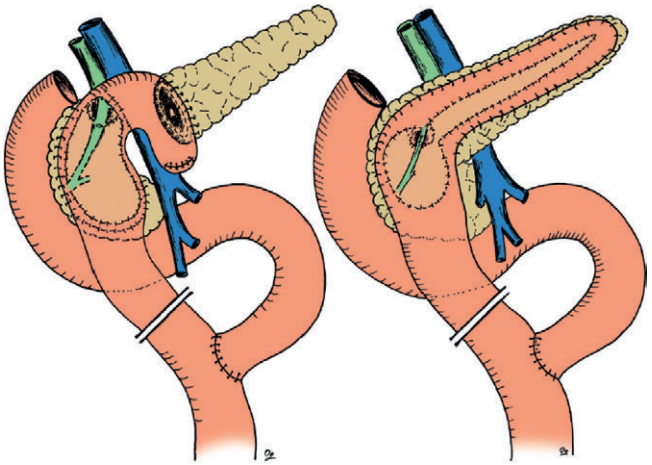

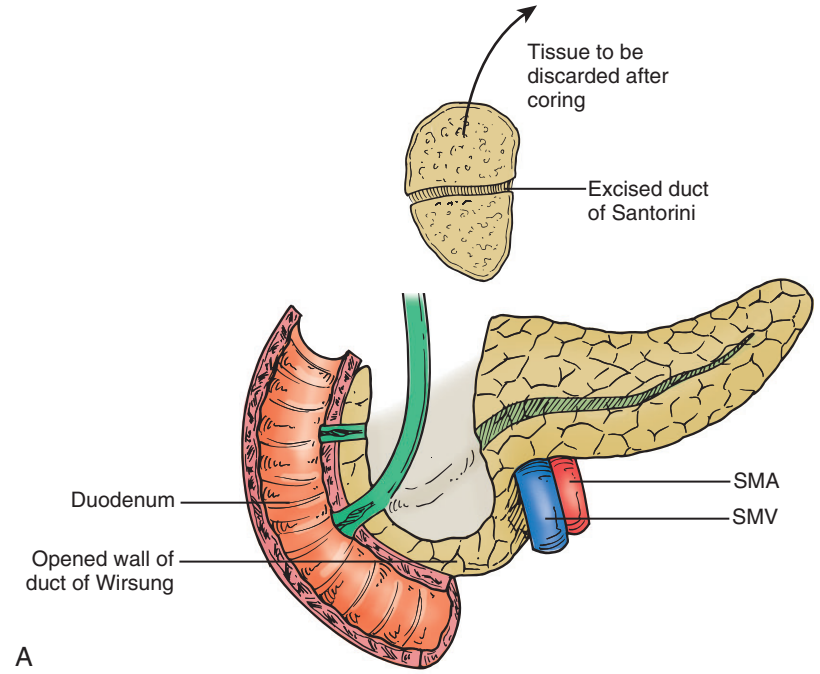

FIGURE 7 The Beger technique (duodenum-preserving pancreatic head resection) on the left is compared to the Frey procedure (LR-LPR, subtotal ventral head or local head resection combined with a lateral pancreaticojejunostomy). *(Reprinted from Köninger J, Seiler CM, Sauerland S, et al: Duodenum-preserving head resection: a randomized controlled trial comparing the original Beger procedure with the Berne modification,* Surgery *143:490–498, 2008.)*

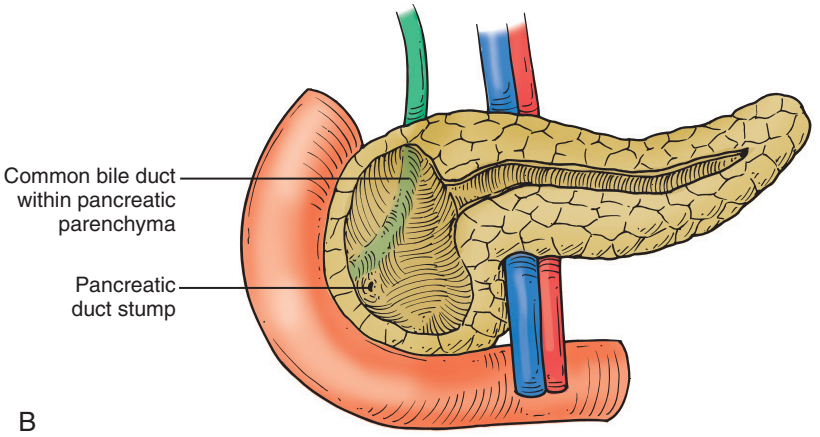

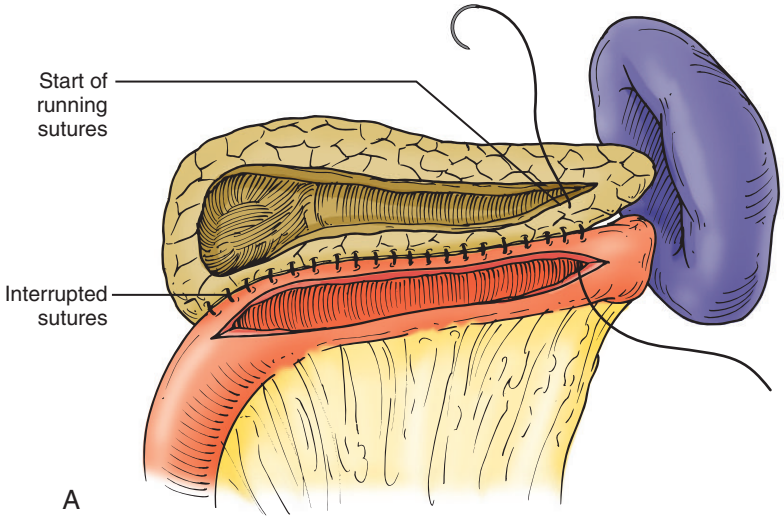

FIGURE 8 **A,** Tissue removed from the head of the pancreas, including the duct of Santorini. Note that we do not try to remove this tissue as a single specimen as shown here, but rather in piecemeal fashion, taking slices outward from the opened duct of Wirsung and duct to the uncinate process. This technique allows us to assess the extent of resection by placing the thumb of the left hand within the head of the pancreas and with the fingers behind the Kocherized head. *SMA,* Superior mesenteric artery; *SMV,* superior mesenteric vein. **B,** Completed local resection of the head of the pancreas and decompressed main duct in the body and tail of the pancreas. It is unnecessary to ligate the pancreatic duct stump (Wirsung), shown at the bottom of the cavity created by the coring. The common duct is shown traversing the posterior head within the pancreatic parenchyma. The intrapancreatic location of the common duct is most frequently associated with clinical and biochemical evidence of biliary obstruction. When performing the local resection in such patients, it is best to place a metal Bakes dilator in the common duct so its position can be identified and injury prevented while freeing up the bile duct from obstructing scar tissue. *(From Frey CF, Reber HA: Local resection of the head of the pancreas with pancreaticojejunostomy,* J Gastrointest Surg *9(6):863–868, 2005.)*

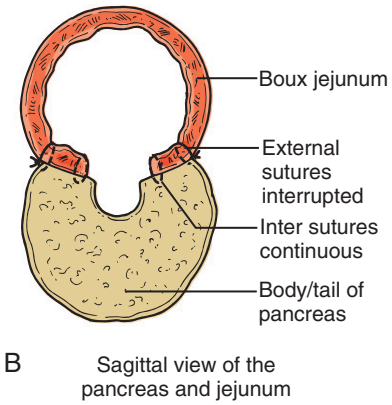

FIGURE 9 **A,** The two-layer anastomosis approximates the opened jejunum to the circumference of the locally resected head and to the decompressed main duct in the body and tail of the pancreas. The inner layer is accomplished with running 3-0 or 4-0 absorbable sutures (e.g., PDS). Note: This layer approximates the capsule of the pancreas (not the wall of the duct) to the jejunum. The outer layer consists of 3-0 or 4-0 interrupted nonabsorbable sutures. **B,** Cross-sectional view of the completed two-layer anastomosis between the opened jejunum and the decompressed main duct in the body of the pancreas. *(From Frey CF, Reber HA: Local resection of the head of the pancreas with pancreaticojejunostomy,* J Gastrointest Surg *9(6):863–868, 2005.)*

Which Operation?

The majority of published studies on the outcomes of the surgical management of painful chronic pancreatitis are retrospective. Moreover, the patients who were analyzed were operated on at different stages of their disease, and often for more than a single indication. Thus, only limited guidance is available from those data. Only a few general guidelines that are derived from better studies are currently available. A meta-analysis of four randomized controlled trials comparing limited resections (Beger or Frey) to pancreaticoduodenectomy revealed that the drainage operations combined with duodenal-preserving limited head resections resulted in greater pain relief with lower perioperative morbidity (Figure 10) compared to the Whipple operation. Moreover, they were associated with lower rates of both early and late development of endocrine and exocrine dysfunction (Table 2). The choice between a Beger or Frey operation should depend on the individual preference and experience of the surgeon. However, if there is suspicion of the presence of a pancreatic cancer, any limited form of resection is contraindicated, and a pancreaticoduodenectomy should be done. Finally, the data from Cahen and colleagues (Cahen D, et al., 2011) (see Figure 4) suggest that early operations to surgically drain a dilated duct are probably better than prolonged efforts at endoscopic manipulations, stone extractions, and dilation of pancreatic duct strictures.

SUMMARY

CP is a debilitating condition for many patients. They are best treated in high-volume centers with a multidisciplinary team of experts who are specialized in pancreatic diseases. At the time of diagnosis, all patients should be encouraged to stop the insulting substance in cases of acquired disease. The timing of intervention is not well established, but there is consensus that patients with a firm diagnosis of chronic pancreatitis and ductal obstruction with a dilated duct need to have ductal drainage. Early intervention *may* delay the progression of disease and development of endocrine and exocrine insufficiency. Endoscopic therapy with stone extraction and stent placement is an option for some prior to surgery, but many patients eventually need definitive surgical duct decompression. There are many factors that are considered when deciding the surgical treatment. The most prominent are the presence of an enlarged pancreatic head and dilated pancreatic duct. A limited resection with duodenal preservation and ductal drainage may be the best option for patients who have both findings.

TABLE 2: Meta-analyses comparing DPPHR versus PD, including sensitivity analyses

Outcome	Comparison	Effect size, RR/WMD (95% CI: P: I^2)
Pain relief	DPPHR vs PD	RR 1.08 (0.88-1.33; 0.46; 43%)

Periampullary Carcinoma

Barish H. Edil, MD, Martin McCarter, MD, Csaba Gajdos, MD, and Richard D. Schulick, MD

OVERVIEW

Periampullary cancers are a set of neoplasms that arise in the pancreatic, biliary, ampullary, and duodenal tissues near the ampulla of Vater. Although these neoplasms arise from distinct tissues, they are often grouped together because of their anatomic proximity, common clinical presentation with signs and symptoms of obstructive jaundice, and surgical treatment requiring pancreaticoduodenectomy (when possible). Pancreatic ductal adenocarcinoma accounts for the majority of the cancers in the periampullary area, comprising nearly 85% of the cases. The other three periampullary cancers are cholangiocarcinoma of the distal bile duct, adenocarcinoma of the ampulla of Vater, and duodenal adenocarcinoma. In fact, it is common for the precise organ of tumor origin to be unknown prior to surgical resection. Taken together, these four cancers have an incidence of approximately 60,000 new cases per year in the United States. Long-term survivals vary widely depending on the tissue of tumor origin, stage at diagnosis, degree of differentiation, and ability to perform a complete (R0) resection.

Besides the four cancers discussed earlier, other, less common tumors can arise in the periampullary region. These include neuroendocrine tumors, pancreatic cystadenocarcinoma, acinar cell and squamous cell carcinomas, gastrointestinal stromal tumors, sarcomas, lymphomas, and metastases from other primaries.

PERIAMPULLARY CANCER TYPES

Pancreatic Ductal Adenocarcinoma

Pancreatic ductal adenocarcinoma is the fourth leading cause of cancer death in the United States. In 2012 there were an estimated 44,000 new cases diagnosed, with 37,000 deaths from this disease. The median age at diagnosis is 71 years of age. African Americans have a higher risk of developing pancreatic ductal adenocarcinoma than do whites. There is a slightly higher incidence in men compared to women. The lifetime risk of developing pancreatic cancer is 1 in 68 men and women in the United States. Smoking and obesity are risk factors for the development of pancreatic ductal adenocarcinoma. Other factors have been suggested as risk factors, but these associations are not clear. These include diabetes, alcohol abuse, and

radon exposure. It is estimated that between 5% and 10% of patients who develop pancreatic ductal adenocarcinoma have a familial form that is associated with mutations in BRCA-2 (familial breast cancer), PRSS1 (hereditary pancreatitis), p16 (familial atypical multiple mole and melanoma), or hereditary nonpolyposis colorectal cancer (HNPCC).

Surgical resection with pancreaticoduodenectomy is the only potentially curative therapy and typically yields 5-year survival rates from 15% to 25%. Only 20% to 30% of patients are able to undergo resection because of distant metastases at the time of diagnosis, locally advanced disease that typically involves the major hepatic and mesenteric blood vessels, or significant medical comorbidities.

Distal Bile Duct Adenocarcinoma (Cholangiocarcinoma)

Distal cholangiocarcinoma is the second most common periampullary cancer. These cancers arise in the most distal part of the bile duct from the junction of the cystic duct to the ampulla of Vater. It is distinguished from perihilar cholangiocarcinomas that arise near the union of the right and left hepatic ducts (also known as Klatskin tumors) or the more proximal intrahepatic cholangiocarcinomas. The incidence of cholangiocarcinoma is between one to two new cases per 100,000 persons per year in the United States. Approximately 30% of these cases are diagnosed as arising in the distal bile duct. It is a disease of the elderly with peak incidence in the seventh decade of life. Risk factors for the development of chlolangiocarcinoma include sclerosing cholangitis, choledochal cysts, hepatolithiasis, and liver flukes.

Surgical resection with pancreaticoduodenectomy is the most effective therapy for this disease, with 5-year survival rates ranging from 20% to 40%. About 1 out of every 10 pancreaticoduodenectomies are performed for distal bile duct cholangiocarcinoma.

Adenocarcinoma of the Ampulla of Vater

Ampullary adenocarcinoma is the third most common of the periampullary malignancies, occurring at a rate of slightly less than 1 per 100,000 per year in the United States. Peak incidence is in the seventh decade of life and is slightly more common in males. These lesions tend to be discovered at a smaller size compared to pancreatic adenocarcinomas because they cause obstructive jaundice early. Additionally they tend to have less biologic aggressiveness than pancreatic and distal bile duct adenocarcinomas. In studies that further subdivide these cancers into the intestinal versus pancreaticobiliary subtypes, it appears that those patients with the intestinal type have better long-term survival. Resection of ampullary adenocarcinomas with pancreaticoduodenectomy results in 5-year survival rates of 35% to 55%.

Duodenal Adenocarcinoma

Duodenal adenocarcinomas are relatively rare and only account for about 5% of all periampullary cancers. These cancers are equally prevalent in men and women and have a peak incidence in the seventh decade. These cancers are thought to arise from duodenal polyps as colorectal cancers tend to do. Duodenal adenocarcinomas tend to be larger at diagnosis than the other periampullary adenocarcinomas because of the ability for significant intraluminal growth prior to the development of symptoms. Duodenal adenocarcinomas have the most favorable biology compared to the other periampullary adenocarcinomas, with patients undergoing resection with pancreaticoduodenectomy with 5-year survival rates in the 40% to 60% range.

CLINICAL PRESENTATION AND PHYSICAL FINDINGS

Obstructive jaundice is the most common presenting sign of the periampullary adenocarcinomas. The earliest symptom is usually pruritus secondary to the deposition of bile salts in the skin. Patients then notice tea-colored urine; pale, chalk-colored stools; and scleral icterus. Patients also typically have anorexia and weight loss. Although the classic teaching is that these patients do not have pain, one third of patients will have some form of pain or discomfort. This pain is typically dull and constant midepigastric abdominal pain that radiates directly to the back. Severe pain may be caused by tumor infiltration of the celiac plexus, which portends a poor prognosis.

Patients may also present with signs and symptoms of pancreatic exocrine insufficiency, including abdominal discomfort, dyspepsia, and steatorrhea. They may also present with pancreatic endocrine insufficiency with the new onset of diabetes. Patients with ampullary or duodenal adenocarcinoma may also present with anemia or even frank gastrointestinal bleeding.

As in all patients, initial evaluation should include a complete history and physical examination to include past history of chronic pancreatitis and family history of cancers, including pancreatic, colon, and breast. In addition to the signs and symptoms of obstructive jaundice—pruritus, scleral icterus, jaundice, dark urine, pale stools, and self-inflicted excoriations due to scratching—patients may also have an enlarged palpable left supraclavicular (Virchow's) node or periumbilical (Sister Mary Joseph) node. They may also have a palpable nodule in the pelvis felt via a rectal examination. These three are signs of distant or metastatic disease. Hepatomegaly and a palpable gallbladder (Courvoisier sign) can be manifestations of distal bile duct obstruction. Ascites that manifests as shifting dullness or a fluid wave can be a sign of advanced liver disease or peritoneal dissemination.

LABORATORY STUDIES

The majority of patients diagnosed with a periampullary tumor present with signs or symptoms that may prompt additional investigations, including laboratory, imaging, endoscopy, and tissue biopsy. Basic laboratory testing includes a complete blood count, electrolytes, liver function tests, prothrombin time, albumin, and tumor markers (carbohydrate antigen, CA19-9, and carcinoembryonic antigen).

Distal biliary obstruction generally results in hyperbilirubinemia, with the direct (or conjugated) bilirubin being more elevated than the indirect (or unconjugated) bilirubin. Similarly, the alkaline phosphatase is generally more significantly elevated than the transaminases (alanine aminotransferase or aspartate aminotransferase). Other possible abnormalities include prolongation of the prothrombin time due to malabsorption of fat-soluble vitamins such as vitamin K. Malabsorption and weight loss may often manifest in the form of hypoalbuminemia. The tumor marker CA19-9 is frequently elevated, but its sensitivity and specificity are limited by several factors. First, the test for serum CA19-9 is dependent on the Lewis blood group antigen phenotype and therefore is not detectable in the 5% to 10% of the population with Lewis AB-phenotype. Second, biliary obstruction, inflammation, cholangitis, and other tumors such as stomach, ovarian, or colon are all associated with increased CA19-9 levels. Therefore, CA19-9 can be supportive of a diagnosis of periampullary carcinoma, but it should not be utilized to assume the diagnosis. If the CA19-9 happens to be elevated secondary to a periampullary tumor (estimated to be around 75%), it may be useful in monitoring for disease progression following treatment.

Imaging

The purpose of imaging periampullary tumors is to determine the extent of disease, obtain staging information, and assess the potential for resection. A three-phase pancreas protocol computed tomographic (CT) scan with fine cuts through the pancreas and liver provides valuable information regarding local and regional spread of disease (Figure 1). For patients with a contrast allergy or renal insufficiency, a magnetic resonance imaging study or magnetic resonance cholangiopancreatography (MRCP) study may be used to obtain similar information about the suitability for resection (Figure 2). If there are no obvious signs of metastatic disease (most commonly noted in the liver), then attention shifts to assessing the relationship of the tumor to the mesenteric vessels that course adjacent to the pancreas. Specific note is made of any abutment or invasion of the portal vein (PV), the superior mesenteric vein (SMV), the superior mesenteric artery (SMA), the celiac trunk, and the hepatic artery (HA). Involvement of these vessels does not prevent resection but is a biologic indicator of the extent of disease that may alter the preoperative treatment planning and the intraoperative approach. In general, unresectable locally advanced adenocarcinoma of the pancreas is defined as tumor abutting the celiac trunk, HA, or SMA by greater than 180 degrees or encasement/occlusion of the SMV/PV (Figure 3). These patients would be offered conversion therapy in the hope of downstaging the tumor and testing the biologic aggressiveness of any occult metastatic disease.

Endoscopic ultrasound (EUS) with fine needle aspiration (FNA) biopsy can sometimes add valuable information regarding the relationship of the tumor to the mesenteric vessels and has the advantage of being able to confirm a tissue diagnosis. The majority of pancreatic tumors are adenocarcinomas; however, the treatment approaches to neuroendocrine tumors, lymphomas, and other tumors that occur in the periampullary region vary significantly such that biopsy confirmation preoperatively may be helpful if there is a question about the diagnosis. For patients who present with unresectable or metastatic tumors, an EUS-guided celiac block may provide substantial pain relief.

The use of positron emission tomography combined with computed tomography (PET-CT) for periampullary tumors is still being debated. Assessment of the local vasculature involvement is superior with a pancreas protocol CT scan, but PET-CT may be useful in resolving potentially metastatic suspicious lesions noted on other imaging (Figure 4). Despite PET-CT and improvements in other imaging techniques, unsuspected distant metastatic disease is still

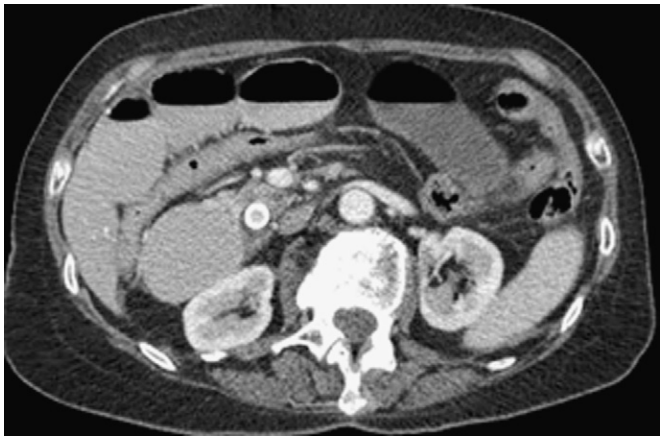

FIGURE 1 Computed tomographic scan demonstrating a resectable tumor in the head of the pancreas (note metallic biliary stent) with clear tissue planes around the superior mesenteric artery and portal vein.

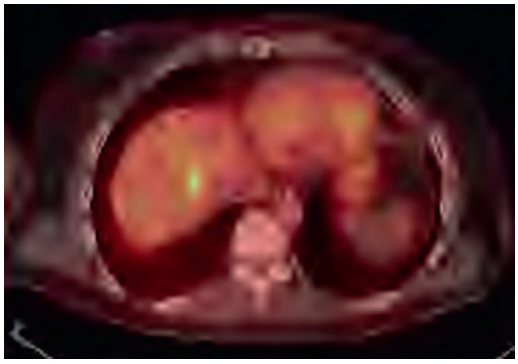

FIGURE 4 PET-CT scan demonstrating hypermetabolic activity in a small lesion at the dome of the liver consistent with metastatic adenocarcinoma of the pancreas.

encountered in roughly 10% to 20% of patients at the time of an operation. Most of these represent small (<5 mm) subcapsular liver nodules or peritoneal implants that are too small to detect with conventional imaging.

Biliary Stenting and Biopsy

Most patients presenting with periampullary tumors do so with evidence of jaundice that prompts further investigation. Endoscopic retrograde cholangiography (ERC) directly visualizes the ampullary region and provides an opportunity to relieve the obstruction while obtaining a provisional diagnosis. Ampullary adenomas or adenocarcinomas may present themselves for immediate biopsy. ERC may uncover benign causes of jaundice such as choledocholithiasis or inflammatory conditions such as primary sclerosing cholangitis. Tumors involving the distal common bile duct generally have features such as an abrupt cutoff that are consistent with malignancy (Figure 5). Obstruction of the common bile duct in conjunction with the pancreas duct (double duct sign) is frequently associated with malignancy (Figure 6). During ERC, attempts at biopsy or brushing of the duct may provide a tissue diagnosis, although the overall sensitivity and specificity of brushings are relatively low, and other approaches such as EUS with FNA or direct cholangioscopic biopsy may be needed.

For patients presenting with metastatic or locally advanced tumors, biliary stenting at the time of ERC provides immediate relief from the obstruction and allows for the patient's symptoms to improve while the remainder of the evaluation is undertaken. Complete resolution of jaundice-associated symptoms such as sclera icterus, pruritus, and changes in stool color may lag several days to weeks behind. The value of preoperative biliary stenting in patients with resectable disease remains controversial, although a prospective randomized trial in patients with pancreatic cancer presenting with a total bilirubin level of 2.3 to 14.6 mg/dL found that routine preoperative stenting was associated with an increase in serious complications with no change in mortality or length of stay. Preoperative stenting may be most valuable in patients with evidence of cholangitis, intractable pruritus, or significant nutritional deficiencies, or in whom surgery cannot be arranged in a timely (<7 days) fashion.

SURGICAL THERAPY

Pancreaticoduodenectomy is the preferred operation for potentially curable periampullary carcinomas. Access to the abdomen is carried out through an upper midline or bilateral subcostal incision. The initial assessment involves exploration of the entire abdomen, focusing on the liver, omentum, peritoneal surfaces, and base of the transverse mesocolon to rule out metastatic disease. The secondary assessment evaluates the relationship of the tumor to the mesenteric vessels. Although the exact sequence of investigation may vary, this phase generally involves a Kocher maneuver to assess the relationship of the tumor to the SMV and SMA and retroperitoneal structures such as the inferior vena cava, the right renal vein, and the aorta. Next, the SMV is identified, emanating from under the neck of the pancreas and followed proximally toward the portal vein. The gastroduodenal artery is dissected near its origin from the proper hepatic artery and test clamped to ensure adequate flow through the hepatic artery prior to being divided. Once divided, access to the PV above the neck of the pancreas allows for creation of a tunnel posterior to the neck of the pancreas to connect with the SMV. At this point a final assessment is made regarding the chances of achieving a margin negative resection (plus/minus vascular reconstruction), and the decision to proceed or abandon the procedure is confirmed.

A cholecystectomy is performed, and the common bile duct is dissected free and divided around the level of the cystic duct insertion. If the tumor is away from the pylorus, a pyloric-preserving approach may be taken by dividing the duodenum 1 to 2 cm beyond the pylorus with a stapling device. If tumor encroaches upon the pylorus, then a wider margin with division of the stomach to include the antrum with the specimen is undertaken. The right gastroepiploic vessels are divided to retract the stomach out of the field and expose the neck of the pancreas. The tunnel posterior to the neck of the pancreas overlying the SMV is developed, and stay sutures may be placed on the superior and inferior edges of the pancreas to control bleeding and provide additional retraction. The pancreas is divided sharply, with attention paid to identifying the location of the main pancreatic duct. If there is concern for potential tumor involvement, a frozen section is obtained from the cut surface of the gland, after which small bleeding vessels may be cauterized.

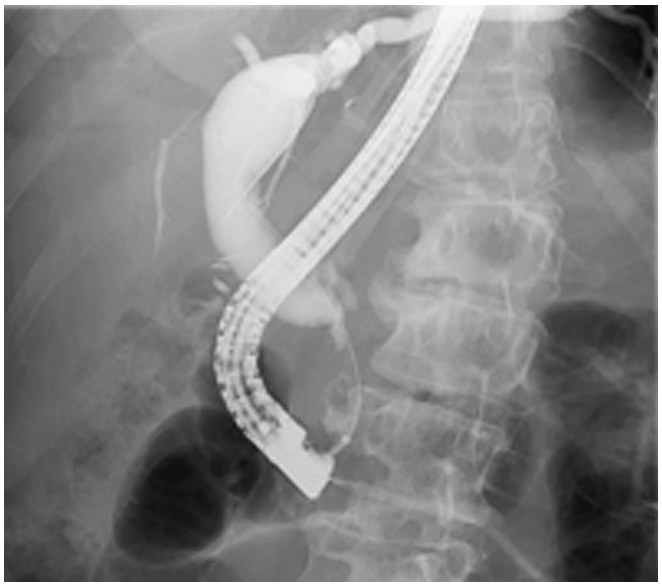

FIGURE 5 Endoscopic retrograde cholangiography demonstrating a narrow tapering of the common bile duct secondary to a tumor in the distal bile duct.

FIGURE 6 Computed tomographic scan with dilated common bile duct and main pancreas duct.

The proximal jejunum is identified and divided with a stapling device approximately 15 cm distal to the ligament of Treitz. The small vessels serving the proximal jejunum and fourth portion of the duodenum are controlled and divided prior to passing the intestine posterior to the mesenteric vessels to the patient's right side. Staying along the lateral border of the SMA and removing all pancreatic tissue from this area and the PV/SMV represent the retroperitoneal dissection, including the uncinate process. Local and regional lymph nodes are included with the specimen, although extended periaortic lymph node dissections have not been shown to improve survival. The specimen should be properly marked and oriented to facilitate pathologic analysis.

Reconstruction

The divided jejunum is passed through the transverse mesocolon to the right of the middle colic vessels to lay in the right upper quadrant as an upside-down "J." The pancreas body is mobilized off the splenic vein for 2 to 3 cm to facilitate the anastomosis. An end-to-side invaginated duct-to-mucosa pancreaticojejunostomy is fashioned in two layers, with a fine, absorbable monofilament used on the mucosa and a permanent suture used on the serosa and pancreatic capsule to buttress the pancreas against the jejunum. A pediatric feeding tube may be trimmed to serve as a pancreatic stent, especially in patients with a relatively small pancreatic duct.

An end-to-side hepaticojejunostomy is constructed 5 to 10 cm away from the pancreaticojejunostomy. In a common bile duct that is generally dilated and fibrotic, a running mucosa-to-mucosa layer is fashioned using an absorbable monofilament suture, with care being taken to avoid occluding the anastomosis. A stent is generally not needed for this anastomosis.

The duodenojejunostomy or gastrojejunostomy is performed in an antecolic fashion 15 to 20 cm downstream from the hepaticojejunostomy. A jejunal feeding tube is used only in select cases. Drains are placed posterior and anterior to the pancreatic and biliary anastomoses.

Recently, periampullary neoplasms at select centers are being approached by minimally invasive or laparoscopic techniques. At our institution, for the properly selected patients, laparoscopic pancreaticoduodenectomy is routinely done. Laparoscopic resection with periampullary and pancreatic tumors can decrease surgical risks, postoperative pain, and particularly wound complications compared to the open operation. This decrease in morbidity has facilitated the integration of surgery into the multimodality cancer care of these patients. There are no prospective randomized trials comparing minimally invasive techniques with open pancreaticoduodenectomy, but there have been studies comparing oncologic parameters that have shown that lymph node harvest and margin status are equivalent between the two approaches.

The laparoscopic approach does vary technically from the previously described open approach. Five ports are used to create a semicircle around the pancreas. After evaluating the abdomen for the absence of metastatic disease, the lesser sac is entered, allowing for the lifting of the stomach and the first portion of the duodenum. This permits evaluation and identification of the hepatic and gastroduodenal artery. Dissection and ligation of the gastroduodenal artery are done, allowing for orientation and evaluation of the portal vein below. At this point, attention is redirected to the superior mesenteric vein, which is found by cutting down on it along the lower edge of the pancreas in relation to the previously identified portal vein. This is followed by blunt dissection of the tunnel underneath the neck of the pancreas. The magnification and angle of visualization of the tunnel secondary to the laparoscope are excellent for assessing resectability. Once completed, the gallbladder is taken down from the gallbladder fossa and used for retraction to allow dissection and transection of the common bile duct. At this point, the colon is lifted, identifying the ligament of Treitz. The ligament of Treitz is dissected down under the root of the mesentery, staying on the duodenal wall. The proximal jejunum is then stapled and transected, but the two ends are sewn to each other loosely. This is an important step because as we remove the specimen, the jejunum will be pulled through the ligament of Treitz in proper orientation under the root of the mesentery, putting it in the perfect position for the pancreaticojejunostomy and hepaticojejunostomy.

Attention is brought back to the right upper quadrant, where the distal stomach is stapled and transected. The neck of the pancreas is also transected, paying attention to good hemostasis of the superior and inferior pancreaticoduodenal artery branches. The final steps include the Kocker maneuver and pulling the mobilized duodenum and sewn proximal jejunum through the ligament of Treitz. This leaves an excellent view of the superior mesenteric artery, allowing for transection of the uncinate process right along it.

Finally, the three anastomoses are completed, in similar fashion to the open technique, using intracorporeal knots in either a running or interrupted fashion to the jejunum, which is already in the proper position from the previous maneuvers. We have found that a pediatric feeding tube for both the pancreas and bile duct facilitates the anastomosis laparoscopically.

Laparoscopic pancreas surgery is a field that is in its infancy and continues to evolve. We currently offer it routinely for the properly selected patient at our institution, allowing for those patients to benefit from the minimally invasive approach.

Postoperative Care

A standardized approach to postoperative care has significantly improved surgical outcomes and reduced hospital stay in our experience. This includes close observation in a monitored unit for the first 24 hours postoperatively and transfer to a dedicated surgical nursing unit thereafter.

Nasogastric tubes are discontinued on postoperative day (POD) #1. Early ambulation, aggressive use of incentive spirometers, and tight blood sugar control are critical. Ice chips and sips of water are permitted early on. Formal introduction of clear liquids usually waits until POD #3 or #4. Diet is advanced to regular in the next 48 hours in the absence of nausea or vomiting. Patients may also receive prokinetic agents (erythromycin or reglan), but this is debated in the literature. Routine feeding tube placement at the time of the operation is unnecessary. While colonic ileus after Whipple procedure is infrequent, signs and symptoms could mimic delayed gastric emptying (DGE).

Systemic signs of infection (fever, elevated white count) on POD #4 to #5, or after, should prompt laboratory and radiographic workup, including cross-sectional imaging. Abdominal or retroperitoneal fluid collections should raise suspicion for an anastomotic leak. These fluid collections typically need to be drained and a sample sent for amylase levels and cultures for targeted antibiotic therapy under appropriate circumstances. With proper surgical techniques, the rate of bile leaks from hepaticojejunostomies should be minimal. Pancreatic leaks in the setting of dilated ducts and firm pancreas in pancreatic cancer patients should also be low. Patients with small pancreatic ducts and a soft pancreas with other types of periampullary cancers (bile duct, ampulla) are at higher risk for an anastomotic leak. Most of these patients can be treated conservatively or with percutaneous drains if necessary.

Surgically placed drains are tested for amylase levels and compared with serum levels after advancement to a regular diet. Low-volume pancreatic fistulas can be managed with little to no change in routine postoperative care as an outpatient. Drain output should be monitored daily, and drain amylase levels checked with postoperative visits. Drains are usually removed 1 to 3 weeks after discharge, depending on output. Management of high-output fistulas can be more challenging. Drains should be well secured to prevent accidental removal. The exact timing of drain removal depends on drain

output and amylase levels. Decreasing drain output can be managed with slow, gradual removal of external drains, allowing enough time for the tissue around the drain to form a track. Alternatively, or in the setting of persistently high drain output, a drain injection study should be performed to rule out a large residual peripancreatic cavity, followed by fibrin glue injection into the drain track. The role of octreotide remains controversial.

A recent study from Europe found that early drain removal in a selected group of patients could be beneficial because it was associated with a decreased pancreatic fistula rate, fewer abdominal/pulmonary complications, a decreased hospital stay, and lower cost.

Postpancreatectomy hemorrhage several days after surgery is a rare but serious postoperative complication. It is frequently associated with pancreatic anastomotic leak and can present with blood loss via abdominal drains, hematemesis/melena, unexplained hypotension, or as a laboratory finding. Sentinel bleed (small amount of blood loss hours prior to massive hemorrhage) could be a warning sign. This is related to a pseudoaneurysm in the area of the gastroduodenal artery (GDA) stump, hepatic artery, or branch off the superior mesenteric artery. In this scenario the patient, if stable, should be evaluated by arteriography, which can be diagnostic as well as therapeutic.

SURGICAL OUTCOMES

Postoperative Complications

Perioperative morbidity and mortality for major pancreatic resections have declined significantly over the last 2 decades. While postsurgical mortality in high-volume centers is low (0% to 3%), postoperative morbidity continues to remain high (30% to 50%). The most frequent serious postoperative complications are DGE (15% to 40%), pancreatic anastomotic leak (10% to 20%), intra-abdominal abscess (8% to 10%), and postoperative hemorrhage (1% to 8%). The high variability in complication rates between studies can partially be attributed to lack of standardized reporting of postoperative adverse events.

The International Study Group of Pancreatic Surgery has greatly contributed to our understanding and better definition of postoperative complications. A series of recent publications by this group standardized definitions for postpancreatectomy hemorrhage (PPH), DGE, and pancreatic anastomotic leakage.

PPH has been categorized by three important parameters: onset (before or after 24 hours from the time of surgery), location (intra- or extraluminal), and severity (low or high). A combination of these variables categorized patients into A, B, and C categories, depending on the time of onset, the site of bleeding, and the clinical impact. DGE has been defined as the inability to return to a standard diet by the end of the first postoperative week. Categories A, B, and C have been established considering the inability to tolerate solid food by 7, 14, or 21 days, or nasogastric tube requirement by 3, 7, or 14 days postoperatively or reinsertion of the tube between the days mentioned above. DGE should also be differentiated from rare causes of mechanical obstruction with appropriate imaging. Postoperative pancreatic fistula has been defined as drain output of any measurable volume of fluid on or after postoperative day 3 with amylase content greater than three times the serum amylase activity. Further categories of leak with A (no clinical impact), B (deviation from normal postoperative course, percutaneous drain placement), and C (reoperation or death) have been established. Currently, existing leak definitions may still miss up to one third of pancreatic leaks. Also, achieving no measurable drain output by day 3 could be difficult, especially in the setting of intraoperative abdominal irrigation. Measurable drain output past 3 days with negative drain amylase signals no leak in the great majority of patients in our experience.

An increasing number of publications have addressed the surgical volume/outcome relationship worldwide. There is mounting evidence that complex pancreaticobiliary resections should be performed in high-volume centers to decrease postoperative complications, hospital cost, number of nontherapeutic laparotomies, and mortality, and to increase the number of patients receiving postoperative adjuvant therapy in a timely fashion. The exact definition of high-volume surgeon/center is debated: 10 to 12 cases per year usually qualify as high volume. While the overall postoperative complication rate between high-volume and low-volume centers could be comparable (likely secondary to the continued lack of standardization of reporting complications), the difference in postoperative mortality is substantial in most studies.

ADJUVANT AND NEOADJUVANT THERAPY AND SURVIVAL

The relative contribution of various treatment modalities to survival in periampullary cancers continues to be debated. Currently accepted treatment modalities include surgery, chemotherapy, and radiation in various combinations. A curative intent resection provides the only potential chance for cure or long-term survival. On the other hand, an up to 80% disease recurrence following pancreaticoduodenectomy argues against surgery alone being an adequate treatment modality. Preoperative or adjuvant chemotherapy likely increases the chances of survival, although the benefit is on the order of months rather than years. The role of radiation is even more debatable, especially in ampullary or biliary cancers. A controversial, prospectively randomized trial studying the effects of radiation in pancreatic cancer from Europe showed potentially detrimental effects of postoperative radiation. Other, retrospective reviews show potential benefit, but the effects of radiation are difficult to separate from the potential benefits of chemotherapy. Study outcomes have also been scrutinized by inclusion of patients with positive or unknown surgical resection margin status. Radiation may be best utilized in the setting of preoperative chemoradiation in pancreatic cancer for concerns of major vessel involvement or for close or involved resection margins in the postoperative setting for periampullary tumors, but the data, especially in ampullary-type or biliary-type cancers, are sparse.

While the safety of pancreaticoduodenectomies has come a long way, little progress has been made in terms of overall survival in periampullary tumors. Population-based studies show dismal results, with overall survival as low as 13 months in the setting of curative intent resection for pancreatic adenocarcinoma followed by adjuvant chemotherapy. Even today, selected centers of excellence continue to report a 24-month or shorter median survival for pancreatic cancer treated with curative intent surgery and adjuvant therapy. This translates into a 5-year survival of about 20%. Five-year survival of patients with resected invasive ampullary adenocarcinoma is significantly better at about 40% to 50%. Patients with resected distal bile duct tend to survive longer than pancreatic cancer patients but shorter than patients with invasive ampullary cancers (25%-35%). Surgical margin status and presence of lymph node metastasis continue to be strong predictors of long-term outcome.

The ideal adjuvant chemotherapy combination continues to be a search in progress. While gemcitabine showed promise in early clinical trials, the recent ESPAC-3 trial for surgically resected pancreatic adenocarcinoma showed no survival benefit over fluorouracil plus folinic acid in a prospective randomized trial, with both drugs resulting in a median overall survival of 23 months. Gemcitabine has been combined with various other drugs in multiple other studies without a significant improvement in overall survival. A recently published study from Europe compared single-agent gemcitabine (11% response rate) with a combination regimen (FOLFIRINOX, 31% response rate) in the setting of stage 4 pancreatic cancer. While results

from this trial that involved patients with metastatic pancreatic cancer are not directly applicable to patients with resected pancreatic cancer, early clinical trials using neoadjuvant FOLFIRINOX in locally advanced pancreatic cancer are encouraging.

The benefits of adjuvant chemotherapy and radiation in resected, early-stage periampullary cancers are poorly studied. Most published trials lump various periampullary tumors together and frequently enroll metastatic and locally advanced patients together. The ABC-02 trial randomly assigned over 400 patients with locally advanced or metastatic cholangiocarcinoma, gallbladder cancer, or ampullary cancer to receive either cisplatin followed by gemcitabine or gemcitabine alone. Median overall survival was 11.7 months in the cisplatin-gemcitabine group compared with 8.1 months in the gemcitabine-only group. While combining cisplatin with gemcitabine appears to be beneficial in locally advanced or metastatic cholangiocarcinomas and ampullary cancers, the trial obviously provides no evidence for its use in resected, early-stage cancers.

A Phase-III EORTC trial studied adjuvant radiotherapy and 5-FU following curative intent resection of cancers of the pancreas and periampullary region. In the trial, 218 patients were randomized into adjuvant therapy versus observation. Over half of the patients had pancreatic cancer. When results were stratified for tumor location, the 2-year survival rate was 63% in the observation group and 67% in the treatment group, showing basically no advantage to adjuvant therapy in terms of overall survival. Progression-free survival was also similar between treatment groups.

Several studies examined the risks and benefits of neoadjuvant chemotherapy or chemoradiation in the setting of resectable and locally advanced pancreatic cancer. Arguments used for administration of neoadjuvant therapy include a high risk of undiagnosed stage 4 disease reflected by short postoperative disease-free survival, the conversion of locally unresectable disease to resectable, and whether preoperative radiation given in well-vascularized tissue may be more effective. Some investigators reported overall survival in the range of 3 years following administration of neoadjuvant chemoradiation to patients with resectable pancreatic cancer, which is almost a year longer compared with survival curves reported from other major institutions in the United States in the setting of curative intent surgery followed by adjuvant therapy. However, these findings are not uniform, and recent meta-analyses of studies addressing the potential benefits of neoadjuvant treatment for pancreatic cancer found little to no evidence of survival benefit for resectable or borderline resectable tumors treated in a neoadjuvant fashion.

Vascular Reconstruction During the Whipple Operation

Russell N. Wesson, MBChB, and Andrew M. Cameron, MD, PhD

OVERVIEW

The importance of Whipple operation (pancreaticoduodenectomy) for pancreatic tumors with portal vein (PV) and superior mesenteric vein (SMV) resection and reconstruction lies in the ability to safely achieve outcomes that are equivalent to those of standard pancreaticoduodenectomy. Resection of these tumors, which, by nature of their location or size, involve the portal or mesenteric vein and classifies them as borderline resectable, allows the potential for complete clearance of disease and the avoidance of R2 resection. Thus, PV/SMV resection allows for R0 or R1 resection in tumors that would otherwise be unresectable.

With the increasing use of neoadjuvant therapy, previously unresectable tumors are now becoming resectable. Additionally, as the knowledge of indications for and outcomes after PV/SMV resection and reconstruction are being more widely disseminated and understood, the authors are seeing PV resection increasingly necessary and utilized. For both these reasons, PV resection and reconstruction is increasingly becoming an important element of pancreaticoduodenectomy and occasionally distal pancreatectomy.

RATIONALE FOR PV/SMV RESECTION

Proximity of the tumor to the SMV does not carry with it the implications that accompany arterial proximity. Tumors adjacent to or invading the superior mesenteric artery (SMA) are at risk of perineural invasion and extension along these autonomic nerves. Where tumors involve the artery, the periarterial neural plexus, together with the propensity of ductal adenocarcinoma for neural invasion, allows for the malignancy to extend locally through the nerve sheath into the retroperitoneum. This underlies the lack of added benefit from radical pancreatectomy in terms of survival and local recurrence rates, as findings from randomized trials show. Mesenteric or portal venous invasion does not in itself carry a worse prognosis as compared with similar tumors without PV/SMV involvement. As evidenced by the presence of circulating tumor DNA early in the

course of the disease, tumors have access to the systemic circulation much earlier in the disease than when large enough to invade the PV or SMV. Additionally, resection of the vein does not carry the symptomatic implications of midgut denervation that accompany arterial resection.

Aside from the significant oncologic benefit in the borderline resectable tumors because of venous involvement, an approach to the vein is also an important technical aspect of pancreaticoduodenectomy. The ability to reconstruct the PV/SMV allows for the surgeon to deal effectively with venous injury, which may occur while attempting to mobilize the pancreatic neck off the PV and SMV where fibrosis or desmoplastic reaction makes this hazardous. Achieving a patent reconstruction avoids significant compromise to midgut venous outflow that results in bowel edema. Interruption of portal venous hepatic inflow can also result in extensive hepatic necrosis that can represent a serious morbidity or even mortality.

PREOPERATIVE IMAGING

The approach to PV resection at pancreaticoduodenectomy begins with interpretation of preoperative images and anticipation of surgical events and requirements.

High-quality computed tomographic (CT) and magnetic resonance (MR) imaging with three-dimensional vascular reconstruction, when performed according to established protocols, provides excellent images that allow for the preoperative determination of tumor resectability. Borderline resectable tumors describe those tumors where venous abutment or encasement by pancreatic tumors is present and, in rare cases, those tumors where a resectable short segment of occluded vein is present in the absence of arterial involvement. Abutment, compression or distortion, and encasement of the vein indicate increasing degrees of involvement. In these circumstances, the need for vascular resection and reconstruction should be anticipated and the venous anatomy and involvement appreciated.

Preoperative appreciation of venous involvement precludes the situation where vascular involvement is inadvertently discovered intraoperatively. Without this determination, attempting to mobilize the pancreatic head off the vein leads to two possible scenarios: either it becomes clear that there will be a grossly positive margin and R2 resection, or attempted mobilization of the pancreatic head results in a torn PV/SMV and potentially torrential hemorrhage. Anticipation of involvement precludes venous injury and is associated with lower blood loss and a technically easier reconstruction.

Preoperative imaging also allows for the defining of aberrant vascular anatomy, including the presence of a replaced right hepatic artery as well as a common hepatic artery originating from the SMA.

SURGICAL ANATOMY OF THE SUPERIOR MESENTERIC VEIN

The confluence of the superior mesenteric, splenic, and portal veins is posterior to the pancreatic neck. The main trunk of the SMV is constituted from a jejunal and an ileal branch that merge caudal to the pancreas. This main trunk receives the gastroepiploic and middle colic vein (which may or may not join as the gastrocolic trunk prior to entering the SMV).

The first jejunal branch of the SMV is usually found posterior to the SMA as it enters the posteromedial ileal branch where these merge to form the main trunk SMV. As the jejunal branch passes posterior to the SMA, it receives branches from the uncinate process. During mobilization of the pancreas from the vein, these branches are divided to release the main SMV and allow the SMA to be retracted laterally. Where the jejunal branch passes anterior over the SMA, the uncinate branches enter the ileal branch rather than the jejunal branch. In this situation, there are often variations of venous anatomy. This may include the inferior mesenteric vein draining directly into the jejunal branch as opposed to the usual merging with the splenic vein.

SURGICAL TECHNIQUE

Mobilization of the portal and superior mesenteric veins above and below the pancreas, respectively, will allow for proximal and distal control of the mesenteric vasculature with vessel loops prior to reconstruction. The portal vein is mobilized by dividing the lymphoareolar attachment between the portal vein and the superior aspect of the pancreas as well as through division of small venous tributaries. Mobilization of the SMV is achieved by dividing the middle colic and right gastroepiploic venous tributaries, or their common trunk, the gastrocolic trunk, in addition to ligation of multiple tributaries from the inferior aspect of the uncinate process and pancreatic head. Perineural and lymphatic tissue between the SMA and the anterolaterally located superior MPV confluence is then divided.

Vein involvement is then addressed with one of several available techniques. Where tumor is adherent to a small area of vein, a Satinsky or DeBakey clamp can be applied to partially occlude the PV or SMV, and a small ellipse of vein can be longitudinally excised along the lateral aspect of the clamp (Figure 1). A running 5-0 nonabsorbable suture closes the defect in the vein (Figure 2). Should the repair result in a significantly narrowed vein with a risk of bowel edema, congestion, and PV thrombosis, the repair may be readdressed and converted from a longitudinal closure to a transverse closure. Other options include the placement of a venous patch, which may be fashioned using saphenous vein, or placement of an artificial (polytetrafluoroethylene [PTFE]) patch (Figure 3). Alternatively, the segment of vein may be resected after obtaining inflow and outflow control, usually with Blalock-Taussig–style clamps. Prior to venous occlusion, arterial inflow may be temporarily occluded with a Rummel tourniquet after the intravenous administration of 2500 to 3000 units of heparin with a circulation time of 2 to 3 minutes prior to occlusion. Some authors believe that arterial occlusion avoids bowel edema, which may complicate the biliary and pancreatic anastomoses; the

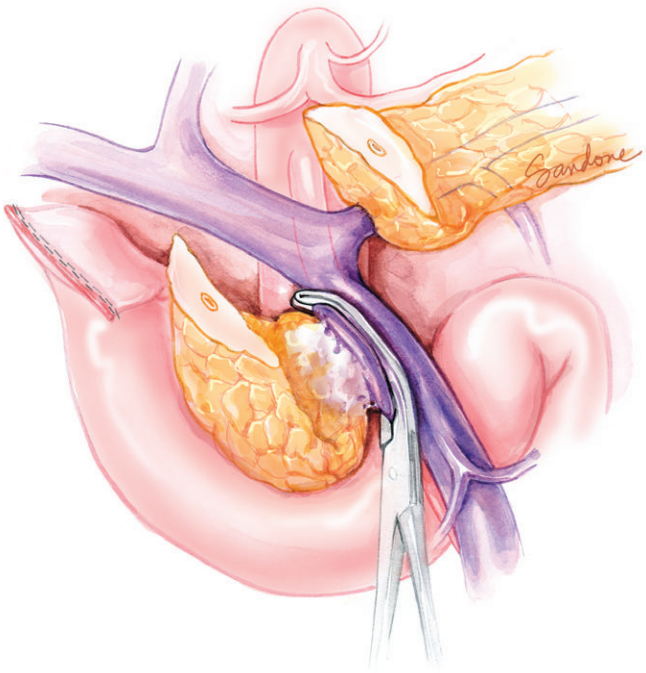

FIGURE 1 Side-biting vascular clamp to facilitate venous excision.

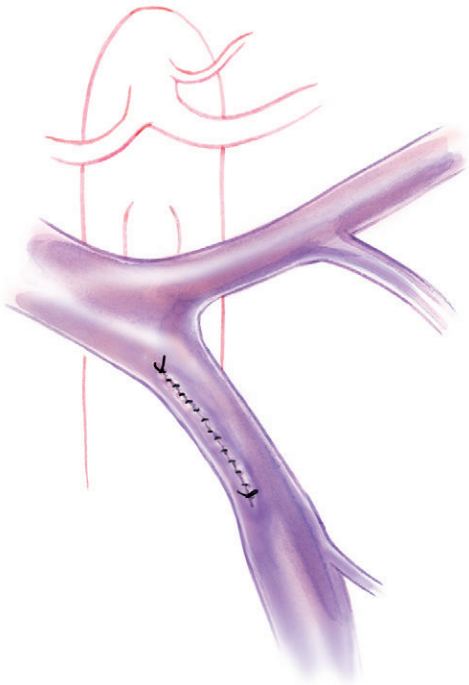

FIGURE 2 Primary repair of venotomy without compromise.

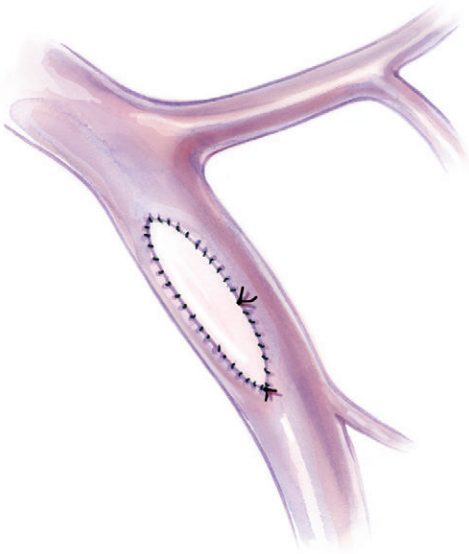

FIGURE 3 Repair with patch to avoid narrowing.

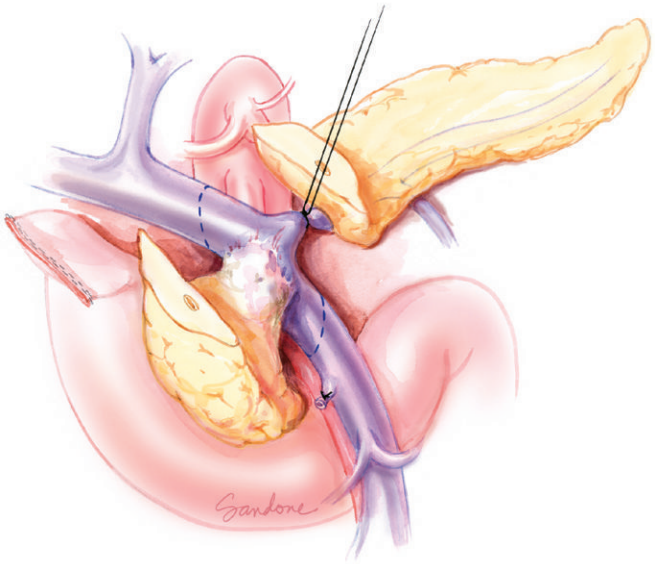

FIGURE 4 Division of splenic vein provides additional length for reconstruction.

authors do not use heparin or arterial occlusion, as the venous resection and clamping is normally quite brief and well tolerated.

After excision of the affected area of vein, margins should appear grossly clear of disease, and frozen section should be sent for pathology review to ensure R0 resection where possible. Revision of the anastomosis and further resection of vein may be necessary should vein margins be microscopically positive. Mobilization of the proximal venous segment toward the liver and distal segment toward the bowel mesentery may enable primary anastomosis across a 2-cm to 3-cm gap directly. Division and ligation of the small venous tributaries to the SMV arising from the uncinate to the jejunal branch may be necessary for mobilization. The jejunal branch joining the medial SMV from the patient's left was exposed when the mesentery between the SMA and the SMV was dissected. The first jejunal branch may then be ligated if involvement by tumor necessitates resection, but the ileal branch must be of sufficient caliber to allow adequate venous flow. Involvement of these vessels with a need for reconstruction is a rare event. Where choices between reconstruction of either branch need to be made, the larger branch should be reconstructed with an interposition graft used as necessary.

Should primary reanastomosis initially not appear achievable because of the presence of a distance greater than 4 cm, various maneuvers may be used to facilitate this. The authors have found that interposition of a graft is rarely necessary. Splenic vein ligation and division will often facilitate primary anastomosis (Figure 4). The splenic vein tethers the SMV and prevents its mobilization to close the gap resulting from the resected vein. Division of the splenic vein frees the SMV and allows for closure of a gap 3 to 4 cm wide (Figure 5). Ligation of the splenic vein in the setting of a divided left gastric vein and inferior mesenteric vein that is a tributary to the splenic vein carries a risk of left-sided portal hypertension and the development of gastroesophageal varices. For this reason, some authors recommend construction of a splenorenal shunt at the time of surgery under these circumstances. However, the authors have found this to be a rare clinical consequence. In 42 instances of splenic vein ligation at PV resection, the authors have noted only 1 episode of variceal bleeding subsequent to this maneuver, occurring months after surgery with control via endoscopic injection.

Another technique facilitating primary anastomosis of the PV and SMV includes division of the hepatic coronary ligaments and the placement of a pack behind the liver that may facilitate caudal mobilization of the liver. Reconstruction is then carried out with a running suture leaving sufficient growth factor to allow for venous expansion and the avoidance of anastomotic constriction.

In rare cases, an interposition graft may be necessary. Many conduits have been used as interposition grafts, including internal jugular, left renal, splenic, and gonadal vein; the authors prefer the first two (Figure 6). Ringed PTFE grafts have been used but should be avoided because of a higher risk of venous thrombosis postoperatively. Although venous thrombosis acutely may cause hepatic ischemia and intestinal congestion necessitating thrombectomy and revision, thrombosis is rarely symptomatic if it occurs late postoperatively.

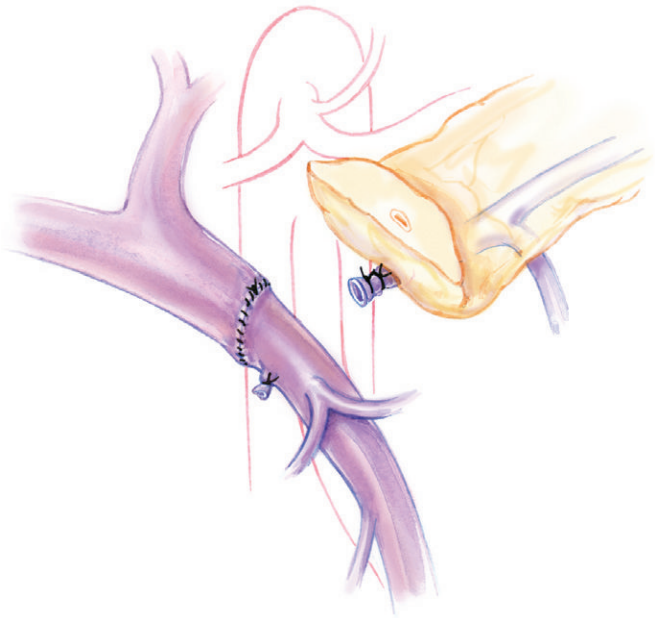

FIGURE 5 Primary anastomosis is usually possible when the splenic vein has been sacrificed.

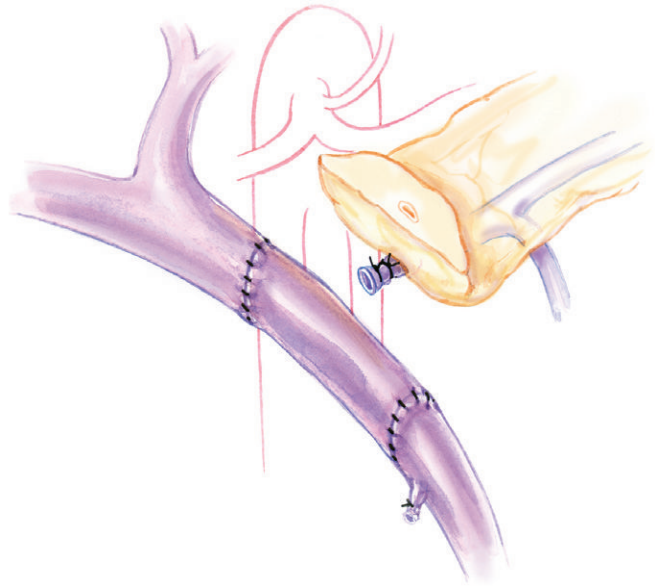

FIGURE 6 Interposition graft to avoid tension when necessary.

ARTERIAL RECONSTRUCTION

Preoperative imaging will show arterial involvement and define arterial anatomy, revealing the presence of replaced left or right hepatic arteries as they arise from the left gastric or SMA, respectively. Aberrant anatomy should be appreciated, and the chances of inadvertent injury of these vessels should be minimized. If a short segment of involved hepatic artery necessitates resection, mobilization of distal and proximal segments of redundant hepatic artery will often facilitate reconstruction with primarily anastomosis or use of conduit.

Where a replaced right artery is resected, reconstruction is performed to preserve common bile duct blood supply and avoid unnecessary compromise of hepatic arterial supply. If an aberrant common hepatic artery originates from the SMA and is involved by tumor, it should be recognized, preserved, or reconstructed. Finally, division of the gastroduodenal artery may compromise arterial supply to the liver if there is inadequate flow through the common hepatic artery via the celiac axis. Defining and dissecting the common hepatic artery down to the celiac axis will allow for division of the arcuate ligament and relief of extrinsic limitation of flow and an improved pulse and Doppler signal in the common hepatic artery.

SUMMARY

PV/SMV resection and reconstruction adds complexity to the already challenging operation of pancreaticoduodenectomy. However, it is increasingly being performed and can be performed safely, avoiding the catastrophic outcomes (through either residual disease or hemorrhage at injury) that may occur when vein involvement is not addressed appropriately or safely. Preoperative planning is an essential element of addressing venous involvement and allows for the anticipation of reconstruction with the performance of a safe and effective operation. In borderline resectable tumors due to venous involvement, outcomes can be achieved that are identical to those of patients without venous involvement who undergo standard pancreaticoduodenectomy. Resection of PV/SMV at pancreaticoduodenectomy gives rise to a median survival rate that equals that of patients undergoing standard pancreaticoduodenectomy. Vein resection therefore allows the possibility of curative treatment in an aggressive and otherwise fatal disease and should be undertaken in appropriately selected patients at high-volume centers and by surgeons experienced in venous resection and reconstruction techniques.

Palliative Therapy for Pancreatic Cancer

Claudius Conrad, MD, PhD and
Keith D. Lillemoe, MD

INTRODUCTION

A surgeon's role in the treatment of pancreatic cancer in patients who are not candidates for resection with a curative intent remains very important, as a significant percentage of those patients will develop symptoms that need surgical or nonsurgical palliative procedures. The three most important symptoms that might require surgical palliation are (1) biliary obstruction, (2) gastric outlet obstruction, and (3) pain.

To put into perspective the role of surgery for palliation, we look to the following recent data from the National Cancer Institute: It was estimated that in 2012, 43,920 people in the United States would be diagnosed with pancreatic cancer and 37,390 would die of the disease. At diagnosis, 8% of the cancer would be localized, 27% would be locally advanced, and 53% would involve distant metastases. Even despite improvements in surgical outcomes and oncologic therapy, primarily with palliative chemotherapy, the corresponding 5-year survival rates for these stages will only be 23%, 10%, and 2%, respectively. Surgical resection with curative intent leads to significantly worse outcomes for patients with pancreatic cancer compared with patients with most other gastrointestinal cancers, with the median survival for resected patients being only 18.3 months and the 1- and 3-year survival rates being 58.4% and 34.8%. These data underscore the aggressive underlying biology of pancreatic cancer and illustrate that despite surgical, chemotherapeutic, and radiation-therapeutic advances, this deadly disease still carries a mortality rate that is dangerously close to the incidence.

Because the majority of pancreatic cancer patients do not undergo surgery with curative intent, addressing the potentially debilitating symptoms is of primary importance. A surgeon who cares for this population of patients needs to be versatile and competent in providing palliative care employing both operative and nonoperative techniques for palliation, including both improved endoscopic or percutaneous guided techniques and conventional open and newer, minimally invasive procedures. The improved outcomes (early success and durability of endoscopic palliation for malignant biliary obstruction) further improved with progress by the development of covered metallic stents, which have become the gold standard for management of this symptom. Further, minimal-access palliative surgical approaches have been developed over the past decade to offer surgical management of gastric outlet obstruction, biliary obstruction, and pain control via laparoscopic or robotic surgery, single-incision laparoscopic surgery (SILS), and even natural orifice transluminal endoscopic surgery (NOTES). Several studies have shown that laparoscopic surgery for pancreatic procedures results in less pain, decreased length of hospitalization, fewer wound infections, and other perioperative benefits that are of particular importance to patients whose survival is limited. Future technologic advances, such as articulating instruments, three-dimensional (3D) cameras, and a growing number of surgeons with advanced laparoscopic skills, likely will improve patient access to these minimally invasive options for palliation.

The management of pancreatic cancer today is an interdisciplinary team effort. Palliative therapy has been shown to improve quality of life, decrease symptom intensity, and elevate mood, as well as minimize unnecessary resource consumption by patients whose survival is limited. Considering the rising awareness and importance of financial responsibility in our healthcare system, a resource-conscious treatment approach to patients with advanced pancreatic cancer is expected to become increasingly significant. A greater integration of surgical input in the interdisciplinary care of these patients might help reduce rehospitalization and length of stay as well as facilitate cost containment.

In this chapter we list indications for palliative intervention and explain nonsurgical as well as surgical treatment options of the three most important symptoms: biliary obstruction, gastric outlet obstruction, and pain. We focus on the existing data with respect to palliative resection for "incurable pancreatic cancer." Finally, we touch on the medical treatment options (chemotherapy and chemoradiation) for patients with unresectable pancreatic cancer to comprehend the surgeon's role in providing care for patients receiving palliative chemotherapy and in managing potential complications.

INDICATIONS FOR PALLIATIVE INTERVENTIONS

It is our strong belief that an experienced pancreatic surgeon should be involved very early, at the first suggestion of the diagnosis of pancreatic cancer, well before invasive procedures such as biliary stenting or endoscopic ultrasound-guided fine-needle aspiration are performed, to ensure optimal timing, technique, or even the need for these procedures. Too often, the initial "knee-jerk" reaction to place a small plastic stent in jaundiced patients is either unnecessary or less optimal than a metal stent based on the overall plan for management. The surgeon should provide initial input as to the role of potentially curative resection and the need for palliative procedures. Comorbidities that render a patient unfit for major surgery, locally advanced disease with inability to achieve R0 resection, and disseminated disease are all contraindications for resection. Ideally this should be determined preoperatively on a high-quality computed tomographic (CT) scan with intravenous contrast with 1-mm thin sections administered as a "pancreas protocol" to depict both arterial and venous phases (Figure 1). The goal of the pancreatic protocol CT scan is to identify pancreatic tumor local extension and metastases, especially to the liver. An elevated CA 19-9 tumor marker value above 130 units/mL in the absence of jaundice has predictive value of radiographically occult systemic disease (26% of patients). In these patients, a staging laparoscopy might be considered before exploration.

The majority of patients (an estimated 80%) with pancreatic head adenocarcinoma seek medical attention for symptoms related to jaundice secondary to mechanical obstruction of the intrapancreatic portion of the distal common bile duct. As a consequence, jaundice is the most common and often the first symptom of pancreatic cancer. In addition to being a symptom for underlying pancreatic cancer, obstructive jaundice is a significant clinical problem in itself, leading to debilitating pruritus, anorexia and progressive malnutrition, liver malfunction and failure, and even premature death if not treated. Thus, relieving obstructive jaundice is of importance in all patients. The impact of successful biliary drainage on quality of life has been assessed prospectively in a cohort of patients with malignant biliary obstruction in the setting of unresectable disease. One month after relieving biliary obstruction via stenting, baseline bilirubin of greater than 14 mg/dL was associated with a lack of improvement in social function, while decreasing bilirubin levels were associated with improvements in social function and mental health.

Another common presenting symptom is gastroduodenal obstruction due to advanced tumor growth, a symptom that develops in 20% to 40% of patients during the course of their disease. Endoscopic or surgical intervention is required to relieve the obstruction.

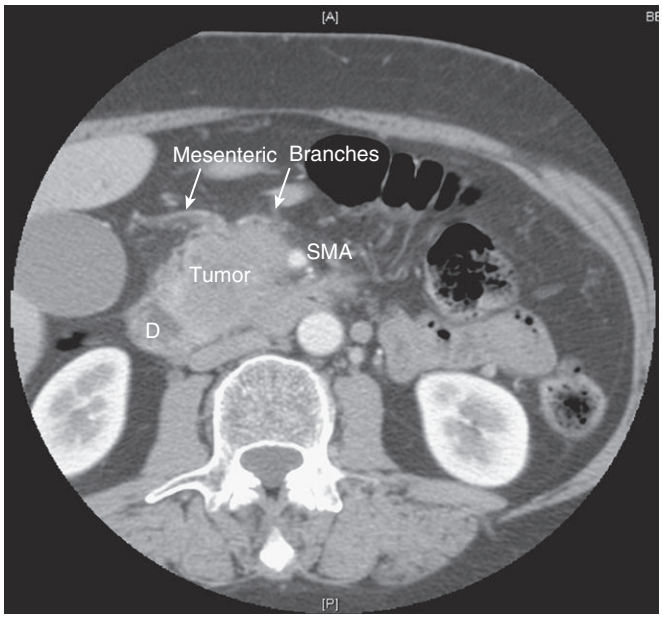

FIGURE 1 Pancreatic protocol CT scan of unresectable pancreatic cancer. This is an axial arterial phase CT image of a pancreatic head adenocarcinoma of a patient who, most surgeons would agree, is not eligible for resection. The superior mesenteric artery (*SMA*) is partially encased by the cancer that is also invading the colonic mesentery. The duodenum (*D*) is narrowed by the mass leading to gastric outlet obstruction, and the intrapancreatic portion of the common bile duct is completely obliterated by the mass, which is causing biliary obstruction and jaundice. *CT,* computed tomographic.

It is important to distinguish mechanical obstruction secondary to tumor growth from motility dysfunction of the stomach and duodenum due to infiltration of the celiac nerve plexus, which can lead to delayed gastric emptying. Motility dysfunction should be treated with pharmaceutical agents rather than surgery or stenting.

The question has been raised as to the role of biliary bypass and gastrojejunostomy in the presence of unresectable disease found at the time of operation. We and other groups have shown that if unresectable disease, with or without symptoms of gastric outlet obstruction, is found at exploration, a prophylactic gastrojejunostomy should be performed because as many as 20% of patients develop gastric outlet obstruction during the course of their disease. In contrast, due to the availability of endoscopic biliary stenting, if necessary, prophylactic biliary bypass is not indicated in nonjaundiced patients. The decision to add an open biliary bypass in a patient who has already been endoscopically stented is usually based on the operative findings for each patient. In a patient who is found to have unsuspected liver metastases, the authors likely would choose not to bypass the stented biliary tree. In contrast, in patients with locally advanced unresectable pancreatic cancer, the bile duct is often divided to assess for resectability. A biliary reconstruction must then be performed.

In contrast to other gastrointestinal cancers in general, where pain has been reported to occur at a relatively low frequency, pain in pancreatic cancer is a frequent symptom: about 20% to 40% experience pain at time of diagnosis and up to 80% experience pain during the course of their disease. The possible etiologies of the pain, which is usually dull and located in the back or upper abdomen, are infiltration of the mesenteric or celiac plexus, or pancreatic duct obstruction, although the precise pathophysiology has not been elucidated. Similar to pain treatment in general, palliating pancreatic cancer pain follows the World Health Organization's Pain Relief Ladder, which prescribes tiered increases in potency of administered analgesics starting with nonsteroidal antiinflammatory drugs (NSAIDs), followed by the addition of opioids and other adjuvant pain medication if needed. Pain medication should be administered on a schedule of every 3 to 6 hours rather than "on demand" and has been reported to have an efficacy of about 80%. Opioids, although more often underdosed than overdosed in the palliative setting, can lead to side effects such as altered mental status, constipation, nausea and vomiting, and loss of efficacy over time, especially if celiac or mesenteric plexus infiltration occurs.

Invasive treatment options should be considered when pharmacologic strategies to control cancer pain fail to provide adequate pain relief despite correct dosing or when treatment side effects become prohibitive. The principle behind these techniques is to interrupt transmission of nociceptive stimuli from the pancreas and infiltrated organs to the central nervous system. For pancreatic cancer, the celiac ganglion is the optimal site to interrupt the pain sensory process. Celiac plexus blocks or chemical splanchnicectomy can be performed percutaneously, endoscopically, or operatively while determining resectability via laparoscopy or laparotomy. Pain relief through these methods is effective, although diarrhea and orthostatic side effects have been reported in as many as 40% of the patients. With both percutaneous and endoscopic blockade of the celiac plexus available today, the surgeon's role in the palliation of pain due to pancreatic cancer is almost exclusively limited to the cases of patients undergoing operation for resection or for palliation of symptoms other than pain. Similar to biliary and gastric diversion, splanchnicectomy should be performed routinely during exploration if unresectability is discovered. We and others have shown that in patients who underwent prophylactic chemical splanchnicectomy with 50% ethanol, effective pain control can be achieved. Furthermore, the subgroup with severe pain showed improved survival following successful pain therapy.

The next three sections will discuss the specific surgical techniques in managing pancreatic cancer in patients with symptoms of (1) biliary obstruction, (2) gastric outlet obstruction, and (3) pain.

PALLIATIVE SURGICAL INTERVENTIONS

Palliation of Biliary Obstruction

Obstructive jaundice is amendable to endoscopic, percutaneous, laparoscopic, robotic, and open drainage procedures. There is good evidence that today the most efficacious initial strategy to relieve biliary obstruction is endoscopic stent placement. Although both surgery and endoscopy are equally effective palliative options, endoscopic drainage with the insertion of a stent into the bile duct has been shown to significantly reduce the length of initial hospitalization and is associated with lower procedural morbidity and mortality as well as improved quality of life. Plastic biliary stents, which have been used in the past, have a tendency to clog and therefore may require repeated endoscopic interventions. Today, self-expandable metal stents have a larger diameter and are associated with a lower occlusion rate than that of plastic stents. Therefore, the use of metal stents has been shown to be cost-effective in patients who are expected to survive longer than 6 months. Metal stents can be (1) uncovered, that is, simply a metal mesh; (2) covered, which were developed because tumor growth through the mesh decreased patency; or (3) partially covered, meaning that the ends consist of an uncovered metal mesh that holds the stent in place, and the middle segment is covered. Conflicting evidence from Europe and the United States exists as to which stent design is the most efficacious. A frequent concern of medical oncologists and gastroenterologists is that the placement of a self-expanding metal stent in a patient who requires drainage but whose resectability is unclear will make a possible pancreaticoduodenectomy challenging if not impossible. In our

experience, metal stents are not a significant obstacle to either surgery for curative or palliative intent and should be deployed in patients whose life expectancy is estimated to be greater than 6 months or in those undergoing aggressive neoadjuvant therapy. Future research should explore the role of drug-eluding stents with, for example, Paclitaxel, with the idea that the chemotherapeutic drug will prevent obstruction secondary to tumor ingrowth.

Transhepatic percutaneous access should be reserved for patients in whom endoscopy fails or is not anatomically possible (e.g., prior gastric bypass). In most cases, after initial percutaneous access with external drainage, stents can be placed that can be totally internal or after initial transhepatic access, the so-called rendezvous-procedure can be performed where a transhepatic guidewire facilitates endoscopic stent placement.

Despite these clear advantages of endoscopic stent placement to relieve biliary obstruction, there are some advantages to having a patient undergo a surgical biliary bypass. Severe complications and readmissions, usually due to stent dysfunction, are more likely to occur in patients treated endoscopically. Furthermore, in patients with gastric outlet obstruction, consideration should be given to an operative approach to bypass both the obstructed biliary tree and duodenum, as the combination of both metallic biliary and duodenal stents is often problematic. Therefore, it is our practice to explain the advantages and disadvantages of both operative and endoscopic procedures, particularly to fit patients.

Our preference for surgical palliation of biliary obstruction is Roux-en-Y hepaticojejunostomy for open biliary diversion and a loop jejunostomy for a laparoscopic approach (Figure 2). The technical details are as follows. Cholecystectomy is performed, if it has not previously been performed, and the common bile duct is mobilized. An important technical point is that minimal mobilization of the bile duct should be performed with an understanding of the vascular supply to avoid ischemia, which can lead to stenosis or leak. The common bile duct or hepatic duct is then transected, and a frozen section of the margin is obtained. This is important to avoid leaving cancer at the anastomosis, which could lead to obstruction due to tumor regrowth. The distal end of the common bile duct is sutured closed. We routinely send aerobic and anaerobic cultures if the patient has had a prior biliary stent in order to have microbiology data to initiate appropriate antibiotic therapy should biliary sepsis occur. The Roux-en-Y limb is created using a 40-cm jejunal limb that is usually anastomosed to a jejunal limb in end-to-side fashion approximately 20 cm distal to the ligament of Treitz. Alternatively, a loop hepaticojejunostomy with a proximal enteroenterostomy is a suitable option. The hepaticojejunostomy is completed with either interrupted 4.0 PDS or Vicryl sutures, or, if the duct diameter is large due to prior biliary obstruction, in running fashion. It is important to incorporate the jejunal mucosa into the anastomosis with great care to prevent transient biliary obstruction from an edematous mucosa. Other techniques for biliary drainage include choledochoduodenostomy or cholecystojejunostomy. These procedures performed via open surgical techniques have been almost entirely replaced by hepaticojejunostomy due to superior short- and long-term results. Patients undergoing gallbladder-enteric anastomosis are at substantially greater risk of requiring subsequent biliary drainage procedures compared to those undergoing a bile duct–enteric anastomosis. This discrepancy is secondary to frequent cystic duct involvement in tumor progression.

Laparoscopic biliary diversion requires advanced laparoscopic skills to safely mobilize the bile duct and to perform a stapled or handsewn hepaticojejunostomy. We construct a laparoscopic hepaticojejunostomy in a loop fashion. A loop of proximal jejunum is brought up to the hepatoduodenal ligament and anchored with a stitch. After transsection of the bile duct, a small enterotomy is made in the approximated jejunum. It is important to not make the enterotomy too large, as it tends to widen during fabrication of the anastomosis. This anastomosis can also be constructed in a side-to-side fashion, which might be technically easier in certain situations (Figure 3). Due to the magnification of a laparoscopic camera of about ×10, even a nondilated bile duct can routinely be anastomosed in a running fashion with double-armed 6.0 PDS sutures that have been shortened to a total length of 30 cm. Alternatively, as it is technically easier, a laparoscopic cholecystojejunostomy is an option for very select patients if the cystic duct is found to be well clear of tumor involvement.

Robotic surgery has recently been applied to the palliation of pancreatic and distal bile duct cancers. This resource intensive technology has the advantage of 3D vision and articulation of the

FIGURE 2 Anatomy after double bypass. The schema demonstrates a Roux-en-Y hepaticojejunostomy of 40 cm as well as a retrocolic loop gastrojejunostomy. We recommend this retrocolic position of the gastrojejunostomy, as it has been shown to have a lower rate of delayed gastric emptying. The gastrojejunal anastomosis should be delivered through the colonic mesentery to prevent obstruction, and care should be taken to avoid vagal branches, as severing them might lead to delayed gastric emptying.

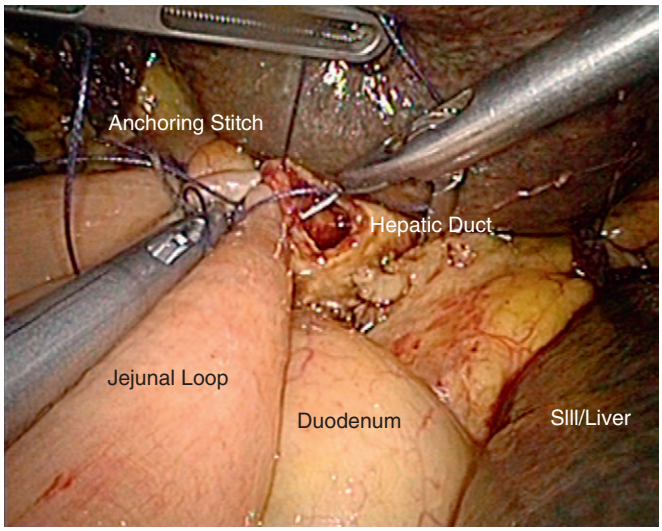

FIGURE 3 Laparoscopic view of a laparoscopic hepaticojejunostomy. A loop of jejunum is anchored at the hepatoduodenal ligament and a side-to-side hepaticojejunostomy constructed. Using a shortened double-arm suture facilitates running the suture for construction of the anastomosis. The magnification of the laparoscope might facilitate this anastomosis when a nonobstructed duct is small.

instruments. Because of these advantages, primarily open surgeons often find it easier to transition to offering patients a robotic approach over a laparoscopic one. However, the need for cost containment in health care today makes robotic palliation of pancreatic cancer an inefficient application of the technology at the present stage.

Palliation of Gastric Outlet Obstruction

We mentioned in the introduction that, based on level I evidence, a gastrojejunostomy should be performed regardless of symptoms if the patient is deemed ineligible for curative resection during operative exploration. Prophylactic surgical bypass at time of exploration does not increase postoperative morbidity or mortality and prevents late gastric outlet obstruction. A gastrojejunostomy can be performed either by laparoscopic or open technique as a simple loop side-to-side procedure or as a Roux-en-Y gastrojejunostomy (Figure 4). Complications of a Roux-en-Y gastrojejunostomy, such as Roux stasis syndrome, can occur; therefore, this technique is rarely indicated. The gastrojejunal anastomosis can be performed using a variety of techniques (handsewn vs stapled, running vs interrupted sutures, single layer vs double layer anastomosis); however, no technique has been shown to be superior over the others. Two different techniques of delivering the loop of jejunum are antecolic, which means ventral to the transverse colon, and retrocolic, where the loop of jejunum is delivered through the transverse colonic mesentery. It had been assumed that antecolic gastrojejunostomy avoids proximity to the tumor bed and therefore prevents late failure due to tumor ingrowth; however, delayed gastric emptying, despite a patent gastrojejunostomy, is a common postoperative problem following antecolic gastrojejunostomy. Retrocolic, isoperistaltic gastrojejunostomy, which has been shown to be associated with a lower incidence of postoperative delayed gastric emptying and even late-occurring gastric outlet obstruction, is therefore our recommendation (see Figure 2). The posterior gastrojejunostomy should be delivered below the transverse mesocolon and fixed in place at the level of the anastomosis to avoid obstruction at the mesenteric slit. Vagotomy of the gastric branches should be avoided during palliative gastrojejunostomy to prevent delayed gastric emptying. Long-term gastric acid suppression with a proton pump inhibitor is advised.

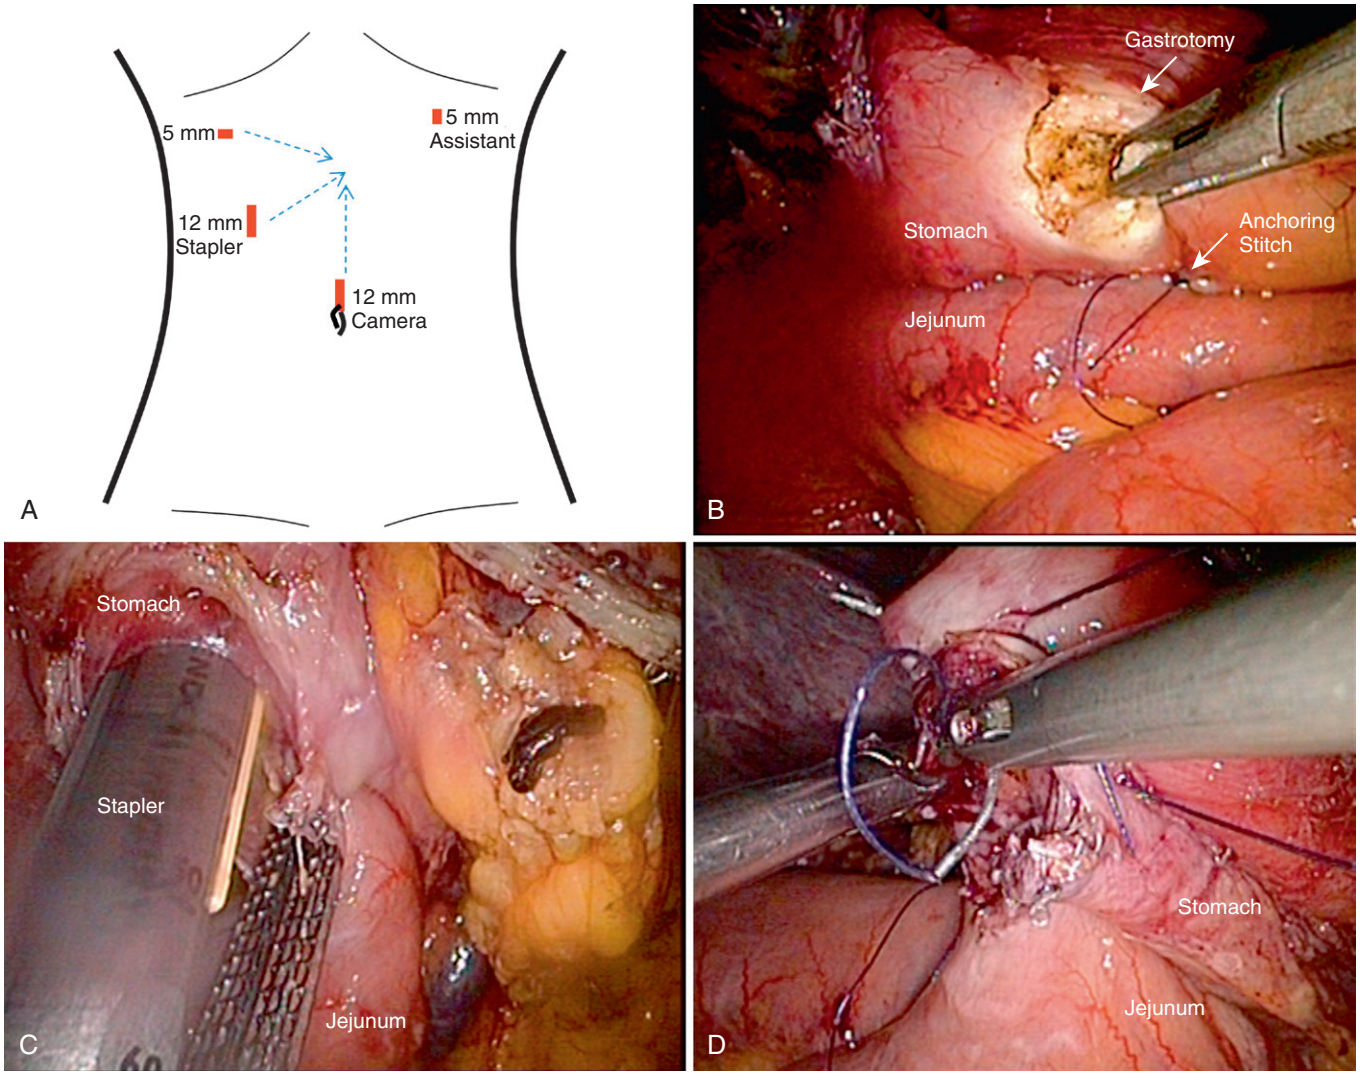

FIGURE 4 Laparoscopic gastrojejunostomy. **A,** Trocar positioning: two 12-mm trocars are used to accommodate camera and endoscopic stapler. The 5-mm port under the right costal margin is an operator working port, and the port under the left costal margin is used by the assistant for retraction. **B,** A loop of jejunum is anchored to the stomach, and a gastrotomy and an enterotomy are performed to accommodate the stapler. **C,** After the stapler is fired, an anastomosis between stomach and jejunum is created. **D,** The small whole that accommodated the stapler is sutured closed.

Duodenal stenting with self-expandable metallic stents is also an option in the treatment of gastroduodenal obstruction. The concept of the stent design is similar to that for the biliary tract, but duodenal stents are typically longer (6 to 12 cm) and of larger calibers (18 to 23 mm). To prevent spontaneous migration and avoid coverage of the ampullary opening, the stents are uncovered. Duodenal stents should be reserved for patients who are not surgical candidates for either an open or a laparoscopic approach because of either comorbidities or advanced disease. While endoscopic stenting for the palliation of malignant gastroduodenal obstruction is associated with early clinical success (i.e., shorter time to oral intake and shorter length of hospital stay), operative gastric bypass procedures are preferable in patients with an expected prognosis of several months, who are likely to benefit from the reliable durability of surgical palliation. Additionally, biliary obstruction leading to cholangitis occurs in 6% of patients if the major papilla is affected by the stent. Although the endoscopist will try to deploy the stent clear of the papilla, this is not always possible. Also, duodenal stenting across the ampulla will make the patient ineligible for endoscopic biliary drainage should biliary obstruction occur later in the disease. Duodenal perforation is yet another potential and catastrophic complication of duodenal stent placement, which occurs because of the need to dilate the stricture and then traverse it with a side-viewing endoscope. Mechanical irritation of the intestinal mucosa can also cause bleeding, erosion, and even perforation. If the ends of the duodenal stent rest at the intestinal curves, such as the duodenal bulb, junction between the second and third portions of the duodenum, or the ligament of Treitz, the fold can lead to stent obstruction. Finally, patients who undergo a surgical bypass can consume a more balanced diet afterward than can patients who undergo duodenal stenting. Therefore, although duodenal stents have their role in patients who are not surgical candidates, further studies and advancements in device technologies are necessary to assign this treatment option a definitive role in the treatment algorithm of palliation of gastrointestinal obstruction.

Palliation of Pain

Surgical procedures for pain management in patients with unresectable pancreatic cancer should be carried out only if an operation is indicated for possible resection or palliation of other symptoms. The surgeon should refrain from operating on patients with inoperable pancreatic cancer for the sole purpose of relieving pain. Our preferred method is chemical splanchnicectomy celiac plexus block with 50% ethanol, which we perform during open or laparoscopic exploration if unresectable disease is found. The procedure is indicated in both patients with and without significant pain, as level I evidence shows that celiac block both reduces pain and prevents the development of significant pain. In the open technique, we place our nondominant hand on the aorta, with index and middle finger on either side. We then move our finger downward along the aorta, and the first branch we encounter is the celiac trunk, where the celiac plexus is located. We then infiltrate 20 mL of 50% alcohol using a 22-gauge spinal needle into the retroperitoneum on both sides of the aorta. The small caliber of the needle will help to prevent leakage from the injection-side from the retroperitoneum into the abdominal cavity when the needle is removed. The laparoscopic approach to target the celiac plexus is performed under ultrasound guidance. A laparoscopic ultrasound probe that has a small channel to guide the needle directly facilitates safe celiac plexus blockade (Figure 5). The incidence of major complications following neurolytic celiac plexus block has been shown to be low at 1 out of about 700 cases, with the most severe complications being death, nonreversible and reversible paraplegia, and anterior spinal syndrome.

Celiac plexus neurolysis can be performed percutaneously via ultrasound, fluoroscopic, or CT guidance. The advantage of CT or ultrasound guidance, usually performed via an anterior approach, is that the target area can be directly visualized to avoid damage to the surrounding structures, including the lung, pleura, liver, intestines, and blood vessels.

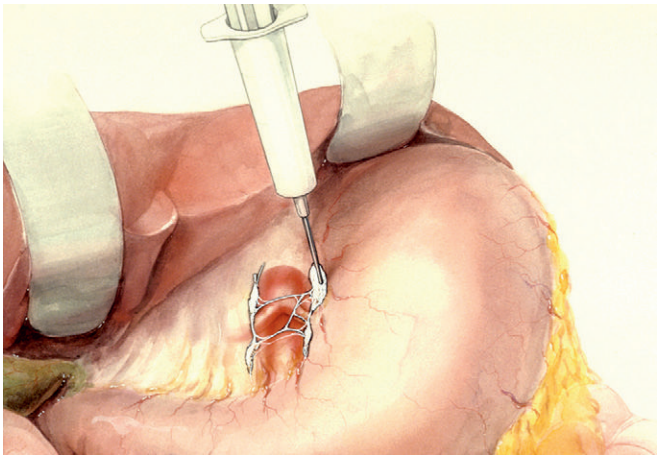

FIGURE 5 A chemical splanchnicectomy (celiac plexus block) can be accomplished by injecting 20 mL of 50% alcohol into the celiac ganglia on each side of the aorta at the level of the celiac axis. The use of a 22-gauge or smaller caliber spinal needle ensures containment of the injection wheal within the retroperitoneum. (Note: The celiac nerves are not frequently as nicely visualized as in this artist's rendition. More commonly the nerve fibers are not seen, and the alcohol is injected into the correct region, by palpating the aorta and celiac axis pulsation, and avoiding their puncture.)

Celiac plexus blocks for abdominal pain management in pancreatic cancer patients can also be performed endoscopically. Endoscopic ultrasound–guided celiac and mesenteric plexus blocks are safe and effective. Real-time imaging and anterior access to the celiac plexus from the posterior gastric wall help to prevent complications related to the puncture of spinal nerves, the aorta and its branches, and the diaphragm.

OUTCOMES AFTER SURGICAL PALLIATION

Surgical palliation of a patient with unresectable pancreatic cancer has several advantages over an endoscopic approach to palliation. The key advantages are that (1) the three most important symptoms—biliary obstruction, gastric outlet obstruction, and pain—can all be addressed during one procedure; (2) the experienced pancreatic surgeon will be able to make a definitive assessment regarding resectability, which is often not possible based on cross-sectional imaging alone; and (3) surgical outcomes are generally more durable than nonsurgical options. The question then becomes what are the outcomes of surgical palliation. In a large series from the Johns Hopkins medical institutions, 1913 patients with pancreatic head adenocarcinoma were explored, and 30.5% underwent palliative procedures. The majority of the patients underwent a double bypass (64.5%), while a minority had either gastrojejunostomy (28.2%) or hepaticojejunostomy (7.2%) alone. The palliative failure rates were favorably low at 2.3% after hepaticojejunostomy and 3.1% after gastrojejunostomy. The overall complication rate was only 22%, and 95% remained free of recurrent duodenal or biliary obstruction. In contrast, in a recent 10-year retrospective analysis of 157 patients from the Memorial Sloan Kettering Cancer Center, the authors did not reach an equally positive conclusion regarding efficacy and morbidity of surgical palliation. In this series, only 38% underwent double bypass. Complications occurred in 28% of patients, 2% of whom died perioperatively, and 46% required interventions following exploration.

Surprisingly, the proportion of patients requiring interventions after surgical palliation was similar between double bypass or single bypass groups regardless of the procedure performed at the initial operation, as were the total number of inpatient days prior to death. Regardless, it is important that the surgical palliation for pancreatic cancer is performed with low morbidity, as complications have been shown to shorten survival after surgical palliation with an odds ratio of 3.

Data on outcomes for palliation using minimal access techniques such as laparoscopy or robotic surgery are limited. However, the limited data that are available indicate that the typical benefits of laparoscopic surgery, such as reduced length of stay and less pain, seem to be preserved for both laparoscopic and robotic surgery for palliation with a comparable or even lower morbidity.

Factors have been identified that help to predict survival after double bypass for palliation of pancreatic cancer. In a recent series of 397 patients with pancreatic adenocarcinoma from Johns Hopkins, four factors were found to predict early mortality: presence of distant metastatic disease (HR 2.59), poor tumor differentiation (HR 1.71), severe preoperative nausea and vomiting (HR 1.48), and lack of previous placement of a biliary stent (HR 1.36). These factors might be valuable in counseling patients regarding their survival, as patients who had all four of these risk factors lived less than 6 months.

In summary, surgical palliation performed with minimal complications is crucial in the treatment of pancreatic cancer to achieve the most efficient use of resources and, more important, to help patients maximize their quality of life for the limited time they have.

PALLIATIVE RESECTION VERSUS PALLIATIVE BYPASS

A question that has been the subject of debate in the past is whether palliative resection of pancreatic cancer is more beneficial for patients with advanced pancreatic cancer compared with the standard double bypass. Those favoring palliative resection contend that tumor debulking improves survival, minimizes or prevents pain from local tumor infiltration, and delays peritoneal and systemic spread. However, palliative resections are associated with significantly increased operative times, longer hospital stays, and higher overall morbidity and mortality rates compared with palliative bypass procedures as shown by cohort studies as well as pooled meta-analysis. Morbidity and mortality are 2 to 3 times higher in the R2 resection group. Although planned tumor debulking is beneficial for patients with other neoplasms such as ovarian carcinoma, the available data support the argument against palliative resection for pancreatic cancer because of the higher mortality and morbidity rates of resection compared with bypass. Therefore, we recommend performing a biliary and gastric bypass in the case of advanced disease during exploration and would strongly caution against planned palliative resection.

PALLIATIVE CHEMOTHERAPY AND CHEMORADIATION

A surgeon caring for patients with pancreatic cancer needs to be familiar with the treatment options of chemotherapy and chemoradiation in order to offer the best possible intervention to relieve symptoms in a context of limited survival and assist in the management of complications. In contrast to other gastrointestinal cancers where tumor size measurement is a good correlate to the efficacy of chemotherapy, the characteristic desmoplastic reaction and inflammatory response that develops around the pancreatic tumor makes this a less reliable predictor of objective response in pancreatic cancer. Metastases are an alternative for use to correlate to disease response and can be followed by serial imaging. We understand more and more that in addition to the objective tumor response and survival, the "clinical benefit" should be considered. For example, a comparison of gemcitabine with 5-fluorouracil (5-FU) showed that patients who did not exhibit a reduction in tumor size still showed threefold improvement in symptoms of a decreasing body mass index, pain, and/or performance status. Based on this information, gemcitabine became the standard chemotherapy for advanced pancreatic cancer. As every third patient treated with gemcitabine will develop symptoms such as diarrhea or fever, the surgeon should be cognizant of the side effect profile in case surgical consultation is requested.

Unfortunately, neither 5-FU in its intravenous or oral preparation nor gemcitabine nor any other single agent chemotherapeutic regimen has shown consistent response rates above 10%. This relative inefficacy led to the development of combination chemotherapeutic strategies, the most important one being a regimen with the acronym, FOLFIRINOX, consisting of the agents 5-FU, leucovorin, irinotecan, and oxaliplatin. In a French trial of 342 patients with metastatic pancreatic cancer, patients with a relatively good performance status were randomized to FOLFIRINOX versus a standard regimen with gemcitabine. In this trial, termed ACCORD-11, the median overall survival was 11.1 months in the FOLFIRINOX group as compared with 6.8 months in the gemcitabine group. Median progression-free survival was 6.4 months in the FOLFIRINOX group and 3.3 months in the gemcitabine group. However, more adverse events and a greater decline in patients' quality of life were noted in the FOLFIRINOX group. Although the median overall survival for patients with unresectable pancreatic cancer with best possible care remains low at less than 1 year, this combination chemotherapy increases the time of survival by almost 40% compared to standard chemotherapy. The trial was stopped after enrolling only 250 patients when a planned interim analysis showed that the primary trial endpoint (improved overall survival) had been met. Other combination chemotherapeutic regimens are not nearly as effective and researchers have difficulties showing any additional benefits of these regimens over single-agent therapy, among which the most efficacious might be gemcitabine plus oxaliplatin (GEMOX).

The prolonged survival of patients treated with FOLFIRINOX might translate into a greater need for durable palliation of symptoms. The surgeon needs to be familiar with this new regimen, as surgical consultation may be required in the presence of complications such as febrile neutropenia, thrombocytopenia, or diarrhea, which occur in 5% of patients undergoing FOLFIRINOX therapy. Prior to initiation of FOLFIRINOX therapy, patients must have normalized bilirubin levels, which usually require either endoscopic biliary stenting, with its associated risk of cholangitis, or surgical bypass. Thus, surgeons will have increasing involvement in the management of patients in the era of palliative FOLFIRINOX chemotherapy to ensure palliation of symptoms both prior to and after this more effective treatment.

Finally, it can be expected that as neoadjuvant regimens including FOFIRINOX have been increasingly employed, a higher percentage of patients with locally advanced pancreatic cancer may become candidates for resection. The data on the role of FOLFIRINOX as neoadjuvant therapy for patients with borderline resectable cancer are still limited, but one small retrospective series has shown that a R0 resection rate with the therapy can be achieved in as many as 44% of patients. If this experience is confirmed and use of FOLFIRINOX is expanded, more patients with locally advanced pancreatic cancer may undergo surgical exploration to attempt resection. As it is likely, some of these patients will still prove to be unresectable, at which point operative palliation will be appropriate.

Locally advanced pancreatic cancer is defined as locally unresectable cancer in the absence of distant metastasis; approximately one out of three patients presenting with pancreatic cancer have this type. Chemoradiation has been applied to this group to convert them to a status where resectability is possible. The precise role of applying chemoradiation to patients who have locally unresectable

pancreatic cancer, however, still needs to be defined, as there is conflicting evidence regarding whether patients indeed benefit from chemoradiation. Treatment with high-dose radiotherapy can be difficult to tolerate, and the constraints of daily treatment with radiation for patients with only few months' range of survival can significantly compromise quality of life. In addition, radiation doses for palliation only of locally advanced pancreatic cancer beyond 30 Gy have been shown in retrospective trials to increase the rate of complications, including strictures, colitis, pancreatitis, and others, which might again require the expertise of a surgeon. Future direction might include the use of more focused energy such as proton beam radiation, which to date is available only at a few centers around the world.

CONCLUSIONS

A surgeon should be a central player in the multidisciplinary team caring for patients with advanced pancreatic cancer. This critical role is directed toward palliating the most common symptoms of advanced pancreatic cancer, which are biliary obstruction, gastric outlet obstruction, and pain, for which both surgical and nonsurgical options exist. Based on level I evidence, double biliary and gastric bypass and celiac axis chemical splanchnicectomy should be performed if unresectability is determined during an exploration, which may be the only way to definitively rule out unresectable disease. The first-line treatment of biliary obstruction is internal biliary drainage by endoscopic stent placement. If this is not possible, biliary bypass in the form of a hepaticojejunostomy should be performed by either an open or a laparoscopic approach. The stent technology for duodenal stenting is not yet at the level of biliary stenting, and therefore an open or laparoscopic surgical bypass for palliation of gastric outlet obstruction should be performed. Pain control via celiac plexus block, either percutaneously or via endoscopic techniques, provides excellent pain relief, and it is clear today that there is no benefit in planned palliative resection. Minimal-access techniques for palliation of advanced pancreatic cancer are excellent options with proven benefits in the perioperative period for patients undergoing pancreatic surgery. Furthermore, all patients with unresectable cancer and good performance status should be considered for FOLFIRINOX chemotherapy, and surgical input might be required to render a patient eligible for this regimen or to assist in the management of complications. Radiotherapy for locally advanced unresectable pancreatic cancer can be considered, but it should always be combined with chemotherapy, and higher dosages might lead to significant side effects in patients whose survival time is limited. In summary, it is expected that the already significant role of the surgeon in the team caring for patients with advanced pancreatic cancer will only expand with device development, improvements in imaging and staging, and new therapeutic agents.

NEOADJUVANT AND ADJUVANT THERAPY OF PANCREATIC CANCER

Ana De Jesus-Acosta, MD, and Dan Laheru, MD

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDA) is a lethal malignancy that remains the fourth leading cause of cancer-related mortality. Surgical resection of the primary tumor offers a potential cure when it is diagnosed at an early stage. Additional therapies are required in the preoperative (neoadjuvant) or postoperative (adjuvant) setting in an effort to achieve cure for this aggressive disease. This chapter focuses on the therapies given in the adjuvant and neoadjuvant setting with PDA.

Determination of resectability of the primary tumor is the most important objective at the initial staging evaluation. Ideally, these cases should be discussed in a multidisciplinary approach that includes surgical oncologists and medical and radiation oncologists. Pathologists and radiologists with experience in imaging of pancreas cancer should also be involved. These discussions are important for determining optimal selection and timing of surgical and nonsurgical interventions.

Imaging should include a specialized computed tomographic (CT) scan study or magnetic resonance imaging (MRI). CT scan should be performed according to a defined pancreas protocol, such as triphasic cross-sectional imaging and thin slices. Optimal

multiphase imaging technique includes a noncontrast phase plus arterial, pancreatic parenchymal, and portal venous phases of contrast enhancement with thin cuts (3 mm) through the abdomen. This technique allows precise visualization of the relationship of the primary tumor to the mesenteric vasculature and detection of metastatic deposits as small as 3 to 5 mm. Pancreas protocol MRI is emerging as an alternative to CT scan.

On the basis of imaging, the pancreatic tumors should be classified as resectable (stage I or II), locally advanced (stage III), or metastatic (stage IV). In most institutions, patients with resectable disease with adequate performance status and comorbidities undergo surgery as the initial therapy followed by adjuvant chemotherapy or chemoradiotherapy after recovery. A subset of tumors have proven to be more challenging to definitively categorize as resectable or unresectable and have been classified as "borderline resectable" tumors. No uniform consensus exists as to the definition or management of borderline resectable and unresectable disease. Table 1 summarizes the anatomic staging described by several entities. Treatment sequences and selection of adjuvant versus neoadjuvant therapies focus on appropriate anatomic staging.

ADJUVANT THERAPY

Surgical resection is offered to patients diagnosed with resectable disease at the time of initial staging. This accounts for 10% to 20% of patients at the time of initial presentation. After resection, more than 80% of patients ultimately die of disease from either local or distant recurrence, which is the rationale for adjuvant treatment. Although the benefit of adjuvant therapy has been shown in the recent decades, the best choice of treatment modality remains highly controversial. For instance, within the North American hemisphere, chemoradiotherapy followed by chemotherapy, or vice versa, is considered a standard approach; chemotherapy alone is the current standard in Europe. Solid data support use of either 5-fluorouracil (5-FU) or gemcitabine as the standard chemotherapeutic option. In contrast, discussion continues regarding the role of adjuvant chemoradiation, specifically in the subgroup of patients with positive resection margins.

Adjuvant therapy should be given to patients who have not had neoadjuvant chemotherapy and who have adequately recovered from surgery and should be initiated within 4 to 8 weeks. Patients who have received neoadjuvant chemotherapy or chemoradiation are candidates for additional chemotherapy after surgery. If systemic chemotherapy precedes chemoradiation, systemic CT scan should be done after each treatment modality.

The Gastrointestinal Tumor Study Group (GISTSG) conducted a randomized clinical trial in the 1980s in which postsurgical patients were randomized to either observation or 5-FU–based chemoradiation followed by systemic 5-FU and leucovorin for 2 years or until evidence of recurrence. The results provided a statistically significant outcome that favored the patients treated with systemic chemotherapy. An additional randomized two-arm clinical trial was conducted by the Radiation Therapy Oncology Group (RTOG) 97-04 in which patients were assigned to receive postsurgical gemcitabine or infusion of 5-FU followed by the same 5-FU–based chemoradiation in both arms. The findings suggested a nonstatistical trend in favor of the gemcitabine arm. Subsequent studies comparing postsurgical treatments and observation supported the GISTSG findings and provided the basis for postoperative treatment.

The Europeans have contributed significantly to the field with several studies in the adjuvant setting. The European Study Group for Pancreas Cancer (ESPAC) and Charité Onkologie (CONKO) trials have further supported the role postoperative therapy over observation. Although the initial ESPAC-1 trial did favor postsurgical treatment over observation after resected pancreas cancer, it also suggested that radiation may not be a necessary component. The chemotherapy used in the initial ESPAC-1 trial was 5-FU and leucovorin. Unfortunately, these results have not ended the controversy as to what should be the appropriate adjuvant treatment because this study was criticized for a complicated study design and the use of noncontemporary radiation therapy. However, it may have convinced the Europeans that chemotherapy alone should be the standard of care. Subsequently, the ESPAC-3 trial evaluated the value of gemcitabine versus 5-FU and concluded that either of these chemotherapy agents were equivalent with regards to overall and progression-free survival outcomes, although severe toxicities were less in the patients with gemcitabine treatment. The CONKO investigators conducted a randomized trial comparing gemcitabine for 6 months with observation in the CONKO-001 trial and showed a statistically significant improvement in disease-free survival in the patients treated with postoperative gemcitabine. Therefore, postoperative chemotherapy alone for a period of 6 months is widely accepted.

There are still unanswered questions in the adjuvant setting, such as the role of the addition of targeted therapy or more aggressive multiagent treatments. Although impressive 5-year survival rates of 55% were reported in regimens with immunochemotherapy (cisplatin, 5-FU, interferon alpha) combined with radiation, no survival difference as compared with 5-FU monotherapy was observed in a subsequent phase III trial. Regimens with substantial antitumor effect are still needed to improve long-term survival in patients with resected pancreas cancer.

Two positive phase III clinical trials for patients with advanced stage IV pancreatic cancer have been published and have again raised the question of use of multiagent chemotherapy or targeted therapy in the adjuvant setting. The first was a phase III clinical trial of gemcitabine versus gemcitabine plus erlotinib, which showed a small survival benefit for the combination therapy. A second phase III trial evaluated patients with stage IV disease treated with single-agent gemcitabine versus the combination of 5-FU, leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX), which showed a significant survival benefit in the patients treated with the multiagent chemotherapy regimen. Given these results, several ongoing trials have been initiated to help to address these questions. The RTOG in collaboration with the European Organisation for Research and Treatment of Cancer (EORTC) has opened a phase III trial to evaluate the efficacy of the addition of erlotinib to gemcitabine and the addition of gemcitabine-based chemoradiation to this treatment in the postoperative adjuvant setting (RTOG 0848, EORTC 40084-22084). This trial will also help to establish the value of modern chemoradiotherapy. The CONKO investigators are evaluating the addition of erlotinib to gemcitabine in patients who have undergone a margin negative resection (CONKO-005). The FOLFIRINOX regimen has also been evaluated in a multicenter study in the adjuvant setting (NCT01526135) compared with single-agent gemcitabine.

As of now, the current standard of care in the United States includes 6 months of postoperative therapy with gemcitabine or 5-FU with leucovorin. Alternatively, chemotherapy with one of these two agents before or after chemoradiation (5-FU–based or gemcitabine-based) is also accepted. Although chemoradiation is still controversial, it is widely used in some academic centers in the United States. The data to support its use are based on large, single-institute series from Johns Hopkins University and the Mayo Clinic and the GISTSG trial designed in 1980s.

NEOADJUVANT THERAPY

The low rate of resectability, near absolute risk of recurrence, and poor long-term survival rate after pancreatectomy have led to the investigation of preoperative therapies. Only 10% to 20% of patients with PDA are candidates for resection at the time of diagnosis, and only 15% to 20% of these patients are alive after 5 years of an intended curative resection. Two group populations who potentially receive neoadjuvant therapy are discussed in this section: patients

1-Year survival rate after surgery	77.9%	79.8%
2-Year survival rate after surgery	47.4%	50.1%

with resectable disease and patients with borderline resectable pancreatic cancer. Use of neoadjuvant therapy may also be reasonable in patients with indeterminate or questionable metastatic disease and in patients with suboptimal performance status or extensive medical comorbidities that necessitate prolonged evaluation and preclude immediate major abdominal surgery.

Neoadjuvant treatment offers hypothetic advantages over adjuvant therapy such as shorter duration of therapy, higher therapy completions rates, tumor downstaging with higher margin negative resections rates, decreased risk of lymph node positivity, and importantly, better patient selection. It may identify those patients (with both initially resectable and nonresectable disease) with rapid progressive or disseminated disease at restaging for whom surgery is unlikely to provide any benefit.

A recent consensus conference with representation from the Society of Surgical Oncology, the American Society of Clinical Oncology (ASCO), and the American Hepato-Pancreatico-Biliary Association attempted to define reproducible and clinically relevant criteria to better categorize resection classifications for nonmetastatic pancreatic cancers (see Table 1). Recommendations are that these patients be discussed in a multidisciplinary team before initiation of treatment and be encouraged to participate in clinical trials. In addition, the initial staging CT scan must be performed before biliary decompression procedures because postprocedure pancreatitis, if it occurs, may prevent detailed anatomic evaluation of tumor-vessel relationships and preclude accurate assessment of the extent of disease on CT scan.

No published phase III data exist for the use of neoadjuvant therapy in pancreatic cancer. However, a recent rigorous systemic meta-analysis reviewed a total of 111 studies (including 56 phase I and II clinical trials) involving 4394 patients with pancreatic cancer who received neoadjuvant therapy. It included patients with resectable disease (group 1) or nonresectable disease (group 2, borderline resectable and locally advanced disease). Chemotherapy was used in 96.4% of these studies as part of the neoadjuvant therapy, and radiation therapy was used in 93.7% of the studies. Patients with borderline resectable and unresectable disease were combined in one group because of the widely different definitions used on published studies for these two entities. Thirty-two percent of patients with nonresectable disease were able to undergo pancreatectomy after neoadjuvant treatment (Table 2). Their survival rates were comparable to patients who were staged as resectable before treatment. In the group of patients with resectable disease, the resection rates and survival rates after neoadjuvant therapy were similar to the ones observed in primarily resected tumors that are treated with adjuvant therapy. The meta-analysis highlights that further investigations are needed in this field and participation in prospective clinical trials should be encouraged.

Borderline Resectable Disease

For borderline resectable disease, although no high level evidence supports its use, an initial approach with neoadjuvant therapy is preferred as opposed to immediate surgery in many centers within the United States. In the largest report published, the M.D. Anderson Group retrospectively studied 160 patients with borderline resectable disease. With use of different types of neoadjuvant chemotherapy or chemoradiation, resection was achieved in 41% of the patients. The median survival time was significantly increased in the patients who were able to achieve resection: 40 months for the 66 patients with borderline disease who completed all therapy as compared with 13 months for the 94 patients who did not undergo pancreatectomy ($P = 0.001$).

Patients with borderline resectable disease may be at higher risk of perioperative complications because of the additional complexity of surgery, at higher risk for early systemic failure because of the advanced nature of the primary tumor, and at higher risk for margin-positive resection with surgery alone. This is important because studies have shown that in addition to nodal status, both completing resection and getting negative margins are factors that translate in increased survival. The survival rate remains poor for patients who undergo an incomplete (margin positive) resection, and the available data suggest that the survival duration of these patients is not different from that of patients with locally advanced, surgically unresectable disease treated with chemoradiation.

Limited evidence suggests any specific neoadjuvant treatment schema off study, although most investigators now agree on gemcitabine-based regimen followed by chemoradiation with either gemcitabine or 5-FU as chemosensitizer. Participation in clinical trials is encouraged. Guidelines from the National Comprehensive Cancer Network (NCCN) support the use of preoperative therapy in carefully selected patients falling into borderline resectable category. Newer regimens with 5-FU–based combinations used in the metastatic setting such as FOLFIRINOX are being explored now in the neoadjuvant setting (NCT01591733, NCT01595321).

Resectable Disease

Neoadjuvant therapy in this group remains experimental in the context of clinical trials. Even in this setting, a hypothetic rationale exists for its use with allowing patient selection. For example, the main limitation of multidetector CT scan is its low sensitivity for low-volume hepatic or peritoneal metastases. Studies suggest that up to 20% of patients who are thought to have resectable disease before surgery actually have CT occult metastatic disease found at laparoscopy or laparotomy. Once laparoscopic or laparotomy procedure is done, there is a delay on restarting systemic therapy until appropriate wound healing, which may further promote disease progression. Neoadjuvant therapy in this setting may allow appropriate patient selection for surgical therapies. Increasing literature is examining neoadjuvant strategies in resectable pancreas cancer, which have been reported in nonrandomized single-institution studies. Most large series have been published by the M.D. Anderson Cancer Center group and use a combination of gemcitabine-based chemoradiation with a short course of 30 Gy of radiation or gemcitabine combined with cisplatin followed by standard preoperative gemcitabine and rapid fractionation. Other groups are investigating neoadjuvant chemotherapy without preoperative chemoradiation. The strategy of neoadjuvant chemotherapy alone for resectable pancreas cancer is under investigation by the American College of Surgeons Oncology Group clinical trial.

Unanswered questions still exist and include the best definition for resectable and unresectable disease to justify its use and the best regimen and sequencing. In addition, a uniform approach for determining resectability on restaging imaging after the neoadjuvant therapy should be defined. Emerging data have recently advocated

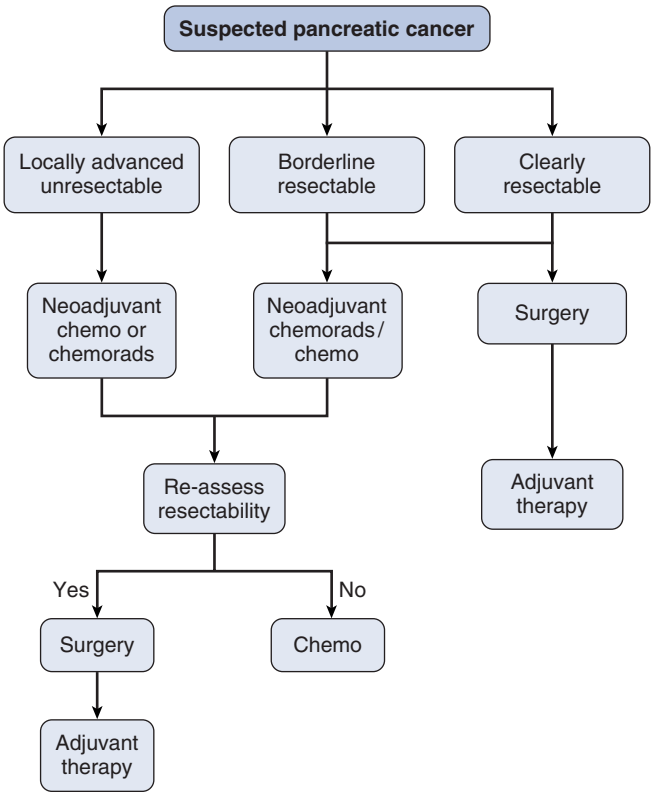

FIGURE 1 Algorithm for management of localized pancreatic cancer.

that response to neoadjuvant therapy is not reflected by traditional radiographic (RECIST) indicators. A recent retrospective study published by the M.D. Anderson group identified 122 patients who had borderline resectable pancreatic cancer and had their disease restaged after receiving neoadjuvant therapy. Of these, only one patient had downstaging to resectable disease based on reimaging studies; however, a total of 85 patients (66%) were able to undergo pancreatectomy, which resulted in increased survival as compared with patients who did not. These findings suggest that patients without evidence of metastases and with good performance status should undergo pancreatectomy after receiving initial neoadjuvant therapy. These findings may prompt more exploratory surgeries in the absence of disease progression.

Ongoing studies with more novel multiagent chemotherapy regimens with likelihood of significant response may further advance the field. Gemcitabine combined with nab-paclitaxel has been used as neoadjuvant therapy in patients with either resectable or borderline resectable PDA. Early reports at the ASCO 2012 annual meeting showed good resection rates for 6 of 16 patients (56%) as presented in national meetings. FOLFIRINOX was recently administered in the neoadjuvant approach in patients with borderline resectable pancreatic cancer and is being evaluated in prospective clinical trials.

At present, patients with borderline resectable disease are recommended to receive systemic chemotherapy for 2 to 4 months followed by chemoradiation; they should deviate from this course only in the event of radiographic evidence of disease progression or a decline in performance status. An algorithm for easy referral is provided in Figure 1.

FUTURE DIRECTIONS

The future for the development of new treatments is promising; significant progress has occurred in the understanding of the genetics and molecular biology of pancreatic cancer. It has been long appreciated that K-*ras* is often mutated in pancreatic cancer tumors. However, to date, there are no direct K-*ras* inhibitors, and targeting of K-*ras* either upstream or downstream has been largely unsuccessful. More recent strategies have included integrating downstream pathways such as *MEK, ERK,* and *AKT*. The development of a pancreatic cancer mouse model that reliably recapitulates human pancreatic cancer not only has allowed for opportunities to learn about how pancreatic cancer grows and develops and metastasizes but also has provided a unique platform with which to test new treatments in a methodic and systematic manner. In addition, much has been learned about the supportive tumor-stromal cell environment that is thought to not only influence the development of pancreatic cancer progression but also support mechanisms for resistance to effective treatment given its inherent protective properties. There is also significant new understanding in the complex relationship and role between inflammation and the immune suppressive tumor microenvironment in pancreatic cancer. Already new treatment opportunities are targeting small molecules that can reverse immune suppression or whole cell immunotherapy approaches that lead to immune activation. Advances in these areas may provide opportunities to test these approaches in the adjuvant and neoadjuvant setting.

Unusual Pancreatic Tumors

Casey Boyd Duncan, MD, MS, and Taylor S. Riall, MD, PhD

OVERVIEW

Ductal adenocarcinoma is the most common pancreatic tumor, but a variety of less common pancreatic tumors may be encountered by the surgeon. This chapter covers unusual pancreatic tumors, both nonneoplastic and neoplastic, that may present the surgeon with a diagnostic dilemma.

Because of increasing use of radiographic imaging, the incidental diagnosis of pancreatic lesions, especially cystic lesions, has become more common. Cystic lesions of the pancreas, such as serous cystadenoma, mucinous cystic neoplasms, intraductal papillary mucinous neoplasms, and pancreatic pseudocysts, can have similar radiographic appearances and presenting symptoms. Signs and symptoms such as abdominal pain, nausea, vomiting, fatigue, weight loss, bloating or abdominal fullness, jaundice, and early satiety may be present with any of the tumors or disease processes discussed in this chapter and are therefore not always helpful in making a diagnosis. Differentiating between these lesions can be difficult, and the diagnosis must be accurate because the management often varies.

Rare solid tumors of the pancreas, including solid pseudopapillary tumors, acinar cell carcinoma, and adenosquamous carcinoma, also have similar symptoms to those of ductal adenocarcinoma and may not be suspected preoperatively. Similarly, autoimmune pancreatitis and pancreatic lymphoma can present with a mass or focal pancreatic enlargement. The management of these entities is not surgical, and accurate diagnosis is critical. Finally, masses that are not of pancreatic origin, such as intrapancreatic accessory spleen and metastatic tumors to the pancreas, are discussed.

The goal of this chapter is to help the surgeon differentiate between unusual tumors of the pancreas, with particular emphasis on differential diagnosis and management. Table 1 details the laboratory, radiographic, and pathologic findings and recommended management of each of the unusual pancreatic tumors mentioned in this chapter.

NONNEOPLASTIC PANCREATIC CYSTS

Lymphoepithelial Cysts

Lymphoepithelial cysts of the pancreas are a rare entity, making up approximately 0.5% of pancreatic cysts. These cysts are benign lesions composed of mature keratinizing squamous epithelium surrounded by an external rim of lymphoid tissue. They are thought to arise from the inclusion of ectopic pancreatic tissue in a peripancreatic lymph node that has subsequently undergone squamous metaplasia.

Lymphoepithelial cysts of the pancreas are more common in men and occur primarily in the sixth decade of life. Serum laboratory values are typically normal in these patients, although cyst fluid may have high levels of carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9).

Sonographically, lymphoepithelial cysts appear hypoechoic with internal debris. Lymphoepithelial cysts have low attenuation and are typically well circumscribed and sharply demarcated from the surrounding pancreatic tissue on computed tomographic (CT) scan. Magnetic resonance imaging (MRI) can be helpful in visualizing the internal keratin component of the cyst (high T1 and low T2 signal). Multiple loculi within a single cyst are common, but the presence of more than one cyst at a time is rare. Pancreatic ductal dilation is uniformly absent. Endoscopic biopsy reveals stratified squamous epithelium, lymphocytes, and the absence of neoplastic cells. The peripheral lymphoid tissue often contains organized follicles and germinal centers, characteristic of a lymph node. The cysts almost uniformly contain dense keratinous debris, often described as "caseous" or "curd-like." The surrounding pancreatic parenchyma and lymph nodes are typically normal, except in cases of cyst rupture, where inflammatory changes and fibrous tissue may be present.

Accurate diagnosis of this entity is crucial and can usually be achieved by means of radiologic imaging and endoscopic biopsy. Lymphoepithelial cysts are truly benign and need only be resected in cases of severe symptoms. In cases where the diagnosis of lymphoepithelial cyst is certain, asymptomatic patients can be observed. In symptomatic patients of acceptable surgical risk, laparotomy should be performed with intraoperative frozen section biopsy of the mass. Enucleation, resection, and biliary drainage (in cases of pancreatic head lesions) are options for symptomatic cysts, depending on the location. Survival is excellent, and recurrence is rare.

Pancreatic Pseudocysts

Pancreatic pseudocysts (Figure 1) are not uncommon and can be confused with other cystic neoplasms of the pancreas. Pancreatic pseudocysts do not have an epithelial lining and are not true cysts. Pseudocysts are surrounded by a wall of collagen and fibrous and granulation tissue. Symptoms of pancreatic pseudocysts are similar to those of other pancreatic cysts. Complications of a pseudocyst may result in upper gastrointestinal bleeding, fever, jaundice, sepsis, or pleural effusion.

CT scan is the imaging modality of choice for visualizing pancreatic pseudocysts, with sensitivity and specificity approaching 100%. CT scan findings consistent with a pseudocyst include a round, fluid-filled cavity, typically surrounded by a thick wall. Pseudocysts are frequently unilocular (see Figure 1).

When the diagnosis is unclear, upper gastrointestinal endoscopy may be used to aspirate cyst fluid for analysis. Cyst fluid levels consistent with pancreatic pseudocyst include a high amylase (>250 U/L), low CEA (<5 ng/mL), and low CA 19-9 (<37 U/mL). Endoscopic retrograde cholangiopancreatography (ERCP) can be helpful in evaluating communication with the pancreatic duct, which influences treatment decisions.

Intervention (endoscopic, percutaneous, or surgical) is indicated in the case of symptomatic pseudocysts, complicated pseudocysts (vascular, gastrointestinal, or biliary compression, fistula, infection, or hemorrhage), and pseudocysts that are large (>5 cm) and have been unchanged for 6 weeks. Importantly, pseudocysts that communicate with the main pancreatic duct are unlikely to resolve spontaneously and require a definitive internal drainage procedure. Endoscopic drainage can be performed with a transpapillary or a transmural approach (cystogastrostomy, cystoduodenostomy) in suitable candidates. Surgical drainage in the form of a cystogastrostomy or cystojejunostomy can be performed with an open or laparoscopic technique. Surgical resection of the cyst may be necessary in cases of a disconnected duct. External (percutaneous) drainage is not routinely performed but can be successful if no ductal connection is present.

TABLE 1: Laboratory, radiographic features, and management of unusual pancreatic tumors

	Serum laboratory values	Cyst fluid laboratory values	Ultrasound scan	ERCP	CT scan/MRI	Pathology/ histology	Management
Lymphoepithelial cyst	Normal	High CEA, CA 19-9	Hypoechoic, internal debris	Ductal dilation absent	Low attenuation; internal keratin (high T1-weighted, low T2-weighted)	Squamous epithelium, germinal centers	Surgical resection when symptomatic
Pancreatic pseudocyst	Normal	High amylase; low CEA, CA 19-9	Anechoic, smooth, round	Ductal communication variable	Round, fluid-filled, smooth, unilocular	Wall composed of collage and granulation tissue, no epithelial lining	Endoscopic or surgical drainage for pseudocysts with ductal communication, older than 6 weeks, symptomatic
Serous cystadenoma	Normal	Low CEA, CA 19-9, amylase	Septations, calcifications	Duct disruption or obstruction	Septations, honeycomb pattern, central scar, hypervascular	Mitoses absent	Resection when symptomatic or enlarging
Serous cystadenocarcinoma	Elevated CA 19-9	Low CEA, CA 19-9, amylase	Septations, calcifications	Ductal disruption or obstruction	Septations	Mitoses may be present, although local invasion and distant metastases not uncommon	Resection when diagnosed before surgery or when malignancy cannot be ruled out
Mucinous cystadenoma	Normal	High CEA, CA 19-9	Round, smooth, loculi	Ductal communication absent	Round, well-encapsulated, septation, macrocystic	Columnar epithelium, ovarian stroma, ER/PR +	Surgical resection
Mucinous cystadenocarcinoma	Normal	High CEA, CA 19-9 (higher than benign MCN)	Calcifications and mural nodules more common with malignancy	Ductal communication absent	Septation, macrocystic, calcifications, mural nodules	Columnar epithelium, ovarian stroma, ER/PR +, mitotic figures	Surgical resection
Intraductal papillary mucinous neoplasm	Normal	High CEA	Mural nodules, ductal dilation	Ductal communication and dilation	Mural nodules, ductal dilation	Various levels of dysplasia, ductal invasion	Surgical resection for all invasive, main duct, and symptomatic IPMN; small, asymptomatic branch duct IPMN may be observed
Cystic neuroendocrine tumor	Normal, unless functioning	Low or normal CEA, CA 19-9	Smooth, round, unilocular or multilocular	Normal ductal anatomy	Round, smooth, internal fluid, hypervascular, hyperintense on T2-weighted	Stain positive for chromogranin and synaptophysin	Surgical resection

Continued

TABLE 1: Laboratory, radiographic features, and management of unusual pancreatic tumors—cont'd

	Serum laboratory values	Cyst fluid laboratory values	Ultrasound scan	ERCP	CT scan/MRI	Pathology/ histology	Management
Solid pseudopapillary tumor	Normal	NA	Well-defined, hypoechoic, posterior enhancement	Ductal disruption rare	Cystic degeneration, calcifications, hemorrhage, solid and cystic	Vimentin, NSE, CD10/56, synaptophysin, α-1 antitrypsin, β-catenin	Surgical resection
Acinar cell carcinoma	High pancreatic enzymes, LFTs; low or normal CEA, CA 19-9	NA	Cystic or solid	Ductal invasion rare	Exophytic, hypodense, cystic or solid	Zymogen granules; stains positive for trypsin, chymotrypsin, amylase, lipase, synaptophysin, chromogranin	Surgical resection
Adenosquamous carcinoma	Elevated LFTs, CEA, CA 19-9	NA	Solid, internal necrosis	Ductal disruption rare	Solid, internal necrosis	At least 30% squamous epithelium	Surgical resection
Autoimmune pancreatitis	Elevated IgG, IgG4, CA 19-9	NA	Diffusely enlarged pancreas	Long segment strictures, strictures from side branches, no ductal dilatation or abrupt cutoff	Diffusely enlarged pancreas with delayed enhancement	Lymphoplasmacytic infiltrate, storiform fibrosis, obliterative phlebitis, IgG4 positive	Steroids, azathioprine or rituximab for relapse
Pancreatic lymphoma	Elevated LFTs, LDH, β2-microglobulin, CA 19-9	NA	Solid, hypodense pancreatic mass	Ductal dilation rare	Solid mass, peripancreatic lymphadenopathy	Large lymphocytes, CD20, CD30, EBV positive	Chemotherapy, radiation, surgical resection debatable
Intrapancreatic accessory spleen	Normal	NA	Solid, posterior acoustic enhancement, similar echogeneity to spleen, vascular pedicle on Doppler scan	NA	Well-circumscribed, zebra-striped pattern of enhancement, low T1-weighted, high T2-weighted	Lymphoid follicles, red and white pulp, CD8 positive	Resection only if diagnosis unclear, symptomatic, or with treatment of hematologic disorders
Metastatic tumors to the pancreas	Elevated CA 19-9	NA	Solid mass in head of pancreas	With or without dilation of pancreatic ducts and biliary tree	Hypervascular, displacement of surrounding structures	Similar to primary	Resection if isolated pancreatic metastases or from renal cell carcinoma primary

CA 19-9, carbohydrate antigen 19-9; *CEA,* Carcinoembryonic antigen; *CT,* computed tomographic; *EBV,* Epstein-Barr virus; *ERCP,* endoscopic retrograde cholangiopancreatography; *ER/PR,* estrogen receptor/ progesterone receptor; *IgG,* immunoglobulin G; *IPMN,* intraductal papillary mucinous neoplasm; *LDH,* lactate dehydrogenase; *LFTs,* liver function tests; *MCN,* mucinous cystic neoplasm; *MRI,* magnetic resonance imaging; *NA,* not applicable; *NSE,* neuron-specific enolase.

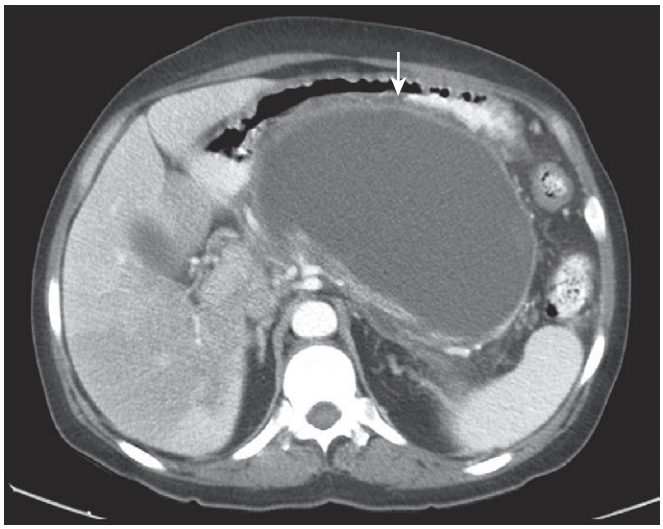

FIGURE 1 Computed tomographic scan shows a large, unilocular pancreatic pseudocyst *(arrow)* in a patient with a history of severe necrotizing pancreatitis 3 months previously. Compression of the stomach is noted.

FIGURE 2 Computed tomographic scan shows a large serous cystadenoma of the pancreas *(arrow)*. The mass has multiple septations and a honeycomb appearance.

PANCREATIC CYSTIC NEOPLASMS

Serous Cystadenoma

Serous cystadenomas (Figure 2) of the pancreas are typically benign tumors composed of a single layer of glycogen-containing cuboidal or flattened epithelial cells. Serous cystadenomas have been reported to constitute 14% of incidentally discovered asymptomatic pancreatic lesions.

Serous cystadenomas are more common in women and present at a mean age of 56 to 65 years. Up to 56% of serous cystadenomas are asymptomatic, with many found incidentally on imaging done for other purposes. Approximately 41% to 56% of serous cystadenomas occur in the body or tail of the pancreas.

The classic CT scan findings in serous cystadenoma include septations, central calcifications, clusters of small cysts, a "honeycomb" or "sponge" pattern, and a central scar or sunburst calcification (see Figure 2). A serous cystadenoma may be visualized as a hypervascular mass on arteriography. Pancreatic duct distortion or obstruction may be seen on ERCP.

Serous cystadenomas are benign. The key component in management of serous cystadenomas of the pancreas is differentiating these from mucin-producing cystic tumors of the pancreas, which have malignant potential. This can often be achieved with CT imaging alone. In cases of diagnostic uncertainty, endoscopic ultrasound scan (EUS) can be used to biopsy the cyst wall or aspirate cyst fluid for cytologic examination, although sufficient specimen volume to make a diagnosis is obtained in less than 50% of procedures. Cyst fluid from a serous cystadenoma tends to be acellular with glycogen-rich epithelial cells. Mucinous, inflammatory, or malignant cells should be absent. Serous cystadenoma fluid typically has low levels of CEA (<5 ng/mL), CA 19-9 (<37 U/mL), and amylase (<250 U/L; see Table 1).

In asymptomatic patients, observation with serial imaging can safely be performed. Surgical resection of a serous cystadenoma is indicated in patients who are symptomatic, in those with enlarging tumors, and when malignancy or malignant potential cannot be ruled out. After surgical resection, survival is excellent and reoperation or recurrence is rare.

Serous Cystadenocarcinoma

Serous cystadenomas are almost uniformly benign, although a few cases (<20) of their malignant counterpart, serous cystadenocarcinoma, have been reported in the literature. Serous cystadenocarcinomas compose only 1% of all cystic pancreatic neoplasms. Patients with serous cystadenocarcinoma present with symptoms similar to patients with serous cystadenoma. Serum CA 19-9 levels may be elevated but are not helpful in differentiating between pancreatic lesions. Because of its nonspecific signs and symptoms, serous cystadenocarcinoma is frequently misdiagnosed before surgery as serous cystadenoma, ductal adenocarcinoma, or gastrointestinal stromal tumor. The recurrence rate after surgical resection for serous cystadenocarcinoma is low, and long-term survival is achievable. Because of the rarity of serous cystadenocarcinoma, surgical resection for serous cystadenomas is currently indicated only in those with symptoms or enlarging tumors and in cases where malignancy cannot be definitively ruled out.

Mucinous Cystic Neoplasms

Mucinous cystic neoplasms (MCNs; Figure 3) occur almost exclusively in women, with a mean age at diagnosis that ranges from 44 to 66 years in various studies. MCNs of the pancreas can be benign (mucinous cystadenoma), borderline, or malignant (mucinous cystadenocarcinoma), based on the degree of epithelial dysplasia within the cyst. Up to 40% of patients with MCNs have invasive malignancy at the time of diagnosis. Most patients with MCNs are symptomatic. Patients with malignant MCNs are more likely to exhibit symptoms, although an absence of symptoms does not necessarily eliminate the possibility of malignancy. Most MCNs are located in the body or tail of the pancreas.

Microscopically, MCNs have an inner columnar epithelial layer and an outer, dense layer composed of ovarian-type stroma, which differentiates them from other cystic neoplasms. Immunohistochemistry of MCNs is frequently positive for estrogen and progesterone receptors. Macroscopically, MCNs appear as round cystic lesions with a smooth surface and fibrous pseudocapsule. Multiple loculi may be present (see Figure 3, *A*).

On CT scan or MRI (see Figure 3, *B*), MCNs appear as round, well-encapsulated, septated, macrocystic tumors. Calcifications may be visualized within the wall of the tumor and occur more frequently in malignant MCNs. Similarly, mural nodules, biliary obstruction,

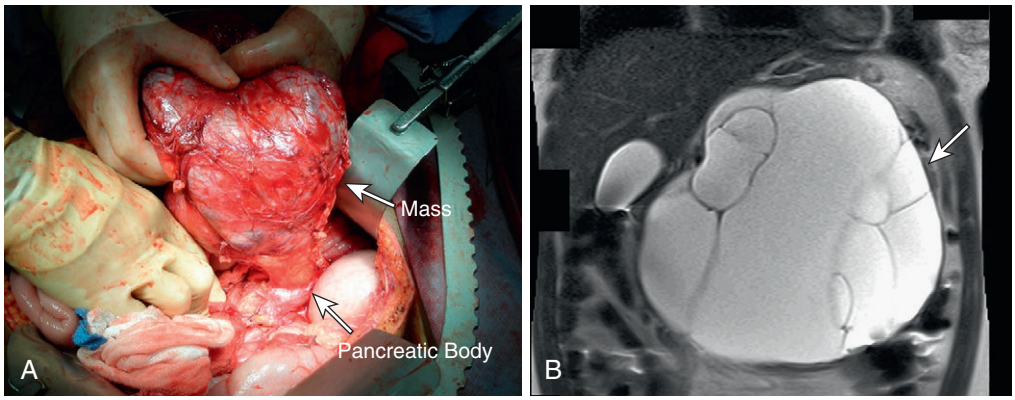

FIGURE 3 **A,** Intraoperative photograph shows a large mucinous cystic neoplasm originating from the body of the pancreas. **B,** Coronal T2-weighted magnetic resonance image shows a large, multilocular mucinous cystic neoplasm of the pancreas *(arrow),* displacing the liver, stomach, and spleen.

invasion of vascular structures, extrapancreatic lesions, ascites, and obliteration of fat planes around the pancreas increase the likelihood of invasive malignancy within the MCN. ERCP shows an absence of pancreatic ductal communication in MCNs. An elevated cyst fluid CEA level strongly suggests a mucinous neoplasm (MCN or intraductal papillary mucinous neoplasm [IPMN]) rather than a nonmucinous cyst, and MCNs with malignancy have even higher CEA levels compared with benign MCNs. A cyst fluid CA 19-9 level greater than 37 U/mL suggests a mucinous lesion (either cystadenoma or cystadenocarcinoma) rather than a serous cystadenoma or pseudocyst.

Because of the risk of occult malignancy within the lesion and future malignant transformation, the treatment of choice for all MCNs is complete surgical resection. Laparoscopy can be used in patients with small MCNs (<4 cm) without mural nodules on imaging. Nonoperative management is only indicated in patients who cannot tolerate surgery. Enucleation or partial resection of MCNs should be avoided, particularly in those with large tumors, because the intraoperative or preoperative recognition of underlying malignancy is limited.

Prognosis is largely determined by the presence or absence of an invasive component. Recurrence after resection of benign MCN has been reported to be less than 5%, but this increases to as high as 37% in those with invasive carcinoma. The 5-year disease-specific survival rates are 100% and 57% for noninvasive and invasive MCN, respectively, and long-term survival even with tumor recurrence has been reported. Patients with resected malignant MCN should undergo surveillance CT scan or MRI every 6 months.

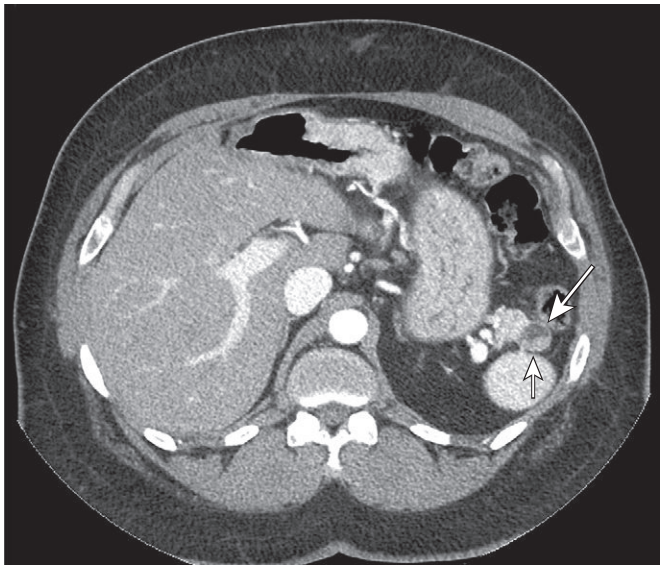

FIGURE 4 Computed tomographic scan shows a cystic intraductal papillary mucinous neoplasm *(large arrow)* with internal solid component *(small arrow)* in the tail of the pancreas.

Intraductal Papillary Mucinous Neoplasms

Intraductal papillary mucinous neoplasms (IPMNs; Figure 4) are defined as intraductal mucin-producing neoplasms that extensively involve the main pancreatic ducts or side branch ducts. IPMNs lack the ovarian stroma characteristic of MCNs of the pancreas. Although both are mucinous neoplasms of the pancreas, MCNs and IPMNs must be differentiated, as the recurrence patterns and surveillance recommendations vary between the two. Compared with MCN, IPMNs occur more commonly in men, present later in life, and are less often located in the body or tail of the pancreas.

IPMNs have been shown to follow a progression from adenoma to borderline IPMN with dysplasia, to IPMN with carcinoma in situ, to invasive carcinoma. IPMNs are classified as main duct IPMN and branch duct IPMN, with the former more likely to harbor invasive carcinoma. Recent guidelines have lowered the threshold for the definition of main duct IPMN. Main pancreatic duct size greater than 5 mm in diameter, segmental or diffuse, without ductal obstruction is highly suggestive of main duct disease. Communication with the pancreatic duct can be seen on ERCP, CT scan, or magnetic resonance cholangiopancreatography (MRCP). The absence of main duct dilation in the presence of IPMN or a cyst greater than 5 mm in diameter that communicates with the main pancreatic duct indicates branch duct disease. Endoscopically, mucin can be visualized extruding from the ampulla. EUS or CT scan may show mural nodules (see Figure 4) within the cyst, which are more likely to be associated with IPMN (versus pseudocyst or serous cystadenoma) and with the presence of invasive carcinoma. Elevated cyst fluid CEA values are indicative of a mucin-producing neoplasm of the pancreas (MCN or IPMN). Preoperative fine-needle aspiration has been shown to have an accuracy of 84%, a sensitivity of 78%, and a specificity of 88% in diagnosing of IPMN.

The management of patients with IPMN has recently changed according to 2012 International Consensus Guidelines. Surgical resection is recommended for all patients with main duct IPMN, preoperatively diagnosed invasive IPMN (main duct or branch duct), and symptomatic patients with IPMN (main duct or branch duct). For patients with branch duct IPMN, those with "high-risk stigmata" (obstructive jaundice, an enhancing solid component within the cyst, pancreatic duct size ≥10 mm) should undergo surgical resection. Those patients without high-risk stigmata but with "worrisome features" (cyst size ≥3 cm, thickened cyst walls, main pancreatic duct size of 5 to 9 mm, mural nodules, distal pancreatic atrophy, lymphadenopathy) should undergo EUS to further characterize the cyst. If EUS shows a mural nodule, main duct features consistent with main

duct involvement (thickened walls, intraductal mucin, or mural nodules), or cytology suspicious or consistent with malignancy, surgical resection should be performed. Patients without worrisome features or suspicious EUS findings should undergo surveillance imaging (CT scan, MRI, or EUS) depending on the size of the largest cyst. In summary, observation is indicated in patients with branch duct disease who meet international consensus guidelines: (1) asymptomatic condition, (2) tumors of less than 3 cm, (3) main duct diameter of less than 10 mm, (4) no mural nodules, and (5) benign cytology.

Patients who do not undergo surgical resection for IPMN require regular surveillance because these tumors have malignant potential. In addition, IPMN is thought to be a field defect in the pancreatic ductal epithelium. Patients with both resected noninvasive and resected invasive IPMN are at increased risk for recurrence in the pancreatic remnant independent of surgical margin status and should undergo routine surveillance. Survival in patients with IPMN is based on the presence of invasive cancer.

Cystic Neuroendocrine Tumors

Cystic neuroendocrine tumors of the pancreas compose approximately 10% of pancreatic neuroendocrine tumors and between 2% and 14% of cystic pancreatic tumors in the literature. These tumors are rare and are frequently confused with other cystic tumors of the pancreas. Cystic neuroendocrine tumors may secrete insulin, glucagon, or gastrin, but most tumors are nonfunctional and nonmalignant. The cystic nature of these tumors may be related to intratumoral hemorrhage.

CT scan findings consistent with cystic neuroendocrine tumors of the pancreas include a round, smooth-walled, cystic lesion, most commonly in the body or tail of the pancreas, with internal fluid of variable density. MRI may show a hyperintense lesion on T2-weighted imaging. Mesenteric angiography may reveal a hypervascular lesion in the pancreas. ERCP shows normal biliary and pancreatic ducts. Cystic neuroendocrine tumors may be unilocular or multilocular. EUS may be used to further visualize the tumor and obtain cyst fluid for analysis. Cyst fluid CEA and CA 19-9 levels may be low or normal. This is similar to pancreatic pseudocysts and serous cystadenomas but is in contrast to mucinous cystic neoplasms, which have elevated CEA and CA 19-9 levels. Tumor cells stain positive for chromogranin and synaptophysin in all cases. Lymph node involvement and distant metastases are rare. Like all pancreatic neuroendocrine tumors, cystic neuroendocrine tumors should be resected.

RARE SOLID PANCREATIC TUMORS

Solid Pseudopapillary Tumor

Solid pseudopapillary tumors (SPTs) are infrequent, typically benign tumors of the pancreas. SPTs represent 1% to 3% of all pancreatic neoplasms, although the incidence rate has been increasing over the last decade. First described by Frantz in 1959, SPTs of the pancreas were first defined by the World Health Organization in 1996. SPTs are distinct in having both solid and cystic components, which may be accompanied by cystic degeneration, necrosis, and hemorrhage. Malignant SPTs are rare and are associated with invasion of surrounding blood vessels, neural tissue, or pancreatic parenchyma. Although distant spread is rare, the most common locations for metastases are the liver, mesentery, peritoneum, portal vein, and spleen.

SPTs occur most commonly in young women, with a mean age at diagnosis ranging from 22 to 38 years. Most commonly, SPTs are located within the tail of the pancreas. More than 80% of patients with SPTs present with symptoms. Serum laboratory values, including alpha-fetoprotein (AFP), CEA, CA 19-9, and CA 125, are typically normal in patients with SPTs.

Abdominal ultrasound scan, CT scan, and MRI are the most commonly used imaging modalities for the diagnosis of SPTs. An SPT appears as a well-defined hypoechoic mass with solid and cystic components. Calcifications, intratumoral hemorrhage, cystic degeneration, and posterior enhancement may be identified.

Preoperative tissue biopsy may be performed with endoscopic guidance, although the correct diagnosis is made in only 50% of patients who undergo biopsy. Most SPTs stain positive for vimentin, neuron-specific enolase, CD10, CD56, synaptophysin, alpha-1 antitrypsin, and β-catenin.

Surgical resection remains the mainstay of treatment for SPTs. SPTs are frequently completely resectable, with most patients undergoing a margin negative (R0) resection and up to 95% cured after surgery. Enucleation is not indicated. Recurrence of disease in patients with SPTs is rare, and the median disease-free survival time has been shown to be 40 months. Patients with locally unresectable or metastatic SPTs can still benefit from surgical resection. Surgical debulking of metastatic disease, including hepatic lobectomy or enucleation of metastatic deposits, can result in long-term survival. Chemotherapy and radiation therapy are not routinely used because of the rarity of this disease and the success of surgical resection in the treatment of SPTs.

Acinar Cell Carcinoma

Acinar cell carcinoma (ACC) of the pancreas is a rare malignant tumor of the exocrine pancreas. ACC is predominantly diagnosed in men, with a mean age at diagnosis ranging from 56 to 64 years. Patients with ACC are almost always symptomatic. Lipase hypersecretion syndrome, a paraneoplastic syndrome characterized by elevated lipase levels, subcutaneous fat necrosis, polyarthralgia, and eosinophilia, has been reported. Laboratory values are nonspecific in patients with ACC and may include elevated liver enzymes and anemia. CEA and CA 19-9 levels can be low or normal and thus are not helpful in diagnosis. ACC has been associated with elevated levels of pancreatic enzymes, including trypsin, chymotrypsin, lipase, and amylase.

The diagnosis of ACC based on radiologic imaging alone is rare. Internally, ACC may be cystic or solid. Larger tumors are more likely to be cystic because of central necrosis, which develops as they outgrow their blood supply. Ductal dilation is uncommon. There is no predilection for location within the pancreas for ACC.

Microscopically, ACC appears hypercellular with granular, eosinophilic cytoplasm. Periodic acid-Schiff (PAS) staining is positive for zymogen granules within the tumor cells. Specifically, ACC tumor cells frequently stain positive for trypsin, chymotrypsin, amylase, lipase, synaptophysin, or chromogranin.

In the Surveillance, Epidemiology, and End Results (SEER) population, 57% of patients with ACC presented with metastatic disease and were not candidates for surgical resection. When compared with patients with pancreatic adenocarcinoma, patients with ACC were more likely to present with localized disease and less likely to have unstaged disease compared with patients with pancreatic adenocarcinoma. In a small case series, one third of patients with ACC had positive lymph node involvement and more than half had metastatic disease at presentation. Portal vein invasion has been shown in 35.1% of patients with ACC, arterial invasion in 21.2%, and extrapancreatic nerve plexus invasion in 15.6%.

Patients with locoregional ACC should undergo evaluation by a surgeon, as surgical resection is the only curative option. Adjuvant and neoadjuvant chemotherapy and radiation have been used in the treatment of ACC, but benefit is unclear.

Patients with ACC have a median survival time that ranges from 19 to 47 months. Overall 5-year survival rates for ACC are approximately 40%. Patients with ACC who undergo surgical resection have

significantly improved survival. In population-based data, patients without resection with locoregional ACC have a 5-year survival rate of 22% compared with 75% in patients with resection. As expected, patients with distant disease have worse survival compared with patients with local or regional ACC.

Adenosquamous Carcinoma

Adenosquamous carcinoma of the pancreas accounts for 1% to 4% of exocrine pancreatic malignancies. According to the Armed Forces Institute of Pathology, pancreatic adenosquamous carcinoma is defined as a neoplasm of the pancreas that is comprised of at least 30% malignant squamous cell carcinoma mixed with ductal adenocarcinoma.

The mean age at diagnosis of adenosquamous carcinoma ranges from 55 to 71 years, similar to that of pancreatic adenocarcinoma. Patients with adenosquamous carcinoma also present with symptoms similar to adenocarcinoma of the pancreas, making a preoperative diagnosis difficult. Bilirubin, alkaline phosphatase, CEA, and CA 19-9 levels may be elevated in patients with adenosquamous carcinoma of the pancreas; however, these values are not helpful in differentiating this lesion from the more common adenocarcinoma.

CT and MRI findings of adenosquamous carcinoma include a large, solid lesion with variable amounts of internal necrosis. Invasion of surrounding organs or distant metastases are not uncommon. Typically, one cannot differentiate adenosquamous carcinoma from adenocarcinoma radiographically. EUS-guided fine-needle aspiration biopsy can be performed, but an adequate sample of tissue must be obtained to make an accurate diagnosis before surgery, as the amount of squamous differentiation in the tumor can range from 10% to 90%.

Compared with adenocarcinoma, adenosquamous carcinoma is more likely to occur in the body or tail of the pancreas and is more likely to be poorly differentiated. Lymph node involvement, perineural invasion, and vascular involvement are common. No significant difference in the stage at presentation is found between patients with adenosquamous carcinoma and patients with adenocarcinoma of the pancreas, with more than half of all patients presenting with distant stage disease.

Although the adenosquamous variant may be difficult to differentiate from adenocarcinoma before surgery, differentiation is not really necessary because surgical resection offers the only chance for cure for both entities. The median overall survival time for patients with adenosquamous carcinoma of the pancreas is 4 to 7 months, similar to that of patients with adenocarcinoma. Median survival is improved to 12 months after surgical resection of locoregional adenosquamous carcinoma, which is worse than that of patients with resected adenocarcinoma. Adjuvant chemotherapy or radiation has been used in the treatment of adenosquamous carcinoma, although the survival benefit is unclear. Palliative chemotherapy may provide some survival benefit for patients with metastatic adenosquamous carcinoma.

AUTOIMMUNE PANCREATITIS

Autoimmune pancreatitis (AIP; Figure 5), also known as lymphoplasmacytic sclerosing pancreatitis (LPSP), is the pancreatic manifestation of a systemic immunoglobulin G 4 (IgG4)–mediated fibroinflammatory disease. Most patients with AIP are male and over the age of 50 years. AIP is uncommon and occurs with a prevalence rate of 2.2 cases per 100,000 people. Patients can present with a pancreatic mass, obstructive jaundice, and abdominal pain; AIP can easily be confused with pancreatic adenocarcinoma. Patients may have a biliary stent placed for obstructive jaundice associated with AIP before a definitive diagnosis is made (see Figure 5, *A*). AIP must be differentiated from pancreatic cancer for two reasons: first, AIP, when definitively diagnosed, should be treated with steroids and not surgical resection; and, second, pancreatectomy can be extremely difficult because of the severe inflammation in the pancreas of patients with AIP.

In the late stages, patients can have both exocrine and endocrine insufficiency develop. Other organ systems can be similarly affected by the systemic inflammatory state, which may result in sclerosing cholangitis, sialadenitis, retroperitoneal fibrosis, interstitial nephritis, thyroiditis, or lymphadenopathy.

The current diagnostic criteria for AIP include a combination of radiographic, serologic, histologic, and clinical findings. Level 1 criteria for the diagnosis of type 1 AIP include: diffuse enlargement of the pancreatic parenchyma, or sausage-like pancreas (see Figure 5, *B*), on radiographic imaging; long strictures or multiple strictures on ERCP; serology (IgG4 more than twice the upper limit of normal); and specific histologic findings (lymphoplasmacytic infiltrate with fibrosis, storiform (swirling) fibrosis, obliterative phlebitis, and IgG4-positive cells [>10 cell/high power field (HPF)]). Type 2 AIP is definitively diagnosed with histologic confirmation of idiopathic duct-centric pancreatitis (IDCP). Serologic findings are absent in type 2 AIP. In addition, extrapancreatic involvement is exhibited in type 1 AIP only and is absent in type 2 AIP.

Radiographic (CT scan, MRI, and ultrasound scan) findings consistent with AIP include a diffusely enlarged (sausage-shaped) pancreas (see Figure 5, *B*) with delayed enhancement, pancreatic calcifications, irregular ductal narrowing, and the absence of

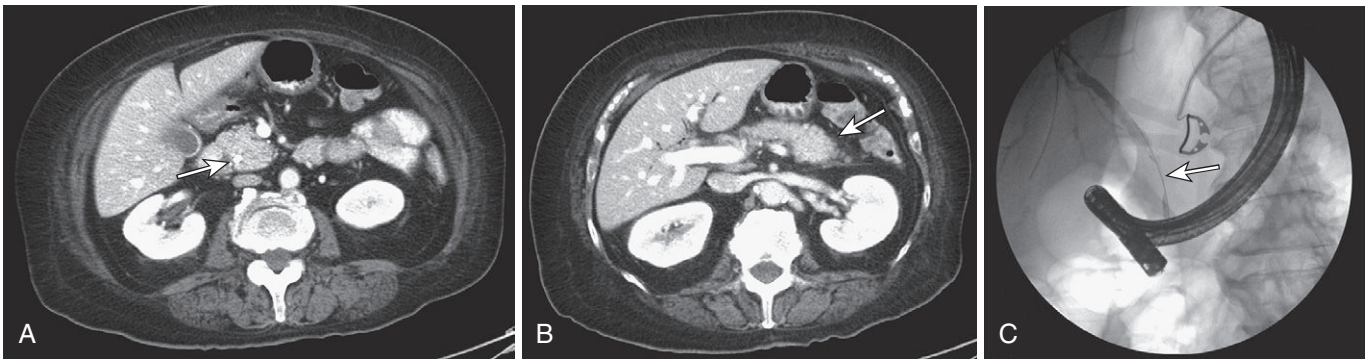

FIGURE 5 **A,** Preoperative computed tomographic scan shows diffuse enlargement of the head of the pancreas without a focal lesion in a patient with elevated serum immunoglobulin G 4. Note the biliary stent *(arrow)* placed for obstructive jaundice. **B,** The body and tail of the pancreas are shown in the same patient. Note the diffuse enlargement or sausage-like shape of the body and tail of the pancreas *(arrow)*. **C,** Endoscopic retrograde cholangiopancreatography is shown in a patient with autoimmune pancreatitis and jaundice. Note the long segment stricture *(arrow)* in the common bile duct that is difficult to differentiate from pancreatic adenocarcinoma.

pancreatic ductal dilatation or abrupt cutoff of the pancreatic duct. A mass or focal enlargement of the pancreas may be seen and may lead the practitioner to suspect pancreatic cancer. ERCP features consistent with AIP include long-segment strictures (see Figure 5, *C*) or multiple noncontiguous strictures with side branches arising from the strictures and without upstream dilation.

Serum total IgG levels may be elevated in patients with AIP, although an elevated IgG4 level is more frequently observed and is more sensitive and specific for the diagnosis of AIP. Specifically, an IgG4 level greater than twice the normal value (>134 mg/dL) is strongly suggestive of AIP, although a normal value should not exclude the diagnosis. Elevations in antinuclear antibodies and γ-globulin may occur but are much less common. Serology alone is not sufficient to make a diagnosis of AIP. Especially in the setting of biliary obstruction, CA 19-9 values may also be elevated in AIP, further confusing the clinical picture with that of pancreatic adenocarcinoma.

Histology is required for diagnosis of AIP and is helpful in excluding the presence of malignancy, although a definitive diagnosis is often not made until the time of surgical resection. EUS can be used to obtain a fine-needle aspirate (FNA) or core biopsy of the pancreas. Similar findings may be seen on pathologic examination of extrapancreatic lesions of AIP, such as salivary glands and lymph nodes.

AIP is notoriously steroid responsive. However, steroids should not be given if malignancy has not been definitively ruled out. A steroid trial (40 mg or 0.6 to 1.0 mg/kg daily) can be given with reassessment of imaging and laboratory work after 2 weeks. Symptomatic improvement alone after steroid administration does not confirm the diagnosis of AIP. Response to steroids is defined as improvement in radiographic abnormalities, including biliary strictures and pancreatic enlargement, and resolution of obstructive jaundice and extrapancreatic manifestations. Rising CA 19-9 levels should prompt investigation for malignancy. IgG4 levels may be falsely elevated in other pancreatic diseases, and a decrease in IgG4 level does not necessarily indicate treatment success. In patients who have a definitive diagnosis of AIP, a total of 12 weeks of oral prednisone should be completed, including an 8-week taper. Restoration of normal pancreatic function and anatomy may not occur in all patients with AIP, even with steroid treatment.

Up to 40% of patients experience disease relapse after an initial course of steroids. Relapse can occur in the pancreas or extrapancreatic sites. Patients with clinical or radiographic relapse require an additional 12-week course of oral steroids, in addition to azathioprine (2 to 2.5 mg/kg) for up to 2 years. Rituximab is currently being studied and may be of benefit in patients with refractory AIP.

PANCREATIC TUMORS/MASSES NOT OF PANCREATIC ORIGIN

Pancreatic Lymphoma

Primary pancreatic lymphoma is defined as extranodal lymphoma originating in the pancreas, and secondary pancreatic lymphoma occurs from direct extension from adjacent peripancreatic lymphadenopathy. Criteria for primary pancreatic lymphoma include: no palpable superficial lymphadenopathy, no enlargement of mediastinal lymph nodes, normal leukocyte count, a pancreatic mass with grossly involved peripancreatic lymph nodes, and the absence of splenic or hepatic involvement.

The mean age at diagnosis of pancreatic lymphoma is 57 years. Nonradiating abdominal pain is the most common symptom, and B symptoms (fever and chills) are uncommon. A palpable abdominal mass or hepatosplenomegaly may be noted on physical examination. Symptoms have been reported for up to 18 months before definitive diagnosis as a result of the difficulty in differentiating this disease from the more common pancreatic adenocarcinoma.

Liver enzyme levels (bilirubin, aspartate transaminase, alanine transaminase, alkaline phosphatase) are typically elevated in patients with jaundice from pancreatic lymphoma. CA 19-9 values may be increased but are not helpful in making the diagnosis or differentiating from adenocarcinoma. Serum lactate dehydrogenase (LDH) and β2-microglobulin levels are useful but are not routinely ordered in the workup of a pancreatic mass.

The CT scan findings of pancreatic lymphoma can be indistinguishable from adenocarcinoma, with a solid hypodense mass with peripancreatic lymphadenopathy, with or without extrahepatic biliary dilation. A large, infiltrating lesion with ill-defined borders may also be seen. Invasion or encasement of the superior mesenteric artery is not uncommon.

Accurate diagnosis of primary pancreatic lymphoma is crucial to ensure appropriate treatment but requires a high index of suspicion based on an atypical history for pancreatic adenocarcinoma. Tissue biopsy is necessary and endoscopic FNA biopsy can be performed. Unfortunately, the sensitivity of FNA biopsy in diagnosing pancreatic lymphoma is 71%, and in many cases, the diagnosis is not made before surgery. CT scan–guided percutaneous or endoscopic core biopsy or laparoscopic surgical biopsy provide actual histology (versus cytology) and may serve as alternative methods to obtain a tissue diagnosis and avoid the high morbidity and mortality of an open operation or pancreatic resection. Tissue samples of primary pancreatic lymphoma typically stain positive for CD20 and may also be positive for CD30 and Epstein-Barr virus (EBV). Large lymphocytes with irregular nuclei and prominent nucleoli are characteristic.

Diffuse large B-cell lymphoma (DLBCL) is the most common histologic subtype of pancreatic lymphoma. Most patients present with stage I or II disease, confined to the abdomen. Historically, treatment for lymphoma has included radiation and chemotherapy without surgery. Chemotherapy regimens include a combination of cyclophosphamide, doxorubicin, vincristine, prednisone, bleomycin, and rituximab. The use of surgical resection for pancreatic lymphoma has been debated by several authors. A study by the Mayo Clinic reports a median survival of 13 months, 22 months, and 26 months for patients with pancreatic lymphoma treated with chemotherapy alone, radiation therapy alone, and combination chemotherapy and radiation therapy, respectively. However, all patients in this study experienced recurrence of disease; the authors recommend surgical resection in an effort to improve local control of disease. A large review by Koniaris and colleagues showed that patients treated with chemoradiation alone have a cure rate of 46%, compared with 94% for patients treated with surgical resection (distal pancreatectomy or pancreatoduodenectomy) and adjuvant therapy. Improvements in pancreatic surgery techniques have led these authors to propose a treatment algorithm, whereby patients with resectable disease (pancreatic lymphoma confined to the pancreas or duodenum and without vascular invasion) should undergo initial surgical resection with or without adjuvant chemoradiation. However, this analysis may be limited by selection bias, in which patients with resectable disease have a better prognosis compared with patients with adenopathy or distant disease who do not undergo surgical resection and have worse survival. Behrns and associates suggest that, because of the low success rate with chemotherapy and radiation alone, patients with localized, bulky lymphoma confined to the pancreas may benefit from surgical debulking with possible neoadjuvant or adjuvant chemoradiation. Surgical biliary and enteric bypass may be necessary to alleviate symptoms associated with pancreatic lymphoma.

Intrapancreatic Accessory Spleen

Accessory splenic tissue has been reported in up to 10% of the general population, with the majority of accessory spleens located at the splenic hilum. Intrapancreatic accessory spleen (IPAS; Figure 6)

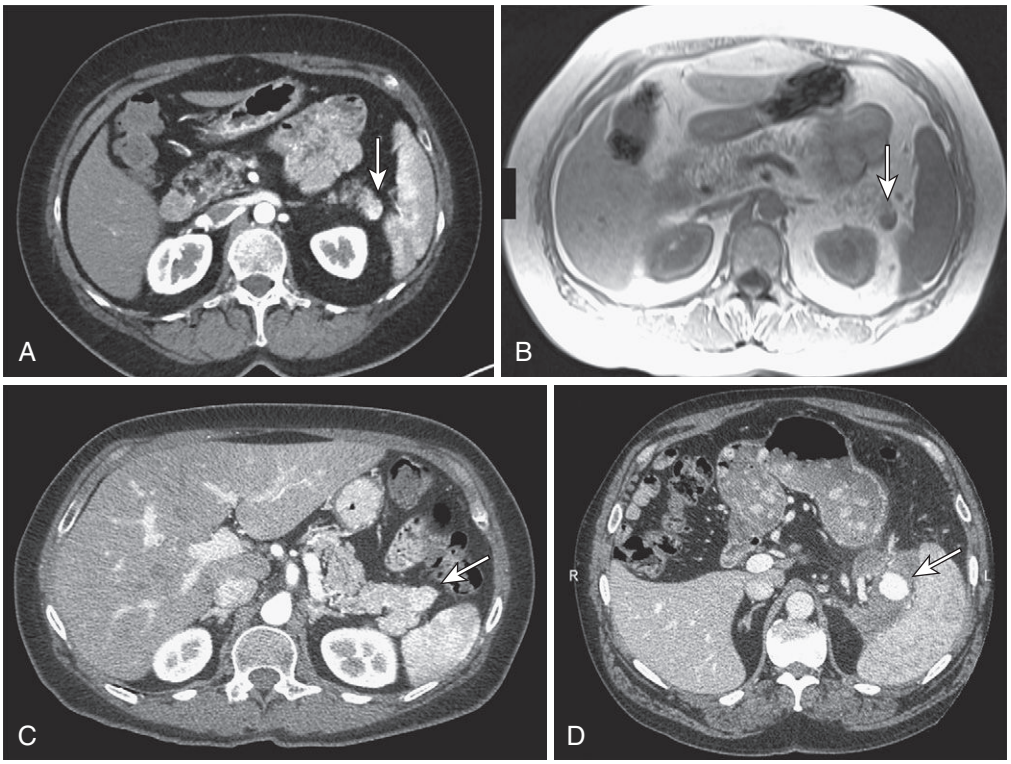

FIGURE 6 **A,** Computed tomographic (CT) scan of a patient with intrapancreatic accessory spleen (IPAS; *arrow),* originally interpreted as neuroendocrine tumor of the pancreas. Note the zebra-striped pattern and similar enhancement to the neighboring spleen on the arterial phase CT scan. **B,** Magnetic resonance imaging on the same patient as in **A** shows IPAS *(arrow)* with similar signal intensity as the spleen. **C,** CT scan shows pancreatic neuroendocrine tumor located in the tail of the pancreas *(arrow).* The tumor enhances greater than the spleen and lacks the zebra-striped pattern of enhancement of the spleen, which may help to differentiate these tumors from IPAS. **D,** Splenic artery aneurysm *(arrow)* is shown. This can be differentiated from neuroendocrine tumors and IPAS because of the enhancement greater than that of the spleen and similar to the abdominal aorta. A pool of blood is noted around the aneurysm.

accounts for almost 20% of accessory splenic tissue and occurs most frequently in the tail of the pancreas. IPAS is frequently identified incidentally during imaging for another etiology. Patients with IPAS are frequently asymptomatic.

Accurate diagnosis of IPAS is vital to avoid unnecessary surgery. Characteristic findings on radiographic imaging can help elucidate the diagnosis. Sonographically, IPAS appears as a round, solid, homogeneous, hypoechoic mass within the pancreas. A fibrous capsule with posterior acoustic enhancement may be seen. Doppler ultrasound scan may show a vascular pedicle entering the mass, as most of the blood supply to IPAS originates from the splenic artery and vein. In all cases, the echogenicity of IPAS should be higher than that of the pancreas and similar to that of the anatomic spleen.

IPAS appears as a well-circumscribed mass on CT scan. An arciform or "zebra-striped" pattern of enhancement is typically present in the normal spleen as a result of varying flow rates of contrast through the red and white pulp, and this pattern, when seen in the pancreas, should point toward the diagnosis of IPAS (see Figure 6, *A).* MRI findings consistent with IPAS include a low-signal intensity mass on T1-weighted images and a high-signal intensity mass on T2-weighted images (see Figure 6, *B).* Superparamagnetic iron oxide-enhanced MRI and Tc-99m heat-damaged red blood cell are additional modalities used to accurately localize IPAS.

IPAS is most frequently misdiagnosed as a pancreatic neuroendocrine or other pancreatic vascular lesions because of the hypervascular, hyperattenuating features on CT scan (see Figure 6, *A).* Of note, pancreatic neuroendocrine tumors enhance greater than the spleen and have a characteristic ring-like enhancement during the arterial phase of CT scan. The zebra-striped pattern of enhancement is notably absent in neuroendocrine tumors (see Figure 6, *C).* A splenic artery aneurysm can be seen on CT scan as a vascular lesion with enhancement similar to the abdominal aorta (see Figure 6, *D*). Metastases to the pancreas are typically hypervascular and rapidly enhance, and splenic vein involvement may be present. A history of previous cancer, especially renal cell carcinoma, can help differentiate metastatic lesions from other hypervascular lesions.

IPAS should only be resected in three circumstances. First, resection should be performed when the diagnosis is unclear and IPAS is misdiagnosed as malignancy. Second, resection is indicated if IPAS causes symptoms, including torsion, infarct, rupture, or cyst formation. Finally, IPAS should be resected during the treatment of hematologic disorders, in which all splenic tissue should be removed. Because of the location of IPAS in the tail of the pancreas, distal pancreatectomy is the most commonly performed procedure.

CANCER METASTASTIC TO THE PANCREAS FROM OTHER SITES

Metastatic tumors to the pancreas are rare, accounting for approximately 2% of all pancreatic tumors. More than 60% of metastatic tumors to the pancreas originate from renal cell carcinoma (Figure 7), although colon cancer, lung cancer, breast cancer, and melanoma are also frequently identified. Typically, widespread metastatic disease is seen at the time of diagnosis, with less than 5% of cases having

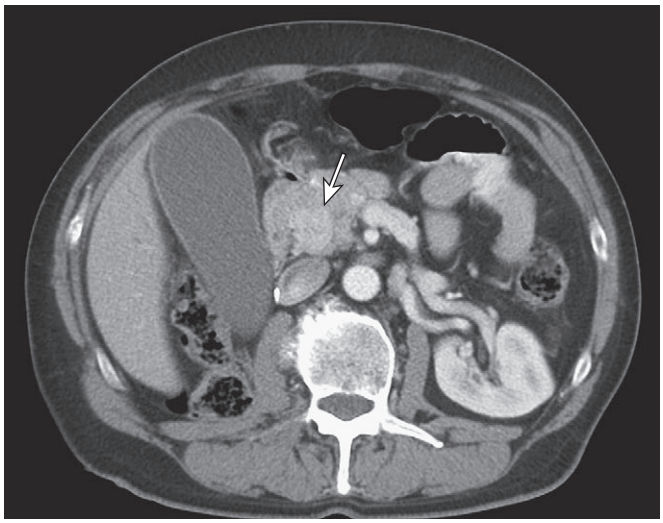

FIGURE 7 Computed tomographic scan shows a patient with a history of renal cell carcinoma status after right nephrectomy who presented with 2 weeks of painless jaundice. Hydropic gallbladder is noted with a hypervascular lesion in the head of the pancreas *(arrow)*. Pancreatoduodenectomy was performed, with final pathology showing renal cell carcinoma metastatic to the pancreas.

isolated pancreatic metastases. The time interval from resection of the primary tumor to the diagnosis of pancreatic metastasis is typically long, ranging from 36 months to 19 years.

Nearly 50% of patients with metastatic tumors to the pancreas are asymptomatic, and thus, a good portion of these tumors are identified on imaging performed for routine surveillance or an alternate reason. When symptoms are present, they depend on the location of the tumor and are similar to those of pancreatic cancer.

Most patients with metastatic lesions undergo CT scan, although MRI and angiography may also be performed. Hypervascular lesions of the pancreas are more likely to be metastatic rather than primary pancreatic carcinoma, which typically presents as a hypovascular lesion. Metastatic tumors may also demonstrate rim enhancement. Displacement of surrounding vascular structures may be more likely than invasion in the case of metastatic lesions.

The most common location for metastatic lesions is the head of the pancreas, and tumors may be solitary or multiple. Tissue diagnosis via percutaneous or endoscopic biopsy may be performed, although a correct diagnosis is not always obtained before surgery. Preoperative tissue diagnosis to distinguish between primary and metastatic pancreatic lesions is not necessary in the case of isolated, resectable disease because the surgical intervention is not altered based on the diagnosis.

Surgical resection can provide survival benefit in patients with metastatic lesions of the pancreas. In one large single-institution study, a margin negative (R0) resection was possible in all 49 patients with metastatic lesions to the pancreas. Survival after pancreatic resection for metastatic lesions depends largely on the site of the primary tumor. Median overall survival for patients with metastatic lesions to the pancreas has been estimated between 19 months and 3.7 years. Patients with renal cell carcinoma metastatic to the pancreas have markedly improved survival compared with patients with primary tumors from other sites; survival may be longer than 10 years in some cases. Pancreatic resection for metastatic renal cell carcinoma is associated with a median survival of 70 to 105 months, with 2-year and 5-year survival rates of 78% and 65%, respectively. Patients with resected colorectal carcinoma metastatic to the pancreas have a median survival of 54 months, and patients with resected metastatic melanoma and lung cancer have the worst prognosis, with a median survival of 14 months and 6 months, respectively. Selection bias and small sample sizes likely play a role in these survival data, with those patients who present to surgeons having resectable disease and improved survival.

Surgical resection for metastatic lesions to the pancreas should be considered in patients who are fit for surgery and who have no additional extrapancreatic disease. No single cancer type is a contraindication for surgical resection. However, patients with more biologically favorable tumors, and those patients who have a long interval between diagnosis of the primary disease and pancreatic metastasis, are more likely to benefit from pancreatic resection.

Intraductal Papillary Mucinous Neoplasms of the Pancreas

Klaus Sahora, MD and
Carlos Fernandez-del Castillo, MD

Intraductal papillary mucinous neoplasms (IPMNs) were first described in 1982 by Ohashi and colleagues, and in the last 30 years, the disease has become one of the most common diagnoses in the field of pancreatology. Although many new insights have been gained recently, its epidemiology, natural history, and proper management remain in a state of flux, and therefore treatment is not standardized.

In its classic form, IPMN presents as a dilated main pancreatic duct (MD-IPMN), full of mucus that extrudes through a bulging ampulla (this was previously referred to as mucinous ductal ectasia; Figure 1). Patients have recurrent episodes of pancreatitis-like pain, with or without hyperamylasemia, and commonly have steatorrhea, diabetes, and weight loss. Not surprisingly, this clinical picture has led to the diagnosis of chronic pancreatitis in many of these patients. Other patients present with jaundice, and still others have no symptoms at all and the disease is detected incidentally. In this form of IPMN, the neoplasm originates in the main pancreatic duct (Figure 2), more commonly in the cephalic portion, and from there spreads to the rest of duct, up to the secondary branches. IPMNs affecting the main pancreatic duct have a high malignant potential, and more than 60% of those resected, regardless of the presence of symptoms, harbor carcinoma in situ or invasive cancer.

It is now well recognized that IPMNs can also originate in the side branches (BD-IPMN) of the pancreatic ductal system (Figure 3). These occur frequently in the uncinate process and neck, but they can be found anywhere in the pancreas. Depending on the imaging method, 40% to 60% of BD-IPMNs are multifocal, involving all pancreatic regions, probably representing a pancreatic "field defect" (Figure 4). A large proportion of patients with BD-IPMN are asymptomatic, and most BD-IPMNs are detected by computed tomographic (CT) scan or ultrasound that was done for other reasons, but other patients can present with abdominal pain, pancreatitis, or jaundice. This variant of IPMN is much more frequent (perhaps 10:1), and, more importantly, the risk of cancer is far less. Currently, most branch duct IPMNs are managed expectantly (see guidelines below), and of those that are resected, the risk of cancer is about 25%. There are also IPMNs that affect both the main duct and its branches. This subvariant, called combined or mixed-type IPMN, shares epidemiologic features with main duct IPMN and has a similar rate of malignancy.

Both main/combined and branch duct IPMN occur typically in the seventh and eighth decades of life. Initial reports suggested a strong male predominance, but more recent series indicate an equal distribution in the United States. The main differential diagnosis of main duct IPMN is with chronic pancreatitis and that of branch duct IPMN with mucinous cystic neoplasms (MCN). The latter occur almost exclusively (>90%) in women, with a mean age of 50 years, and are located predominantly in the tail of the pancreas. Although both entities can form multilocular cysts lined by mucinous epithelium, MCNs have no obvious communication with the ductal system of the pancreas and typically show an ovarian-like stromal layer around the cysts.

Histopathologically, IPMNs encompass a spectrum of epithelial changes ranging from low-grade lesions (adenoma) to invasive adenocarcinoma, with borderline tumors harboring high-grade dysplasia in between. Oftentimes, the entire spectrum can be found in the same specimen, and therefore thorough sampling is required for these tumors. The pathologic classification of IPMN has evolved over the last decade, revealing complex cellular diversity in the mucinous epithelium. Nonmalignant IPMNs can be subclassified into the gastric (most BD-IPMN), intestinal (most MD-IPMN), pancreatobiliary, and oncocytic types, whereas invasive IPMNs are divided into the colloid and tubular types. It has been shown that the histopathologic subtype in invasive IPMN is an important prognostic factor, with a much more favorable outcome in colloid carcinoma. Tubular carcinomas, which primarily originate in the gastric epithelial neoplasia found in BD-IPMN, have a behavior and prognosis that are similar to conventional ductal adenocarcinoma.

Overall, the average age of patients with malignant main duct IPMNs is 6 years older than those with low-grade or high-grade dysplasia. This supports the current view that most, if not all, main duct IPMNs eventually become malignant. By contrast, this age differential is not seen in branch duct IPMNs.

PREOPERATIVE WORKUP

The extent and type of preoperative workup in patients with IPMN depends on the nature of the presenting symptoms, the certainty of the diagnosis, the likelihood that malignancy is present, and the age and surgical risk of the patient.

CT or MRI

Pancreatic protocol CT or gadolinium-enhanced magnetic resonance imaging (MRI) are indispensable, and they can give very precise information on the type, location, and extent of the tumor (see Figure 1). Both modalities are comparable in detecting associated masses, adjacent organ infiltration, and lymph node or organ metastases. MRI is the procedure of choice of many radiologists, being superior in the recognition of septae and nodules. In addition, magnetic resonance cholangiopancreatography (MRCP) provides a noninvasive way to assess the biliary and pancreatic ducts, and it can detect the small communication between the cyst in side branch IPMNs and the main pancreatic duct.

All surgically fit patients with "high-risk stigmata" (obstructive jaundice, enhanced solid component, main pancreatic duct [MPD] size of >10 mm) on CT or MRI should proceed with surgery without further radiologic or cytopathologic workup.

Indications for EUS

IPMNs with "worrisome features" (cysts ≥3 cm; thickened, enhanced cyst walls; MPD size of 5-9 mm; nonenhanced mural nodules; abrupt change in the MPD caliber with distal pancreatic atrophy; and lymphadenopathy) should undergo endoscopic ultrasound (EUS) for further evaluation.

EUS with fine-needle aspiration allows for sampling of both fluid and solid components of the tumor and can also assess the extent of involvement and detect small nodules (see Figure 4). For side-branch IPMN, which often presents as an asymptomatic isolated cyst or cluster of cysts in the pancreas, this is the optimal method to confirm diagnosis and distinguish them from small oligocystic serous cystadenomas (SCN). Sampling of the fluid will typically show mucus, a high amylase level, an elevated carcinoembryonic antigen (CEA) (a marker that is always low in SCN), and cytology with mucinous

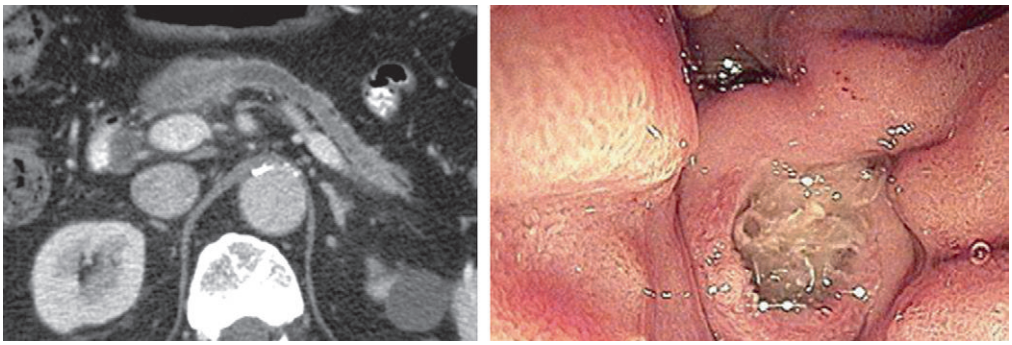

FIGURE 1 Computed tomographic scan (*left*) and endoscopic image (*right*) of a main duct intraductal papillary mucinous neoplasms (IPMN) demonstrating main duct dilation and mucus protruding out of the papilla vateri. The patient presented with three episodes of moderately severe upper abdominal pain. The pancreatic duct is dilated throughout the neck and proximal body, and tapers throughout the distal body and tail. The patient underwent a Whipple procedure, and final pathology revealed mixed-type IPMN with invasive tubular carcinoma.

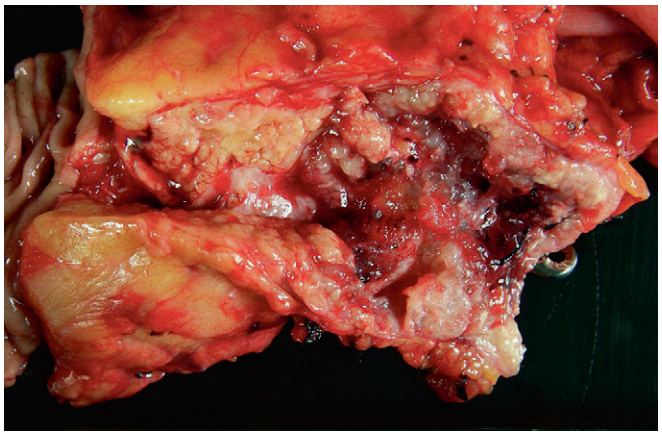

FIGURE 2 Resected main duct-intraductal papillary mucinous neoplasms (MD-IPMN) revealing typical intraductal papillary growth after opening of the main pancreatic duct.

epithelium and papillae. In recent years, the use of molecular markers has evolved. It has been demonstrated that K-RAS mutations are found in approximately 50% of mucinous lesions compared to non-mucinous, but they do not correlate with the grade of atypia. Recent studies showed that GNAS mutations can be found in 66% (KRAS or GNAS in 96%) of IPMNs but not in MCN or SCN, and therefore this may offer a promising tool to distinguish these cystic neoplasms from one another.

ERCP

The role of endoscopic retrograde cholangiopancreatography (ERCP) has widely been displaced by MRCP. ERCP may disclose a bulging papilla with a patulous orifice extruding mucus. While this image is pathognomonic of IPMN, it is seen in only about 25% of cases. According to the 2012 International Association of Pancreatology (IAP) guidelines, routine ERCP for sampling of fluid or brushings in IPMN is no longer recommended. In patients who present with jaundice, ERCP will allow temporary stenting if surgery will be delayed for any reason or Wallstent placement if the tumor is unresectable or if the patient is not an operative candidate.

Because the majority of these tumors are now being identified as an incidental finding during a CT or ultrasound done for other reasons, in many cases it will be important to document the diagnosis before proceeding with surgery, and this may require EUS and/or ERCP.

INDICATIONS FOR RESECTION

Because of the well-documented frequency of malignancy (mean 62%) in MD-IPMN, surgical resection is recommended in all fit patients. In patients with BD-IPMN, the indication for surgical resection has changed over the last decade, and it is still the subject of controversy. Nevertheless, there is a consensus that all young and surgically fit elderly patients with BD-IPMNs should be resected if they present with obstructive jaundice, an enhanced solid component, an MPD size of greater than 6 mm, or cytology that is suspicious or positive for malignancy (Figure 5).

Approach to Multifocal BD-IPMN

Indications for resection in multifocal BD-IPMNs are the same as for unifocal. In cases where all cysts are located in a pancreatic region, segmental anatomic resection should be performed. In patients presenting with multifocal BD-IPMN in different locations (i.e., the head and the tail of the pancreas), a segmental resection should be performed to remove the lesion with the highest oncologic risk.

OPERATIVE STRATEGY

The surgical management of IPMNs is different from other pancreatic tumors. In the latter, the surgeon can accurately locate the tumor from preoperative studies and accordingly plan a segmental pancreatic resection (Whipple, distal, or middle pancreatectomy), but that is not always the case in IPMNs. In IPMNs, the preoperative studies will show a dilated pancreatic duct in the main duct variety but not necessarily the intraductal mass, which is often small. Due to the overproduction of mucus, dilation can occur both proximally and distal to the tumor, making location problematic. This difficulty is compounded by the propensity of the tumor to spread microscopically along the duct.

With the available preoperative studies, the surgeon can determine which portion of the pancreas is primarily affected and plan the surgical intervention, but he or she should be prepared to change this plan depending on the intraoperative findings. At Massachusetts General Hospital, we have not found that intraoperative ultrasound adds much more to the preoperative imaging, but we rely heavily on the frozen section diagnosis of the transection margin of the

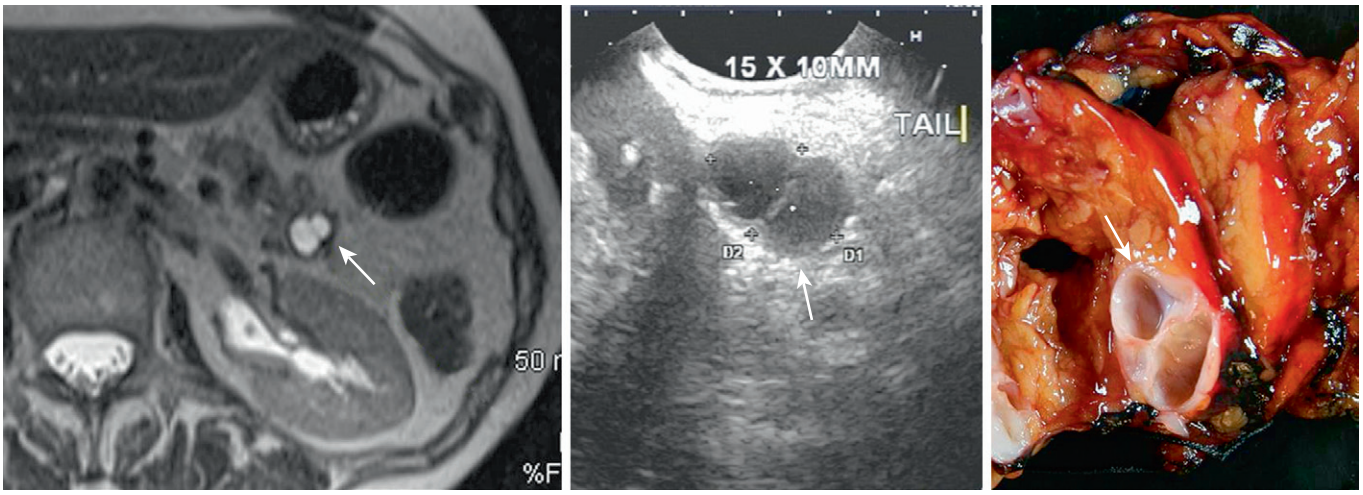

FIGURE 3 T2 magnetic resonance imaging (MRI) (*left*), endoscopic ultrasound (EUS) (*middle*), and pathologic specimen (*right*) of a bilobed branch duct intraductal papillary mucinous neoplasms (BD-IPMN). The patient was incidentally diagnosed with a cystic lesion (15 to 10 mm) in the tail of the pancreas during workup for diverticulitis. Fine-needle aspiration (FNA) revealed high-grade, atypical epithelial cells. The patient underwent distal pancreatectomy, and the final diagnosis was BD-IPMN with moderate dysplasia.

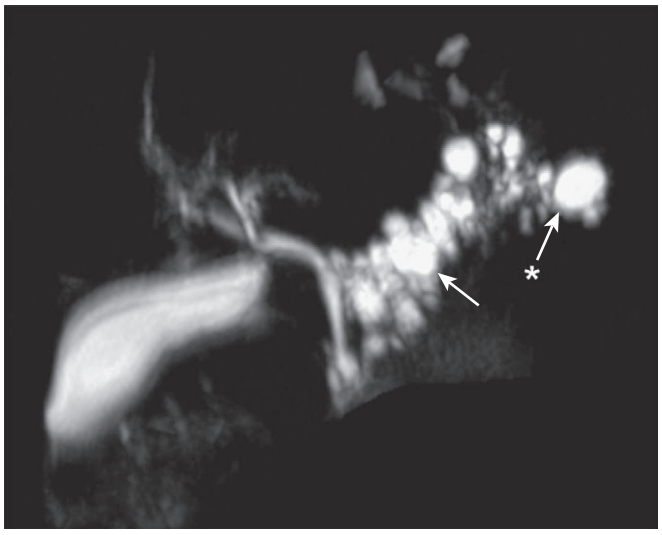

FIGURE 4 Magnetic resonance cholangiopancreatography (MRCP) of a patient with multifocal intraductal papillary mucinous neoplasm (IPMN) involving the whole pancreas. The largest lesion is located in the junction of the head and body of the pancreas and measures 30 mm in diameter. A smaller lesion can be seen* in the junction of the body and tail. Cytology of the smaller cyst suggested that it had at least high-grade dysplasia. The patient underwent distal pancreatectomy, and the final diagnosis after histologic workup was BD-IPMN with low-grade dysplasia. This patient is now being followed for the remaining lesions, which are still stable 2 years after surgery.

pancreas. Because IPMN extends along the pancreatic duct and can do so without obvious macroscopic tumor, it is important to rule out the presence of tumor at the margin so no tumor is left behind. A denuded epithelium in the duct is not uncommon in this pathology, and deepithelialization should not erroneously be interpreted as a "negative" margin because recurrence has occurred in this setting. To reduce operative time, we have found it useful to excise a segment of pancreas from the end to be examined intraoperatively before we remove the entire specimen, thus giving the pathologist ample time to perform this exam. A 3- to 4-mm slice is enough, and it should be done with a scalpel rather than cautery to facilitate the interpretation, which can often be challenging for the pathologist. If the margin shows tumor is present, we extend the resection a few centimeters and obtain a new margin. The process is usually continued until a negative margin is obtained, and it can potentially lead to total pancreatectomy (see later discussion).

We also use intraoperative pancreatoscopy whenever there is a dilation of the pancreatic duct. This allows for inspection of the ductal system of the remaining pancreas and can potentially identify "skip" lesions if they are macroscopic. The presence of these skip lesions has been proposed based on recurrence of IPMN in the remaining pancreas in the setting of a truly negative transection margin. Pancreatoscopy can be done using the laparoscopic choledochoscope, which is small enough to fit in a 4-mm pancreatic duct.

Because of the potential to modify or extend the surgical resection plans at the time of surgery, it is important that the surgeon discuss and evaluate preoperatively the risks and consequences of a total pancreatectomy with the patient. This obviously needs to be individualized carefully. Whereas a total pancreatectomy may be appropriate in a young, fit patient who has an IPMN with carcinoma in the head of the pancreas that is extending into the body and tail, it may not be the right operation for an elderly or frail patient with an IPMN that is only an adenoma or borderline tumor, even if present at the transection margin. In our experience with 404 patients, 59% required a Whipple resection, 3% an extended pancreaticoduodenectomy, 5% a total pancreatectomy, 25% a distal pancreatectomy, and 8% resection of the middle segment of the pancreas.

Although preoperative determination of malignancy is sometimes available from ERCP brushings or the EUS-aspirate of the fluid or solid component, most often this is not the case. Patients with malignant IPMN tend to have larger tumors, a larger portion of solid component, and a higher incidence of jaundice, recent-onset diabetes, or steatorrhea. If malignancy is not anticipated based on the preoperative imaging and clinical presentation, the surgeon can consider more conservative resection, such as middle pancreatectomy or a distal pancreatectomy without splenectomy.

PROGNOSIS AND FOLLOW-UP

The prognosis of patients with resected IPMN is quite good. In our series, the median survival for all patients is over 10 years. The survival in patients who had high-grade dysplasia is very similar to

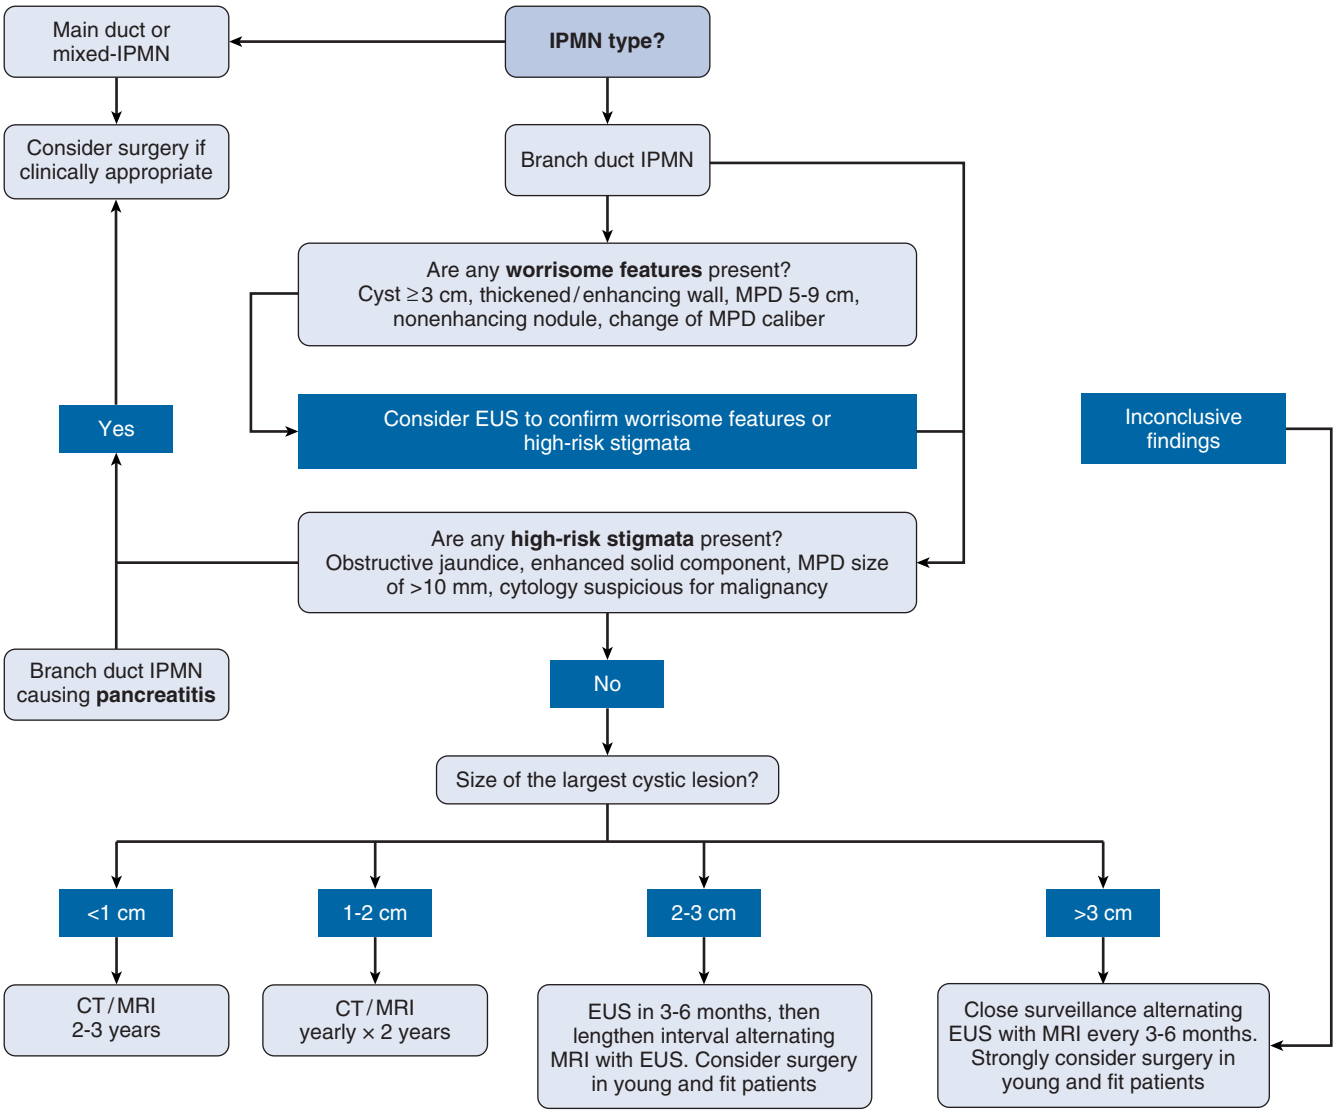

FIGURE 5 Algorithm for the management of intraductal papillary mucinous neoplasms (IPMN) according to International Association of Pancreatology (IAP) 2012 guidelines. *CT,* computed tomographic; *EUS,* endoscopic ultrasound; *IPMN*, intraductal papillary mucinous neoplasms; *MPD,* main pancreatic duct; *MRI,* magnetic resonance imaging.

that of patients with low-grade dysplasia. Depending on the histopathologic subtype of invasive IPMN, median survival in patients with colloid cancer is much more favorable (median 132 months) than in patients with tubular carcinoma (median 35 months), which is only marginally better than in pancreatic ductal adenocarcinoma.

The recurrence rate of IPMN in the remaining pancreas (when no known lesions are left behind and the margin is negative) ranges in the literature from 0 to 20%. Often it is not clear if ductal dilation in the pancreatic remnant is IPMN recurrence or is caused by postresectional anastomotic stenosis. Several studies, mostly from Japan, have shown an increased incidence of conventional ductal adenocarcinoma of the pancreas both in patients being followed with branch duct IPMN and in those that have been resected. The actual frequency of this phenomenon is unclear, but it has been described as 3% to 10%.

Follow-up of patients who underwent resection for IPMN depends on multiple factors. Patients with clear resection margins and without a known remaining IPMN in the pancreatic remnant should be followed at 2 years and 5 years to rule out recurrence. Those with low-grade or high-grade dysplasia at the resection margin should be closely followed twice a year by MRCP, CT, or EUS. Patients with multifocal IPMN and a known lesion left behind should be followed according to the guidelines for nonresected IPMNs. In the case of invasive IPMN carcinoma (stage II/III), the follow-up schedule is the same as that of ductal adenocarcinoma.

The Management of Pancreatic Islet Cell Tumors Excluding Gastrinomas

Scott P. Albert, MD, Mark Bloomston, MD, and E. Christopher Ellison, MD

OVERVIEW

Pancreatic neuroendocrine tumors (PNETs), also termed islet cell tumors, are rare and represent about 3% of all pancreatic tumors. Modern analyses have suggested that the incidence has been increasing over the last three decades, in part because of the growing use of endoscopic and radiographic examinations. The peak incidence for PNET is between the ages of 40 and 69 years, which is earlier than with pancreatic adenocarcinoma. Most tumors are sporadic, but they can be associated with syndromes such as multiple endocrine neoplasia (MEN), neurofibromatosis type I, tuberous sclerosis, von Recklinghausen's disease, and von Hippel-Lindau syndrome. In patients with MEN 1, pancreatic tumors occur between 20% and 40% of the time and are often multiple in nature.

Recent evidence suggests that PNETs arise from pluripotent stem cells and have a distinct tumor development pathway as compared with pancreatic adenocarcinomas. PNETs commonly contain mutations in MEN and mammalian target of rapamycin (mTOR) signaling pathways, and K-*ras* mutations are associated with pancreatic adenocarcinomas. These mutational differences allow for more systemic therapeutic options in patients with neuroendocrine cancers.

PNETs are a diverse group with a wide spectrum of biologic behavior that ranges from low-grade indolent tumors to high-grade aggressive tumors with propensity to metastasize. These tumors can also be broadly classified into nonfunctional or functional types based on symptoms, although most are capable of producing any type of hormone. Functional tumors are commonly named after the dominant hormone-related syndrome, such as insulinomas, gastrinomas, vasoactive intestinal polypeptide-secreting tumors (VIPomas), glucagonomas, somatostatinomas, and other rare functional tumors (Table 1). Nonfunctional tumors compose 40% to 90% of all pancreatic neuroendocrine tumors and are more common than their functional counterparts. Serum levels of pancreatic polypeptide are not infrequently elevated in nonfunctional PNET, but there is no associated clinical syndrome. Current neuroendocrine tumor staging uses American Joint Committee on Cancer (AJCC) tumor node metastasis (TNM) classification guidelines that are based on the previously developed staging system used for exocrine pancreas cancers.

TABLE 1: Summary of functional tumor types

Tumor	Annual incidence	Presentation	Location	Malignant	MEN associated
Insulinoma	0.1 per million	Whipple's triad: neuroglycopenia, hypoglycemia, symptom improvement with glucose administration	Entire pancreas	10%	5%
Glucagonoma	Rare	Necrolytic migratory erythema	Tail	>70%	Occasional
VIPoma	Rare	Watery diarrhea, hypokalemia, achlorhydria	Tail	50%	Occasional
Somatostatinoma	Extremely rare	Diabetes, diarrhea, cholelithiasis	Pancreas, duodenum, small bowel	70%	Rare
Nonfunctional	2.2 per million	Variable	Entire pancreas	>50%	Rare

MEN, Multiple endocrine neoplasia; *VIPoma,* vasoactive intestinal polypeptide-secreting tumor.

Consideration for other classification systems has been evaluated, including a European staging classification that may be more prognostic of overall survival. In addition, PNETs can be further characterized by tumor grade (i.e., NET1, NET2, NET3) which is determined by the mitotic index or Ki-67 activity during pathologic assessment. Tumor grade can be helpful information in making further treatment decisions. High-grade neuroendocrine cancers behave very aggressively and are treated more like small cell lung cancers.

DIAGNOSIS

Patients with functional tumors frequently present with symptoms related to the type of hormone produced in excess, whereas nonfunctional tumors are often asymptomatic until later in the disease course. Nonfunctional tumors are often an incidental finding on imaging or result from mass effect symptoms, such as abdominal pain, weight loss, anorexia, nausea, or jaundice. About 50% of patients with nonfunctional tumors have liver metastases as part of the initial presentation. Although this implies a greater metastatic potential for nonfunctional tumors, recent data suggest a lead-time bias with patients harboring functional tumors that present earlier in their course rather than a true difference in tumor biology.

High-quality cross-sectional imaging is necessary for diagnosis and allows for assessment of the primary tumor and evaluation of the liver for metastatic disease. PNETs appear as hypervascular lesions on computed tomographic (CT) scan; on magnetic resonance imaging (MRI), these tumors are best visualized on fat-suppressed T1-weighted images with contrast enhancement. Somatostatin receptor scintigraphy (octreotide scan) can be used selectively for tumor detection in challenging cases, monitoring of tumor response, or definition of metastatic disease (Figure 1). This test uses a radiolabeled somatostatin analog and can image the entire body, which makes it especially useful for identification of distant metastatic disease. Endoscopic ultrasound scan (EUS) is another effective diagnostic tool for localization of small hormonally active tumors and obtainment of tissue samples (Figure 2). Other tests to include in the workup are serum electrolyte levels, liver function tests, measurement of 24-hour urine 5-hydroxyindoleacetic acid (5-HIAA) and serum chromogranin-A (CGA) levels. CGA is frequently elevated in both functional and nonfunctional types. Plasma levels of CGA and pancreastatin, a functional split product of CGA, have been shown to be useful markers for monitoring tumor response to various treatments. Awareness that CGA levels can be falsely elevated in patients with renal insufficiency or liver disease or in patients taking proton pump inhibitors is important.

FUNCTIONAL TUMORS

Insulinoma

Presentation

Insulinomas are the most common functional tumor and are more common in women. Approximately 90% of insulinomas present with limited local disease, which makes them amenable to curative surgery. The most frequent presentation corresponds to symptoms related to hypoglycemia, such as headaches, blurred vision, and incoherent thinking. The release of catecholamines from the associated hypoglycemia may result in excessive sweating, tachycardia, and nervousness. The classic presentation, Whipple's triad, consists of neurologic symptoms of hypoglycemia (neuroglycopenia), plasma glucose of less than 50 mg/dL at the time of symptoms, and relief of symptoms with administration of glucose. Patients may present with sudden or rapid weight gain as a result of compensatory eating to offset fasting hypoglycemia. The differential diagnosis in these patients includes hepatic insufficiency, factitious hypoglycemia, chronic adrenal insufficiency, and hypopituitarism.

Diagnosis

The first step in diagnosis is demonstration of elevated insulin to glucose ratio during fasting and associated elevated C peptide levels. Measurement of levels of sulfonylurea is often necessary if factitious hypoglycemia is suspected. An insulin to glucose ratio greater than 0.4 is consistent with an insulinoma. The preferred diagnostic test is a 72-hour fast with the measurement of glucose, insulin, and C peptide levels every 6 hours, until symptoms of hypoglycemia appear. This requires in-hospital monitoring. Symptoms develop in 75% of afflicted patients after 24 hours, and 95% of patients have symptoms after 48 hours of fasting if an insulinoma is present.

The next challenge is often localization because most are less than 1.5 cm in diameter and occur equally throughout the pancreas. CT scan or MRI is often adequate for localization, although EUS can be valuable if localization of the lesion becomes difficult. Occasionally, indium 111 diethylenetriaminepentaacetic acid (DTPA)-octreotide

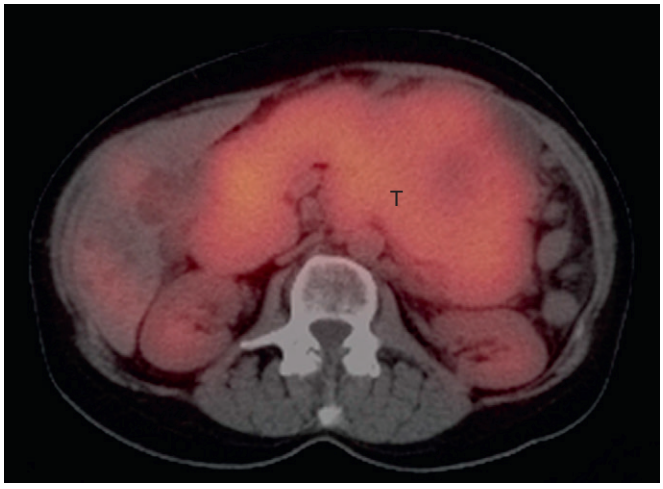

FIGURE 1 Octreotide scan shows increased activity in the pancreatic tumor *(T)*. The patient is administered octreotide radiolabeled with indium 111. Note the tumor enhancement caused by the uptake of octreotide by tumor-bearing somatostatin receptors.

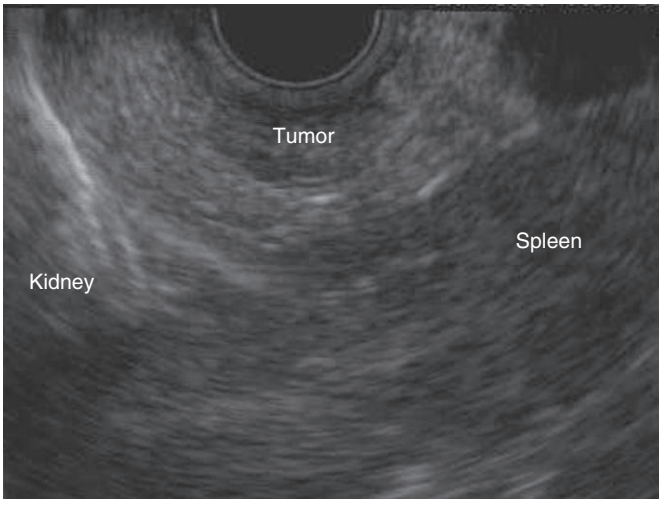

FIGURE 2 Endoscopic ultrasound scan image shows a neuroendocrine tumor in the tail of the pancreas. The spleen and left kidney are in view.

(octreotide scan) can be helpful for localization, although insulinomas are less likely to have a positive scan as compared with other PNETs. An invasive procedure that requires selective cannulation of pancreatic arteries followed by the injection of calcium and measurement of insulin levels in the portal circulation can be performed in difficult cases or for recurrent disease. However, most can be localized with modern cross-sectional imaging.

Treatment

Preoperative hypoglycemia can be managed with frequent small meals. Octreotide should be used with caution because it can worsen hypoglycemia by suppressing glucagon secretion. Diazoxide can be used to suppress insulin secretion. Surgical resection is the mainstay of treatment, with enucleation or pancreatectomy appropriate depending on the size and location of the tumor. Figure 3 shows a robotic enucleation of a small insulinoma in the body of the pancreas. Blind pancreatic resection is not indicated, and rarely surgical exploration with intraoperative ultrasound scan is required to make the diagnosis.

Glucagonoma

Presentation

Patients often present with diabetes, anemia, stomatitis, weight loss, and diarrhea. Two thirds of patients present with necrolytic migratory erythema, a severe rash with raised, scaly, erythematous patches that sometimes begins on the perineum and progresses to the trunk and extremities (Figure 4). The differential diagnosis for this type of rash includes psoriasis, pemphigus, eczema, zinc deficiency, pellagra, end-stage liver disease, and epidermal necrolysis. Deep venous thrombosis occurs in 30% of patients. Patients frequently have deficient amino acid levels as a result of stimulation of gluconeogenesis and associated amino acid oxidation.

Diagnosis and Treatment

The diagnosis can be made with measurement of glucagon to blood glucose ratios. A fasting glucagon level greater than 1000 pg/mL (normal, 0 to 150 pg/mL) is consistent with the diagnosis of glucagonoma. Cross-sectional imaging is used to identify the mass and assess resectability. These tumors most often arise from the tail of the pancreas (Figure 5). Glucagonomas have a high incidence of metastatic disease (60%), with the liver the most common site for metastases. Other conditions that can cause elevated glucagon levels include fasting, sepsis, pancreatitis, Cushing's syndrome, renal failure, and hepatic failure. Nutritional supplementation and replacement of

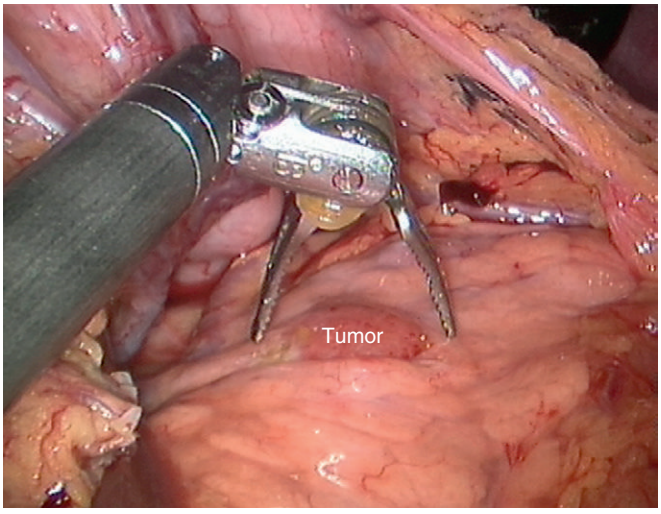

FIGURE 3 Minimally invasive robotic enucleation of an insulinoma in the tail of the pancreas. On preoperative cross-sectional imaging and intraoperative ultrasound, the mass was noted to be away from the main pancreatic duct.

FIGURE 4 Patient with characteristic rash from a glucagonoma. The rash is erythematous and scaly and located on the pretibial region but can also affect the perioral and intertriginous areas.

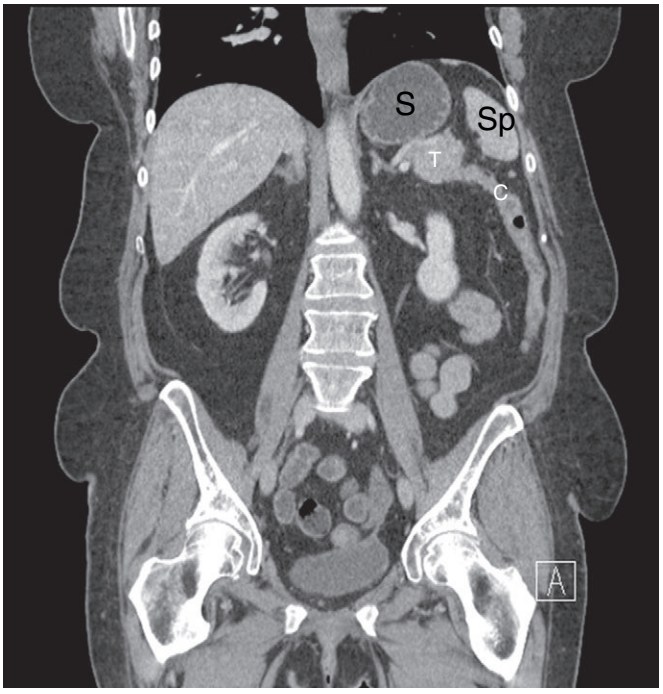

FIGURE 5 Coronal computed tomographic scan image shows a tumor *(T)* in the tail of the pancreas consistent with the patient's diagnosis of a glucagonoma. The stomach *(S)*, spleen *(Sp)*, and colon *(C)* can be seen adjacent to the mass.

amino acid losses may be necessary before any surgical intervention. Patients should also receive supplemental zinc. Octreotide can be used in the management of symptoms. Formal pancreatectomy is usually required for the management of glucagonomas.

Vasoactive Intestinal Peptide-Secreting Tumor

Presentation

First described in 1958 by Verner and Morrison, the classic presentation of a VIPoma is known as WDHA (watery diarrhea, hypokalemia, and achlorhydria) syndrome. Patients present with profuse diarrhea with volumes of 10 L/d that persists despite fasting. Not surprisingly, because of the severe diarrhea, patients are frequently hypokalemic and acidotic. Rarely, patients may also present with neurocognitive symptoms.

Diagnosis and Treatment

Plasma vasoactive intestinal peptide levels greater than 200 pg/mL are suggestive of a VIPoma, but typically levels are closer to 1000 pg/mL in most cases. These tumors are often located in the tail of the pancreas and are commonly metastatic (~50%). Cross-sectional imaging is needed to localize the tumor and determine resectability. The initial step in treatment is correction of severe electrolyte abnormalities. Octreotide can be used to help with symptoms before surgery.

Somatostatinoma

Presentation, Diagnosis, and Treatment

Patients most often present with diabetes, cholelithiasis, steatorrhea, and diarrhea. The inhibition of insulin, cholecystokinin, and pancreatic enzyme secretion by somatostatin leads to the associated disorders commonly seen in this syndrome. Somatostatin levels are greater than 100 pg/mL. Most somatostatinomas (70%) are metastatic at presentation. Seventy percent of these tumors are located in the pancreas, but they can also be found in duodenum and proximal small bowel.

Other Rare Functional Tumors

Other rare pancreatic functional tumors include adrenocorticotrophin-producing tumors (ACTHoma) parathyroid hormone-related peptide (PTH-RP) secreting tumors, and pancreatic polypeptide-producing tumor (PPoma). The treatment of these tumors is similar to the management of nonfunctional tumors.

Surgical Considerations

Localized

Surgery is central to the treatment of PNETs, and formal pancreatic resection is usually required, although small tumors (<2 cm) can be treated with enucleation in select cases. Minimally invasive approaches can be used for resection at institutions with experience (see Figure 3). For patients with small tumors and multiple comorbidities, close observation may be appropriate, although progressive disease should be resected, if feasible. Studies have shown that small tumors (<2 cm) are less likely to behave in a malignant fashion, but short-term follow-up is required to confirm tumor stability. The goal of surgical intervention is to achieve a complete resection with negative margins (i.e., R0). Often, removal of contiguous organs (e.g., stomach, colon, kidney) is necessary to achieve complete resection (Figure 6). If incidental liver metastases are found at the time of primary tumor resection, resection and cholecystectomy (in anticipation of future octreotide or liver-directed embolic therapy) is recommended if it can be completed safely and with minimal added morbidity.

Metastatic

Patients with neuroendocrine tumors can present late in the disease course and often with synchronous liver metastases. As such, quality and quantity of life is often determined by the hepatic disease burden. In cases of synchronous liver disease, the goals of surgical treatment should be palliation of symptoms in hormonally active tumors or complete surgical resection of both the primary and the liver metastases. Complete surgical resection of all disease should be the goal. Debulking surgery is more controversial, especially in the asymptomatic patient with bulky liver metastases. In the symptomatic patient, complex approaches combining surgical resection with ablation or embolic therapy might be used to achieve symptom control. In cases where the primary pancreatic tumor is readily resectable, it may be appropriate to proceed with resection if complete primary tumor removal is expected, thus allowing treatment, namely regional embolic therapies, to focus entirely on the liver disease. A recent multicenter analysis showed that patients with low-volume disease or symptomatic high-volume liver disease benefited most from palliative cytoreductive hepatectomy. Asymptomatic patients with a larger (>25%) liver tumor burden benefited equally with surgery or transarterial chemoembolization (TACE). The role of neoadjuvant systemic treatments is still evolving, but with the development of more effective systemic therapies, more patients might be converted to surgical candidates (Figure 7).

Metastatic liver tumors derive most of their blood supply from the arterial circulation, whereas portal circulation supplies the healthy liver. These differences in blood supply allow for effective regional liver therapies that include TACE, bland arterial embolization (transcatheter arterial embolization [TAE]) and radioembolization with radionuclide-laden spheres (e.g., Yttrium-90). Objective responses to regional therapy are variable (usually >50%), with stabilization of progressing disease commonplace (80% to 90%). Perhaps more importantly, most patients experience improvement in their symptoms from functional tumors. Peptide receptor radiation therapy (PRRT) with a radiolabeled somatostatin analog potentially treats somatostatin receptor-positive tumors. This novel therapy specifically delivers a cytotoxic dose of radiation directly to active tumor

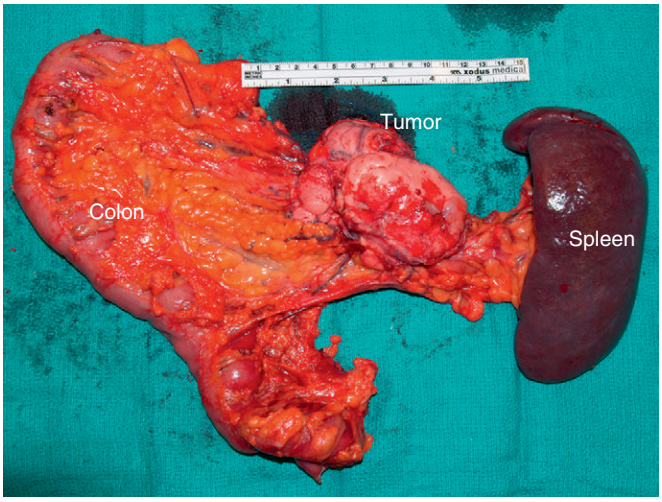

FIGURE 6 En bloc resection specimen after treatment with capecitabine and temozolomide. The colon and spleen along with the distal portion of pancreas were removed.

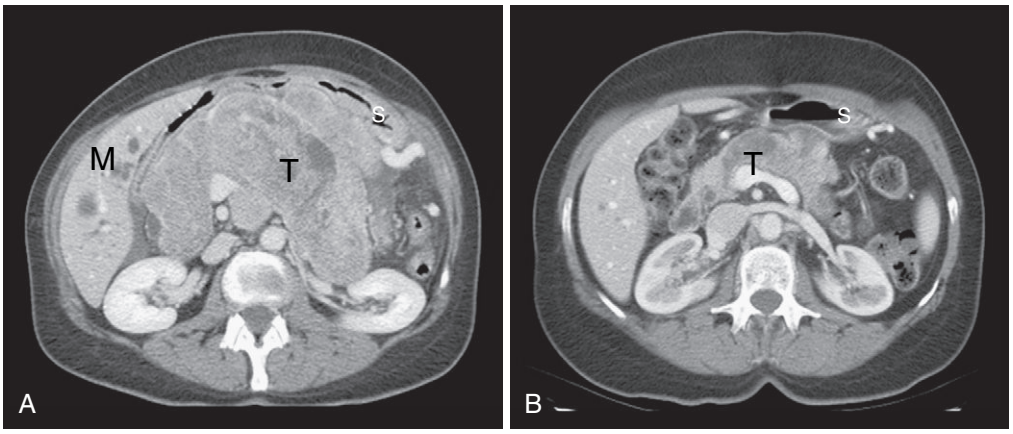

FIGURE 7 **A,** Axial contrast-enhanced computed tomographic scan images shows a large pancreatic neuroendocrine tumor *(T)*. **B,** A dramatic response to preoperative treatment with capecitabine and temozolomide is shown. and is gaining popularity in Europe, although it is currently only available in the United States in clinical trials.

Systemic Treatments

An improved understanding of neuroendocrine tumor biology has led to new systemic therapies and a more targeted approach to treatment. Several encouraging clinical trials that include patients with metastatic pancreatic neuroendocrine tumors have recently been completed. These newer treatment options include somatostatin analogs, tyrosine kinase inhibitors, mTOR inhibitors, and novel combinations of chemotherapeutic agents.

Somatostatin Analogs

Somatostatin analogs inhibit the growth of tumor cells that express somatostatin receptors; thus, these drugs have been shown to have a stabilization effect on tumor growth. A randomized clinical trial evaluated the use of long-acting octreotide in patients with metastatic midgut carcinoid tumors. This study included a significant proportion of patients with pancreatic neuroendocrine tumors. The group that received long-acting octreotide had a significantly longer time to disease progression as compared with the placebo group. Although the use of somatostatin analogs for tumor stasis is still an open debate, its use in reducing symptoms, especially in patients with metastatic disease, is the standard of care.

Targeted Treatments

Multiple recent randomized trials have shown promising results with the use of targeted drug therapies for PNETs. Sunitinib, a multikinase inhibitor that blocks the VEGF receptor, has shown activity against PNETs. In a phase II study, patients with PNETs achieved a 17% partial response rate with minimal significant side effects. A follow-up phase III trial in which patients were randomized to sunitinib or placebo was stopped early because of clear benefit in the study group. The median progression-free survival time was 11.4 months in the sunitinib group compared with 5.5 months with placebo. Overall survival was also significantly better with sunitinib. Another targeted agent, everolimus, blocks a separate kinase along the *Akt* pathway known as mTOR. This pathway has been shown to be involved in PNET cell growth. A phase III trial randomized patients to everolimus or placebo, and again, the targeted treatment group showed encouraging results. The median time to progression was significantly better in the treatment group (11.0 months vs 4.6 months). Patients included in both the everolimus and sunitinib trials had low-grade or intermediate-grade PNETs and were deemed to have unresectable or metastatic disease.

Chemotherapy

The only chemotherapy drug currently approved in the United States for metastatic PNETs is streptozocin. Additional older regimens have included doxorubicin or 5-fluorouracil (5-FU). Early promising phase II data combine capecitabine with temozolomide. Capecitabine is an oral prodrug for 5-FU, and temozolomide is an oral alkylating agent. In patients with metastatic pancreatic neuroendocrine tumors treated with this drug combination, the objective response rate was a surprising 70% (21 of 30 patients), and progression-free survival was improved over historic controls. In some cases, patients may show a dramatic response to newer combinations of systemic therapy as seen in Figure 7. The continued understanding of the various biologic pathways in neuroendocrine cancers allows for more options in targeted and chemotherapeutic treatments. More studies are looking at various combinations of regional therapies, targeted treatments, and chemotherapy agents.

Transplantation of the Pancreas

Niraj M. Desai, MD and
James F. Markmann, MD, PhD

INTRODUCTION

Type 1 diabetes mellitus, formerly known as *juvenile diabetes,* is characterized by hyperglycemia resulting from destruction of the insulin-producing beta cells of the pancreatic islets of Langerhans. This loss of beta cells is caused by T lymphocyte–mediated autoimmune destruction that typically occurs during childhood or early adolescence. Insulin replacement can lead to acceptable control of blood glucose levels; however, affected individuals are subject to the development of various secondary complications, including cardiac disease, stroke, retinopathy and blindness, nephropathy and renal failure, peripheral and autonomic neuropathy, and amputation. Although careful blood glucose control has been demonstrated to decrease the number of diabetes-related secondary complications, it has also been shown to lead to an increased number of dangerous hypoglycemic episodes. Technological advances (insulin pumps and continuous glucose sensors) may help reduce the incidence of secondary complications and the number of hypoglycemic episodes.

Transplantation therapy for type 1 diabetes was developed as an alternative to insulin administration with the goal of reducing or eliminating the development of secondary complications of the disease by perfecting glycemic control. The pancreas—both the whole organ and isolated pancreatic islets—is being transplanted into individuals with type 1 diabetes. Clinical islet transplantation remains experimental and is available at only select centers, but it is expected to become an approved therapy in the United States during 2015. It has proven efficacy in diabetic individuals with severe hypoglycemia unawareness. In contrast, whole-organ pancreas transplantation is an established and widely available therapy for the treatment of type 1 diabetes. Whole-organ pancreas transplantation is the focus of this chapter.

WHOLE-ORGAN PANCREAS TRANSPLANTATION

History and Early Results

On December 20, 1893, Dr. P. Watson Williams grafted pieces of a sheep pancreas into the subcutaneous tissues of a diabetic child who died 3 days later of unrelenting diabetic ketoacidosis. This first attempt to treat diabetes with transplantation, although unsuccessful, preceded decades of animal experimentation in which investigators developed the methods necessary to perform a vascularized pancreas transplantation.

The first vascularized pancreas transplant in a patient was performed on December 17, 1966, by Drs. William Kelly and Richard Lillehei at the University of Minnesota. The patient achieved temporary insulin independence but eventually required graft removal and ultimately died of postoperative complications. The subsequent early experience with pancreas transplantation was characterized by some technical success, but no graft functioned beyond 1 year. Most pancreas grafts that were successful from a technical perspective were lost as a result of rejection. The initial enthusiasm for this procedure dwindled so much that it was nearly abandoned by the mid-1970s. However, further technical refinements and the introduction of more potent immunosuppressive medications (first cyclosporine and then tacrolimus) allowed for better outcomes after pancreas transplantation. Throughout the 1980s and early 1990s, the number of pancreas transplants performed in the United States increased dramatically, peaking at nearly 1500 transplantations during 2004. However, this number has declined since, with fewer than 1100 transplants performed in the United States during 2012.

Indications and Patient Selection

The majority of patients undergoing pancreas transplantation have type 1 diabetes mellitus and end-stage renal disease. In these individuals, pancreas transplantation is performed with simultaneous kidney transplantation (SPK) or after successful kidney transplantation (pancreas after kidney [PAK] transplantation). The normal blood glucose control achieved by the transplanted pancreas should protect the transplanted kidney from recurrent diabetic nephropathy and is beneficial from an overall quality-of-life perspective. In a small proportion of patients with difficult-to-control diabetes but with preserved renal function, pancreas transplantation alone (PTA) is performed. In the United States for the 3-year period ending in 2011, 75% of pancreas transplantations were SPK, 12% PAK, and 13% PTA. SPK and PAK recipients require immunosuppressive therapy to protect both the kidney and pancreas from rejection, whereas in the case of PTA recipients, the need for immunosuppression is solely for the pancreas itself. For this reason, careful individual risk to benefit consideration is essential in selecting PTA recipients.

Potential pancreas recipients are carefully screened for contraindications to transplantation, such as an ongoing infectious process or malignancy. These candidates almost always have medical comorbid conditions resulting from secondary complications from diabetes; therefore, a thorough assessment of a candidate's cardiovascular status is essential. Cardiac contraindications to pancreas transplantation include the presence of noncorrectable coronary artery disease, ejection fraction of less than 40%, or myocardial infarction within the previous 6 months. Recipient age is also important, although there is no consensus as to what an upper age limit should be for undergoing pancreas transplantation. National data indicate that almost all pancreas transplantations in the United States are performed in recipients younger than 65 years.

The Donor Operation

Selection of an appropriate deceased donor for pancreas procurement includes standard donor selection criteria. In addition, there is a bias toward using organs from younger, leaner, and hemodynamically stable deceased donors. Donor organs that require high doses of vasopressor are considered higher risk for complications in the recipient. In addition, pancreata with significant infiltration of fat in the parenchyma are usually avoided because they are associated with a greater likelihood of postoperative complications such as pancreatitis, peripancreatic fat necrosis, and infection. On the basis of these relatively stringent selection criteria, only a fraction of deceased donors are deemed suitable for whole-organ pancreas donation. In the United States, there were 8143 deceased donors during 2012; however, only 1079 pancreata were transplanted (from 13% of all deceased donors, in comparison with 5941 livers (73%) and 11,991 kidneys (75% of all deceased donors).

Pancreas procurement from a deceased donor is performed in careful conjunction with liver procurement. The blood supply to the liver is identified to ensure that both organs can be removed and

transplanted. In most cases, aberrant blood supply should not preclude the transplantation of both organs. Initial dissection involves division of the gastrocolic ligament, so as to expose the anterior surface of the pancreas. Visual inspection is considered an important element in pancreas procurement because this is an opportunity to assess the organ for the presence of infiltrating fat, fibrosis, or hematoma that might preclude transplantation. The portal triad is carefully dissected, with division of the common bile duct and the gastroduodenal artery. In addition, the common hepatic, the proximal left gastric, and the proximal splenic arteries are all dissected free from surrounding lymphatic tissues. Further dissection of the pancreas includes performing Kocher's maneuver to mobilize the pancreatic head and dividing the lienophrenic and lienocolic ligaments to mobilize the pancreatic body and tail. Of note, the spleen is left in continuity with the pancreas to minimize manipulation of the gland, and it is removed later during backbench preparation. The duodenum is decontaminated by flushing of a solution containing povidone-iodine, an antibiotic, and an antifungal through a nasoduodenal tube.

After the donor has been prepared with heparin, the abdominal aorta is ligated at the iliac bifurcation, and a cannula is placed in a retrograde direction for perfusion. The liver surgery team may also place a cannula into a portal vein tributary, such as the inferior mesenteric vein, for portal perfusion. The supraceliac aorta is cross-clamped, the vena cava is vented, and the abdominal organs are flushed in situ with preservation solution (Belzer UW Cold Storage Solution) at 4° C. In addition, topical cooling of the organs is performed. Once the organs have been adequately flushed, the liver and pancreas are removed either en bloc and divided on the back table or removed separately from the donor. In the latter situation, the liver is removed first, by division of the portal vein 1 cm cephalad to the superior margin of the pancreatic head (approximately at the level of the coronary vein), and division of the splenic artery 5 mm beyond its origin, which thus preserves the entire celiac axis with the liver. Next, removal of the pancreas proceeds. The proximal duodenum (just beyond the pylorus) and the distal duodenum (near the ligament of Treitz) are divided with GIA staplers. The small bowel mesentery and transverse colon mesentery that lie inferior to the pancreas are divided. The superior mesenteric artery is divided at its origin from the aorta. Long segments of iliac arteries and veins are removed for vascular reconstruction on the back table.

Backbench Preparation of the Pancreas

In relation to other solid organs, the pancreas requires more preparation before transplantation into the recipient. This back table preparation is performed in ice-cold preservation solution to minimize further ischemic injury to the organ. The duodenum is often shortened with a GIA stapler, with care to exclude any gastric tissue and also not to compromise the opening of the ampulla of Vater. The surgeon divides the small bowel mesentery by firing a stapler across this mesentery and then reinforcing it with Prolene suture. The transverse colon mesentery is divided in a similar manner. The surgeon removes the spleen by dividing the vessels in the splenic hilum, being careful not to injure the tail of the pancreas. Finally, the arterial inflow to the graft is reconstructed because the organ has two major sources of blood supply that are not in continuity: the splenic artery, which supplies the pancreatic body and tail, and the superior mesenteric artery, which supplies the pancreatic head. In most instances, arterial reconstruction can be performed with a donor iliac artery as a Y-graft. The internal iliac artery is joined to the splenic artery, and the external iliac artery to the superior mesenteric artery. Both anastomoses are performed in an end-to-end manner with fine Prolene (6-0) sutures. The common iliac artery of the Y-graft can then be anastomosed to the recipient artery to provide the arterial inflow to the pancreas. In rare instances, it is necessary to create a portal vein extension graft on the backbench with donor iliac vein; however, this technique is avoided when possible because it may increase the risk of venous thrombosis of the pancreas graft.

The Recipient Operation

Unlike the techniques for most solid-organ transplantations, those for transplanting the pancreas have evolved significantly. Partial segmental grafts containing only the pancreatic body and tail were once common; however, this technique is rarely used now. Exocrine secretions were previously managed by pancreatic duct ligation or by injection of a polymer that would cause duct obliteration; today the exocrine secretions are handled by internal drainage.

The two significant areas in pancreas transplantation in which current techniques differ are the drainage of exocrine secretions and the venous drainage of the graft. Exocrine drainage is performed either via the intestinal tract or via the bladder. Throughout most of the 1980s and 1990s, drainage of the pancreatic secretions into the recipient bladder was the most common form of exocrine drainage. This technique is convenient for monitoring organ function by measurement of amylase levels in the urine. However, problems with hematuria, cystitis, bicarbonate loss, and dehydration are all associated with bladder drainage. These complications necessitate surgical revision to enteric drainage in 20% of bladder-drained pancreas recipients. Because of these issues and the lower rejection rates observed with newer immunosuppressive medications, the majority of transplant centers now perform enteric drainage of exocrine secretions. This enteric drainage is either directly into a loop of jejunum in a side-to-side manner or into a Roux limb of jejunum.

The venous drainage of the graft is either to the systemic circulation (via an iliac vein or the inferior vena cava) or to the portal circulation. Portal venous drainage has the advantage of delivering insulin in a more physiologic manner inasmuch as insulin undergoes a "first pass" through the liver and the hyperinsulinemia that results from systemic drainage is avoided. An immunologic advantage of portal drainage has also been observed in several experimental studies in which the delivery of foreign antigen via the portal system results in diminished immune responses. Despite these theoretical advantages, there has been no demonstrable difference in outcomes between portal and systemic venous drained pancreatic transplants in humans, and systemic venous drainage is how the majority of pancreas transplants are performed.

There are two common locations in the abdomen where a pancreas transplant is placed, on the basis of the type of venous drainage planned: either in the pelvis (most commonly the right side) for systemic venous drainage or in the midabdomen for portal venous drainage. When the graft is placed in the pelvis, the donor portal vein is anastomosed to the external iliac vein, the common iliac vein, or the inferior vena cava. In this pelvic position, the graft is oriented with the duodenum inferiorly if bladder drainage is planned (Figure 1, *A*) or with the duodenum in either the superior (see Figure 1, *B*) or inferior direction if enteric drainage is planned. Alternatively, for portal venous drainage, the pancreas is placed in the midabdomen below the transverse colon with the duodenum oriented superiorly. The portal vein of the pancreas is anastomosed to the major branch of the superior mesenteric vein found in the small intestine mesentery in an end-to-side manner (Figure 2). Enteric drainage for exocrine secretions must be used with portal venous drainage. With either technique, the arterial Y-graft of the pancreas is anastomosed in an end-to-side manner with either the iliac artery (common or external) or the aorta.

COMPLICATIONS

The major complications after pancreas transplantation are often technical in nature. Thrombosis (arterial or venous) is more frequent in pancreatic grafts than in other solid-organ transplants, and the

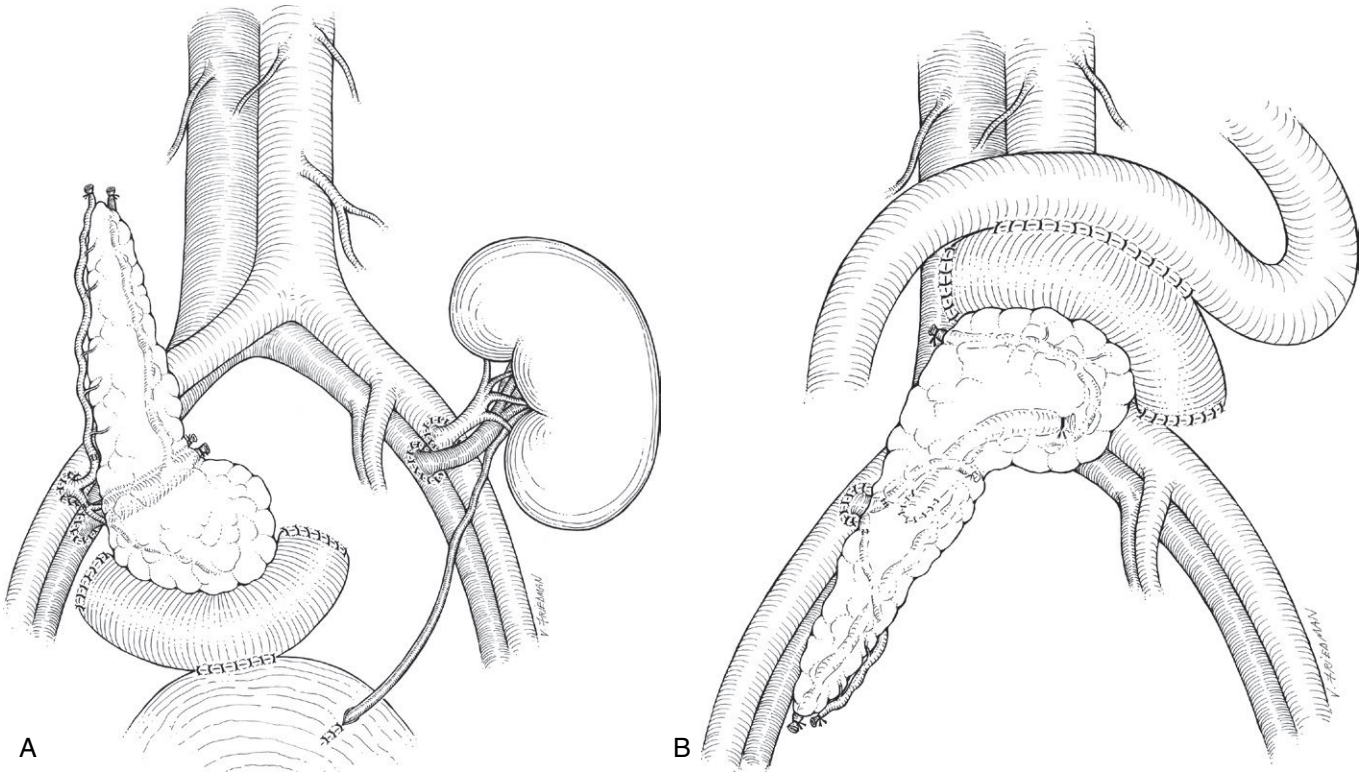

FIGURE 1 Whole-organ pancreas transplantation with systemic venous drainage. The pancreas is placed in the right side of the pelvis with anastomosis of the donor portal vein to the recipient iliac vein for venous drainage. The donor iliac artery Y-graft is sewn to the recipient iliac artery for arterial inflow to the graft. Kidney transplantation can be performed simultaneously with the left-sided iliac vessels. **A,** The donor duodenum is oriented inferiorly to allow anastomosis to the recipient bladder *(shown)* or to the recipient small intestine *(not shown)* for pancreatic exocrine drainage. **B,** Alternatively, the donor duodenum is oriented superiorly to allow anastomosis to the recipient small intestine for pancreatic exocrine drainage.

reported incidence is approximately 5% to 10%. Thrombosis often occurs within the first week after transplantation and is characterized by a sudden increase in serum glucose level. In most instances of thrombosis, graft removal is necessary. Early pancreatitis occurs in 10% to 20% of cases and is largely a reflection of ischemic damage to the gland during preservation and subsequent reperfusion injury. Elevated serum amylase levels and graft edema are characteristic, and graft pancreatitis is usually treated with octreotide. Leakage at the site of pancreatic exocrine drainage is another early complication, with management often dictated by the method of drainage. Bladder-drained transplants with a small leak at the duodenocystostomy can often be managed by Foley catheter drainage of the bladder, which allows the site of leakage to heal over time. Leaks at the duodenojejunostomy in transplants with enteric drainage usually result in peritonitis, and operative intervention is necessary to control the leak.

Rejection after pancreas transplantation was once very common. The diagnosis of pancreas rejection is often difficult, and a variety of indicators are used to help establish the diagnosis. These include increased serum amylase levels, decreased urinary amylase excretion (if bladder drainage is used), biopsy of the pancreas, and the presence of hyperglycemia. Hyperglycemia is a late indicator of rejection, however, and the pancreas is often difficult to salvage once hyperglycemia has occurred. If SPK transplantation is performed, then renal allograft dysfunction can often assist with the diagnosis of pancreatic rejection, since the rejection process is usually occurring in both organs. As a result of the high incidence of rejection and the difficulty in establishing the diagnosis, pancreas transplant recipients usually receive potent induction immunosuppression with a T cell–depleting agent and maintenance therapy with tacrolimus, mycophenolate mofetil, and corticosteroids.

The total amount of immunosuppression that pancreas transplant recipients receive is among the highest for any solid-organ transplant. As a result, they are more susceptible to the complications of immunosuppressive therapy. These complications include infection with opportunistic bacteria, viruses, and fungi; malignancy; and gastrointestinal complications. The high incidence of these complications highlights the importance of effective prophylaxis strategies.

RESULTS

Patient and graft survival after pancreas transplantation have improved significantly since the 1990s. The rates of patient survival are approximately 97% at 1 year and 92% at 3 years after SPK transplantation. Similar patient survival rates are reported for PAK and PTA recipients. Graft survival is variable, depending on the type of pancreas transplant performed (Figure 3). For SPK recipients, 1- and 3-year pancreas graft survival rates are 89% and 80%, respectively. For PAK and PTA recipients, 1- and 3-year pancreas graft survival rates are 84% and 66%, respectively.

The effect of a successful pancreas transplant on the complications associated with diabetes mellitus is debated. Because the successful transplant restores euglycemia and normal hemoglobin A_{1C} levels, most proponents argue that diabetic complications should cease and the damage perhaps be reversed. Neuropathy appears to stabilize and often improve after pancreas transplantation, whereas retinopathy progression is slowed after several years of graft function. The development of diabetic nephropathy in the transplanted kidneys of SPK and early PAK recipients appears to be prevented by successful pancreas transplantation. In PTA recipients, diabetic

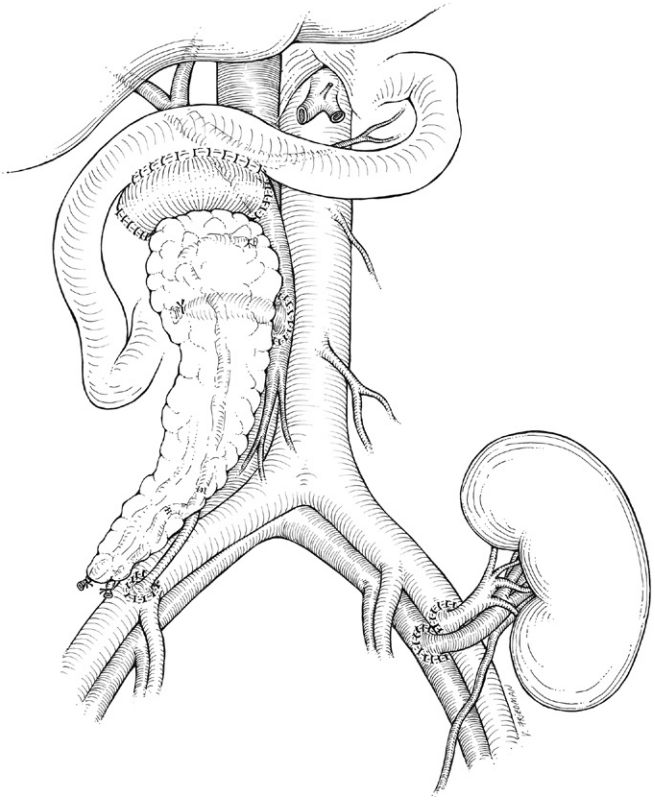

FIGURE 2 Whole-organ pancreas transplantation with portal venous drainage. The pancreas is placed in the midabdomen with anastomosis of the donor portal vein to the major branch of the recipient superior mesenteric vein for venous drainage. The donor iliac artery Y-graft is sewn to the recipient iliac artery for arterial inflow to the graft. The donor duodenum is oriented in the superior direction for anastomosis to the recipient small intestine. Kidney transplantation can be performed simultaneously with either the left *(shown)* or right iliac vessels.

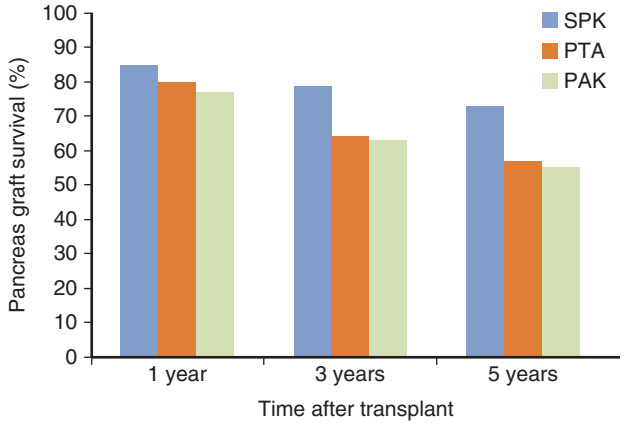

FIGURE 3 Pancreas graft survival rates at 1, 3, and 5 years after whole organ transplantation by transplantation category. *PAK,* pancreas-after-kidney (transplantation); *PTA,* pancreas transplantation alone; *SPK,* simultaneous kidney (and pancreas) transplantation.

nephropathy appears to stabilize after the transplantation; however, the renal benefit is probably outweighed by the detriment to renal function caused by the maintenance immunosuppressive agents, specifically tacrolimus or cyclosporine.

RISK/BENEFIT CONSIDERATIONS

Considerable evidence suggests that a pancreas transplant can stabilize the secondary complications of diabetes and, in some cases, reverse the damage. Despite this evidence, the procedure is considered appropriate for only a subset of patients with type 1 diabetes because of its highly invasive nature in comparison to insulin therapy and because of the potential for significant surgical complications. Therefore, risk/benefit considerations are of utmost importance in pancreas transplantation and play an essential role in the recipient selection processes.

In several important studies, researchers have evaluated the survival benefit of pancreas transplantation by examining large data sets to compare the survival of pancreas recipients with that of patients who were on a waiting list for transplantation but did not receive a pancreas. In this study design, the two patient groups were as similar as possible. Because the indications, risks, and benefits differ depending on whether a patient has underlying renal failure, these analyses were stratified according to whether a patient remained waitlisted or underwent an SPK, PAK, or PTA procedure. All studies revealed a marked survival benefit for patients who received simultaneous pancreas and kidney transplants, with more than a 50% reduction in mortality at 4 years, in comparison with similar patients who remained on the waiting list.

In contrast to the clear survival benefit of SPK transplantation, the data for PAK and PTA recipients are less clear. In one study, the rate of mortality among both PAK and PTA recipients was increased 4 years after transplantation; PAK recipients exhibited a 42% increase in mortality and PTA recipients exhibited a 57% increase in mortality, in comparison with the patients who remained on the waiting list. However, another study demonstrated no difference in mortality rates among PAK and PTA recipients, with a trend toward improved survival in the PAK and PTA recipients in comparison with patients who remained on the waiting list.

There are two important caveats to these risk/benefit studies. The first is that the effect of pancreas transplantation on quality of life was not evaluated in these nonrandomized retrospective analyses and would probably heavily favor the PAK and PTA recipients. Whether this factor would outweigh any survival disadvantage in the short term and the significant cost of these complex procedures has not been evaluated. A second critical outcome measure that is lacking from these studies is the long-term effect of successful pancreas transplantation on the secondary complications of diabetes. There is considerable evidence that diabetic nephropathy, neuropathy, and retinopathy may be positively affected by the long-term normoglycemia conferred by transplantation.

These results substantiate the marked clinical benefit observed in the care of patients who receive simultaneous pancreas and kidney transplants. The relative contributions of the transplanted kidney and of the transplanted pancreas to the overall survival benefit have not been differentiated. This issue is significant because of the marked survival benefit that has been documented in the setting of kidney transplantation alone in diabetic recipients.

Although the survival benefit for SPK recipients is clear, the data demonstrating a lack of survival benefit for PAK and PTA recipients remain controversial. At a minimum, the studies available to date suggest a narrow therapeutic margin for PAK and PTA recipients. Perhaps the most meaningful conclusions that can be drawn at present are that recipients should be selected with the utmost care, donor organs should be optimal, and the surgery should be performed at transplantation centers with good outcomes. The field is dynamic as a result of both improvements in surgical techniques

and in perioperative care, and the frequent introduction of new immunosuppressive agents with more favorable safety profiles. It is expected that a clear survival benefit for pancreas transplantation will be established with further advances in the field.

The Spleen

Hematologic Indications for Splenectomy

Tiffany Stoddard, MD, and
Adrian Park, MD, FRCSC, FACS, FCS (ECSA)

OVERVIEW OF SPLENIC STRUCTURE AND FUNCTION

Although the spleen is not an essential organ, it does perform a variety of significant functions. These functions include filtration of blood, destruction of senescent or malformed erythrocytes and the removal of inclusion bodies, antigen processing and clearance, antibody production, hematopoiesis, and storage of erythrocytes, lymphocytes, and platelets. The splenic architecture is designed to maximize its ability to perform these functions. The white pulp is the portion that contains lymphoid nodules, which expand in response to infection or inflammation. The red pulp contains venous sinuses that ultimately drain into the splenic vein. The sinusoids are lined by a fibrocellular network that contains macrophages. The absence of tight junctions between the endothelial cells facilitates diapedesis and further enhances the filtering abilities of this portion of the spleen. The red and white pulps are divided by a marginal zone that contains white blood cells.

Given the functions of the spleen, that this organ has a central role in many hematologic disorders is no surprise. The hematologic indications for splenectomy have evolved throughout history, but there are still many diseases for which this surgery remains an integral part of their management. These disorders cover a broad spectrum of pathologies involving erythrocytes, white blood cells, platelets, and bone marrow.

ERYTHROCYTE DISORDERS

Red blood cell (RBC) disorders can be divided into membrane defects, hemoglobinopathies, enzyme deficiencies, and autoimmune phenomena.

Membrane Defects

This category includes a spectrum of disorders characterized by a deficiency or dysfunction of cytoskeletal elements that results in altered RBC morphology, which increases the susceptibility to destruction. The end result is varying degrees of hemolysis and anemia. The best known disorder in this group is hereditary spherocytosis (HS). It is the most common inherited chronic hemolytic disease in northern Europe and North America. It can be associated with abnormalities in spectrin, ankyrin, band 3 protein, and protein 4.2 that result in a more spherical RBC morphology and render it more susceptible to destruction within the spleen. HS is associated with varying degrees of hemolysis and anemia, but most commonly the anemia is compensated (i.e., normal hemoglobin, reticulocytosis). The severity of HS is measured with hemoglobin and bilirubin levels, the spectrin content, and reticulocyte count. Splenectomy is generally indicated in children with severe cases (hemoglobin, 6 to 8 gm/dL), should be considered in cases of moderate disease, and probably should not be performed in mild cases. Although splenectomy does not correct the membrane deformity, it is curative in that it eliminates the problem of hemolysis and resultant anemia.

Other membrane disorders are elliptocytosis, ovalocytosis, and stomatocytosis. Splenectomy is not necessarily indicated for these conditions, and in the case of stomatocytosis, splenectomy may actually be contraindicated as a result of some reports of an increased incidence of thromboembolic events after splenectomy in this patient population.

Hemoglobinopathies

Various disorders of hemoglobin organization also result in hemolysis. Sickle cell disease and the thalassemias are representative of this category.

Sickle Cell Anemia

Initially described in 1904 by James B. Herrick after his intern found "peculiar elongated and sickle shaped" erythrocytes in a patient's blood smear, sickle cell disease is a defect in hemoglobin that results from a single amino acid substitution on the beta chain that leads to the incorporation of valine instead of glutamic acid. This results in an unstable molecule that is more susceptible to oxidative stresses and makes the red cell less deformable and more susceptible to splenic sequestration and destruction. The spleen is enlarged in the first decade of life but usually atrophies from repeated episodes of vascular occlusion and infarction. Splenectomy may be indicated in a variety of circumstances, such as persistent splenomegaly, acute severe or recurrent sequestration crises, hypersplenism, massive infarction, and splenic abscess. Splenectomy does not reverse sickling.

Thalassemia

The thalassemias comprise a group of disorders that arise from defective synthesis of the alpha and beta globin subunits such that they

may simply be reduced or absent. Hemoglobin production and erythrocyte survival are reduced as a result of unstable homotetramers that precipitate as inclusion bodies. These disorders are characterized by varying degrees of hemolysis, ineffective erythropoiesis, lymphadenopathy, and hepatosplenomegaly. The mainstay of treatment is chronic transfusion, but significant risks are associated with iron overload. Splenectomy may be indicated in the setting of painful splenomegaly and in cases of hypersplenism that are associated with transfusion volumes exceeding 225 to 250 mL/kg/y. Splenectomy can be beneficial in protecting against extramedullary hematopoiesis and in decreasing the transfusion requirement. Unfortunately, these patients have very high rates of overwhelming postsplenectomy sepsis. Splenectomy should be individually considered in this population.

Autoimmune Hemolytic Anemias

Autoimmune hemolytic anemias (AIHA) are very rare; when they do occur, they are mostly seen in association with other autoimmune phenomena, such as lupus. AIHA is characterized by the presence of autoantibodies to RBC antigens. Whether the antibodies are associated with a secondary cause must first be determined. In addition, the antibody isotype and the optimal binding temperature for the antibody must be determined. Warm AIHA is defined by an optimal antibody binding temperature of 37°C, and cold AIHA is characterized by an optimal binding temperature of 30°C. Splenectomy has no role in the management of cold AIHA.

Steroids are the primary treatment of choice in warm AIHA. They decrease autoantibody formation and decrease the density of Fc receptors on splenic macrophages. They result in remission in 70% to 85% of patients, but most cases that respond need maintenance steroids to maintain a normal hematocrit value. Splenectomy is considered to be second-line therapy and may be necessary in patients who require high doses of steroids (>15 mg/d) for maintenance of hemoglobin levels. Splenectomy is associated with decreased anti-RBC antibody production and decreased RBC destruction. After splenectomy, as many as 20% of patients experience long-term remission or cure and 50% have a significant decrease in the steroid requirement, but the remainder of patients experience little significant remission.

Enzyme Deficiencies

Erythrocyte enzyme deficiencies are rare, and splenectomy generally has a limited role in their management. Pyruvate kinase deficiency is the only disorder in this group for which splenectomy has shown consistent benefit. It is usually reserved for patients who have severe anemia or who do not tolerate anemia. Although it does not eliminate hemolysis, splenectomy usually results in a 1 to 3 g/dL increase in hemoglobin and may reduce or eliminate the transfusion requirement.

PLATELET DISORDERS

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is the most common indication for elective splenectomy. It is characterized by the formation of platelet autoantibodies and the subsequent removal of the platelet-antibody complexes by the reticuloendothelial system. The spleen manufactures the anti-platelet immunoglobulin G (IgG) and plays a major role in the removal of those complexes. Splenomegaly is rarely part of the clinical presentation. The childhood and adult forms differ. The childhood form tends to follow an acute infectious process and commonly spontaneously resolves; adults tend to have a more chronic course that rarely resolves without medical intervention. Usually no therapy is necessary if the patient does not have any bleeding complications and the platelet count is above 30,000/mm^3. Corticosteroids are the first line in management in adult patients who need therapy, but the long-term response rate is about 20% to 30%. Many other medical therapies including intravenous immunoglobulin, various immunosuppressive therapies, and thrombopoietin receptor agonists, have been used as second-line therapies. However, many of these agents require continuous administration to achieve a response and therefore can be associated with toxicities.

Before the introduction of glucocorticoids in 1950, splenectomy was the only treatment modality available. Although it is no longer first-line therapy, it is still indicated in cases of medically refractory disease and in cases that require prolonged steroid therapy. The initial response to splenectomy has been reported to be as high as 80% to 90%, but the sustained response rates to splenectomy are consistently reported lower at around 60%, and some patients may need additional therapy such as thrombopoietin receptor agonists or rituximab to increase platelet counts. Many studies have sought to determine whether there are factors predictive of the response to splenectomy, but the findings have been inconsistent.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a disease that has been characterized by a deficiency of the metalloproteinase that cleaves the large multimers of von Willebrand's factor and results in platelet clumping in the vasculature and subsequent deleterious effects. The classic features include fever, thrombocytopenia, anemia, renal dysfunction, and neurologic sequelae all secondary to the pathology in the microvasculature. Although the condition is rare, with approximately 11 cases per million per year, early recognition and intervention is critical; the outcome is dramatically improved when timely therapy is implemented.

Historically, splenectomy and steroids in combination was the treatment of choice and resulted in a response rate of only 50% and a mortality rate of 40%. The exact mechanism of the benefits of splenectomy is not completely understood, but it has been postulated that removal of the spleen eliminates a potential source of antimetalloproteinase antibody production and a site of platelet sequestration. Plasma exchange was introduced in 1977 and yielded remission rates of 70% to 80%. Splenectomy continues to play a role in the management of TTP as 20% to 30% of patients have disease resistant to or recurrent after plasma exchange. However, of those patients who undergo splenectomy, as many as 8% to 17% experience relapsing disease.

Myeloproliferative Neoplasia

This category includes essential thrombocythemia, polycythemia vera, primary myelofibrosis, and chronic myelogenous leukemia. These diseases involve proliferation of one or more of the myeloid, erythroid, or megakaryocytic cell lines. Splenomegaly is a common feature of these proliferative disorders because the spleen is a site of extramedullary hematopoiesis. However, splenectomy does not cure any of these disorders and is usually only indicated in cases of symptomatic portal hypertension, drug-refractory splenomegaly associated with severe symptoms (e.g., pain and early satiety), transfusion-dependent anemia, severe thrombocytopenia, and uncontrollable hemolysis.

White Blood Cell Disorders

Similar to the myeloproliferative neoplasias, splenectomy does not correct the disease process but may be indicated in cases of

symptomatic splenomegaly or hypersplenism. Some diseases in this category include chronic lymphocytic leukemia (CLL), hairy cell leukemia (HCL), Hodgkin's disease (HD), and non-Hodgkin's lymphoma (NHL).

HCL and HD deserve special mention because splenectomy was historically central to the management of these diseases. HCL is a chronic B cell lymphoproliferative disorder associated with characteristic cells displaying cytoplasmic projections. Splenomegaly and pancytopenia are frequent features of the disease. Before advances in medical therapy, splenectomy was the treatment of choice and resulted in improvement in or normalization of the peripheral smear in 40% to 75%. However, purine analogues are associated with significantly higher hematologic response rates and are the mainstay of therapy currently.

HD is a disorder characterized by the presence of Reed-Sternberg cells and is often associated with bulky lymphadenopathy but less so with massive splenomegaly. Historically, splenectomy was a part of the staging process for HD but, with the introduction of more advanced imaging techniques and the more liberal use of chemotherapy splenectomy, is no longer considered routine in the management of the disease.

PREOPERATIVE CONSIDERATIONS

There are special considerations in preparation for splenectomy. Laparoscopic splenectomy is considered the gold standard technique for most indications for splenectomy, but this technique increases in difficulty with increasing size of the spleen and may be impossible in cases of massive splenomegaly. Therefore, preoperative imaging is helpful to provide information regarding splenic anatomy. The guidelines of the European Association for Endoscopic Surgery suggest that all patients should undergo preoperative imaging, which may be an ultrasound scan to evaluate splenic size and volume. However, computed tomographic (CT) scan may be preferable when more information is needed about splenic anatomy and vasculature. CT scanning may also facilitate the search for accessory splenic tissue, but obtaining this study should not preclude a thorough intraoperative search. Although preferred by some surgeons, the routine use of preoperative splenic artery embolization is not recommended and may in fact lead to severe pain and ischemic complications if performed too far in advance of splenectomy.

Perhaps the most important preoperative consideration is that of vaccination. Patients who have undergone splenectomy have an extremely high risk of septic events compared with the general population, and every precaution should be taken to minimize the risk of these events. In the setting of elective splenectomy, preoperative vaccination against the most common encapsulated pathogens that may cause overwhelming postsplenectomy sepsis is paramount. In addition, antibiotic prophylaxis should also be administered at the time of splenectomy. Another point of consideration is the risk of thrombosis in this population, especially of the portal and splenic venous systems. Therefore, all patients should receive appropriate perioperative prophylaxis.

LAPAROSCOPIC SPLENECTOMY

Since it was initially described in 1991, laparoscopic splenectomy has been adopted as the standard of care for most indications for splenectomy. Although more technically challenging than open splenectomy, the laparoscopic technique has been shown repeatedly to be safe when performed by experienced surgeons, and no difference is found in hematologic outcomes when compared with open splenectomy. There have been concerns that this approach is not amenable to patients with splenomegaly, but again, when performed by experienced surgeons, laparoscopic splenectomy remains the preferred method even in this setting.

POSTOPERATIVE CONSIDERATIONS

Infection is the most common complication after splenectomy. Although rare, the most feared infectious complication is overwhelming postsplenectomy sepsis (OPSS). Although all patients have a significant risk for this commonly fatal complication after splenectomy, patients undergoing splenectomy for hematologic or malignant indications have the greatest risk, and patients who undergo splenectomy for trauma or iatrogenic injury have the lowest risk. The risk is also highest within the first 2 years after surgery; it declines over time but never reaches zero.

Because of the special adaptations of splenic macrophages, they have an increased avidity for antigens that other macrophages lack. Therefore, patients after splenectomy are more susceptible to infections caused by encapsulated organisms, the most common being *Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria meningitidis.* OPSS rapidly progresses from a febrile illness to circulatory collapse and death within a matter of hours. Because of the rapid progression of disease and often fatal course despite antibiotic therapy, the best management of OPSS includes educating patients and families about the features of the disease and the necessity of prompt evaluation of febrile illness and prevention.

Although difficult to quantify in the literature, vaccination of asplenic patients against the most commonly encountered pathogens is accepted as the mainstay of preventive therapy. The benefits of vaccination against pneumococcus have been reported, and one study observed a decrease in the risk of postsplenectomy sepsis from 7.8% in unvaccinated patients to 2.4% of vaccinated patients during a 17-year follow-up study.

In the setting of elective splenectomy, patients should be vaccinated 2 weeks before surgery to optimize antigen recognition and processing. If splenectomy is performed emergently, vaccinations can be administered after surgery; some advocate delaying administration for 2 weeks to avoid the transient immunosuppression associated with general anesthesia and surgery.

Thromboembolic events are also cited as fairly common and potentially devastating complications after splenectomy. These events include arteriothrombosis (myocardial infarction, stroke), venous thrombosis, and pulmonary hypertension. Some studies have reported an increased risk of arteriosclerotic events in patients who have undergone splenectomy for trauma, HS, and thalassemia. Venous thrombotic events have been more commonly reported. Interestingly, the risk of portal venous thrombosis has been reported to range from 5% to 37% after splenectomy. This phenomenon appears to occur most commonly within the first 2 weeks after surgery, may be related to the technical aspects of surgery, and has not been clearly shown to be influenced by the degree of postoperative thrombocytosis. The rates of deep venous thrombosis and pulmonary embolism have also been noted to occur with increasing frequency after splenectomy, with the greatest risk appearing to be associated with a history of thalassemia. Finally, the incidence of pulmonary hypertension has been reported to be increased after splenectomy. Again, patients with thalassemia appear to have the greatest risk compared with the general population. Various pathologic mechanisms have been proposed to explain these thromboembolic events, including alterations in the lipid profile, a relative hypercoagulable state, and potential alterations in platelet and endothelial activation. No evidence suggests that specific antithrombotic therapy beyond routine perioperative prophylaxis is necessary after splenectomy.

CONCLUSION

Despite medical advances, splenectomy continues to play a significant role in the management of many hematologic disorders. With the appropriate prophylactic measures and careful evaluation of each patient, splenectomy will continue to be a safe procedure.

Cysts, Tumors, and Abscesses of the Spleen

Thomas McIntyre, MD, and Michael E. Zenilman, MD

Cysts, tumors, and abscesses of the spleen are entities that occur rarely but often require surgical treatment (Box 1). Splenectomy in cancer surgery for tumors or processes in other organs, such as pancreatic and gastric, is much more common, as is a splenectomy for trauma and its complications.

CYSTS

Splenic cysts are classified as either primary (true) or secondary (false) based on the presence of an epithelial lining of the lumen. False cysts are also referred to as pseudocysts. The diagnosis of cyst is now made more frequently as a result of the increased use of abdominal imaging. Both true and false cysts can become quite large and symptomatic and can even rupture.

Primary (True) Cysts

Primary cysts with an epithelial lining are either parasitic or nonparasitic. In the United States, approximately 5% of splenic cysts are parasitic. However, in geographic regions where hydatid disease is endemic, such as South America and parts of the Mediterranean region, most splenic cysts are parasitic.

Parasitic

Parasitic cysts occur after infection with the *Taenia echinococcus.* The most common organism is *Echinococcus granulosus,* which forms a unilocular cyst. Rare infections from *E. multilocularis* and *E. vogelii* form multiloculated cysts. These cysts are typically asymptomatic and are associated with manifestations of echinococcal (hydatid) disease elsewhere. The most commonly affected organ is the liver, followed by the spleen and lungs. A parasitic cyst should be suspected if the splenic cyst has wall calcifications and internal daughter cysts. Serologic testing for parasite antibodies should be sent to confirm the diagnosis. In all cases, splenectomy is indicated to avoid the potential complications of rupture and bacterial superinfection. Splenectomy should be combined with medical management of echinococcal disease. Appropriate intraoperative precautions and surgical techniques should be used to minimize cyst rupture and intraperitoneal contamination.

Nonparasitic

Nonparasitic epithelial-lined cysts account for 20% of all splenic cysts and can be congenital or neoplastic. Neoplastic splenic cysts are exceedingly rare. Congenital cysts are either epidermoid or dermoid

BOX 1: Classification of splenic cysts, tumors, and abscesses

Cysts
- Primary (true)
 - Parasitic
 - Nonparasitic
 - Congenital
 - Epidermoid
 - Dermoid
 - Neoplastic
- Secondary (false), or pseudocysts

Tumors
- Malignant
 - Lymphoproliferative disease
 - Non-Hodgkin's lymphoma
 - Hodgkin's disease
 - Hairy cell leukemia
 - Chronic lymphocytic leukemia
 - Myeloproliferative disease
 - Chronic myelogenous leukemia
 - Myelofibrosis
 - Primary tumors
 - Angiosarcoma
 - Metastatic tumors
- Benign
 - Hemangioma
 - Hamartoma
 - Lymphangioma
 - Littoral splenic angioma

Abscesses
- Bacterial
- Fungal
- Lymphangioma

Reprinted from McIntyre T, Zenilman ME: Cysts, tumors and abscesses of the spleen. In Cameron J, editor: Current surgical therapy, *ed 9, Philadelphia, 2008, Elsevier Saunders.*

and are usually detected in children or young adults. Epidermoid cysts account for 90% of all nonparasitic true cysts.

Symptomatic splenic cysts can cause left upper quadrant pain, early satiety, and postprandial nausea and vomiting. Of the asymptomatic patients, half have a palpable mass on physical examination. Computed tomographic (CT) scan typically shows a solitary cyst with occasional wall calcifications.

Secondary (False) Cysts or Pseudocysts

Secondary cysts or pseudocysts account for the vast majority of splenic cysts seen in the United States. The spleen is the most commonly injured organ after abdominal trauma, and most secondary cysts are posttraumatic in origin. They may also occur in association with a pancreatic pseudocyst after acute pancreatitis and splenic infarcts or infections. The diagnosis of splenic pseudocysts is increasingly common because of the widespread nonoperative management of splenic trauma and increased use of diagnostic abdominal imaging for trauma.

Treatment

Indications for treatment of splenic cysts are based on the patient's symptoms and cyst diameter. Possible complications of an untreated cyst include: spontaneous rupture with peritonitis or bleeding, abscess formation, hypersplenism, and portal hypertension. For asymptomatic cysts less than 5 cm, conservative treatment is advocated because these cysts often resolve. If the cyst is greater than 5 cm or symptomatic, surgical intervention is recommended. Percutaneous drainage should be avoided because of the high incidence of recurrence and subsequent inflammatory reaction that ensues and renders subsequent operations difficult.

Surgical options include complete or partial splenectomy, unroofing of the cyst, and fenestration. All of these can be accomplished with open or minimally invasive techniques. A spleen-preserving minimally invasive procedure is recommended if possible. Splenic preservation is advocated because the spleen plays an important role in regulation of the circulating blood volume, hematopoiesis, and protection against infection and malignant disease.

Splenectomy

Complete splenectomy is recommended in polycystic cases and when cysts are inaccessible for fenestration or partial splenectomy. Splenectomy should be performed laparoscopically when possible. The laparoscopic procedure is typically performed with the patient in the lateral position and uses four subcostal ports. The spleen is first mobilized from its attachments to the colon and retroperitoneum. The short gastric vessels can be clipped and divided or transected with a Harmonic scalpel (Ethicon Endo-Surgery, Cincinnati, Ohio) or Ligasure device (Covidien, Covidien, Mansfield, Mass). The vascular pedicle can then be isolated and divided. The specimen is placed in a bag, morcellation is performed, and the specimen is removed from one of the subcostal port sites.

Partial Splenectomy

It is believed that at least 25% of the splenic parenchyma should be preserved to ensure adequate postoperative splenic function. Partial splenectomy is recommended if the cyst cavity is deep within the splenic parenchyma. In general, splenic cysts respect the segmental blood supply of the spleen, which makes partial splenectomy possible without major blood loss. Control of splenic arterial inflow and complete splenic mobilization are first performed. Segmental vessels are ligated until a desired line of ischemic demarcation is achieved. Transection and hemostasis of the splenic parenchyma is undertaken within the cyanotic area with a variety of techniques that include: parenchymal fracture, electrocautery, clips, endoscopic gastrointestinal anastomotic staplers, argon beam coagulation, sutures, and topical hemostatic agents. The use of high-energy tools such as the Harmonic scalpel (Ethicon Endo-Surgery, Cincinnati, Ohio) or Ligasure device (Covidien, Covidien, Mansfield, Mass) make this operation more feasible. Polar lesions are more amenable to a laparoscopic approach.

Unroofing or Fenestration

These techniques are recommended for superficial and peripherally located cysts and can almost always be done laparoscopically. The major problem with unroofing and fenestration is a slightly higher risk of recurrence. In most cases, however, the residual cysts are small and asymptomatic. To reduce the risk of reappearance, the surgeon should remove as much cyst wall as possible and fill the resulting parenchymal defect with omentum.

In traumatic pseudocysts, however, most conservation treatment, such as fenestration or unroofing, ultimately fails, and splenectomy is required.

TUMORS

Malignant

Malignant tumors of the spleen can be grouped into these categories: lymphoproliferative disease, myeloproliferative disease, primary splenic (nonlymphoid) neoplasm, and metastatic lesion. In lymphoproliferative and myeloproliferative diseases, the spleen is rarely the primary site of malignancy and is usually secondarily involved (Figure 1).

Lymphoproliferative Disease

Non-Hodgkin's lymphoma (NHL) is the most common malignant disease that involves the spleen. It is rarely the primary site of

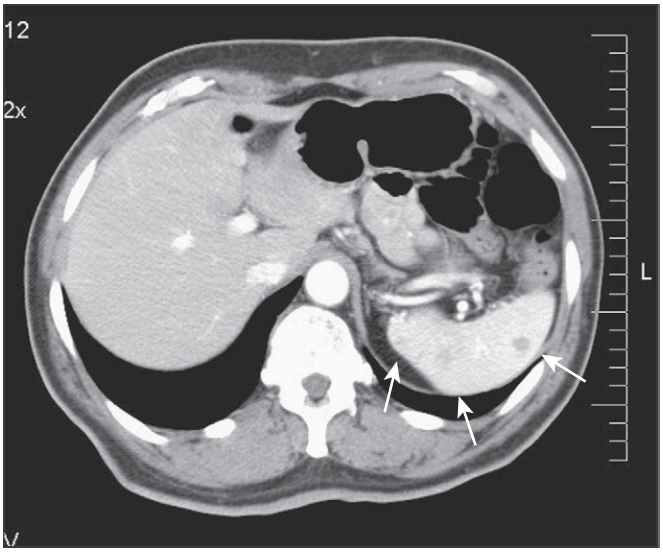

FIGURE 1 This abdominal computed tomographic scan of a 72-year-old man with weight loss and weakness shows multiple hypodense lesions in the spleen *(arrows)*. Splenectomy was performed and revealed non-Hodgkin's lymphoma. Typically in this disease, the diagnosis is made before splenectomy, and surgery is for symptoms, not diagnosis.

malignancy (as seen in Figure 1) but is secondarily involved in up to 40% of all patients with NHL. Once a diagnosis is made, multiagent chemotherapy with or without radiation is the primary mode of treatment. Splenectomy is reserved for patients with development of cytopenia or symptomatic splenomegaly. Splenectomy in these patients does improve peripheral blood counts but has no effect on long-term survival.

Hodgkin's disease is a highly curable disease that progresses in a predictable fashion from one nodal group to another. Critical to effective treatment is accurate staging based on extent of disease. Determination of the presence of infradiaphragmatic disease is difficult in patients with clinical stage I or II supradiaphragmatic disease. Up to 35% of all patients with stage I and II disease have occult splenic disease or upper abdominal nodal involvement. This was the rational for staging laparotomy in the past. Because of the dramatic improvements in radiographic imaging and chemotherapeutic regimens, currently less than 5% of patients require staging laparotomy. An abdominal CT scan is currently the principal investigational tool for infradiaphragmatic disease, although staging laparotomy is still considered the most accurate technique to determine abdominal disease. Staging laparotomy should be performed only if results would change the final treatment regimen. The staging procedure can be safely done laparoscopically and should include inspection of the peritoneum, splenectomy, and wedge; core biopsies of the liver; and biopsies of the para-aortic, iliac, portal, and mesenteric lymphatic node basins.

Hairy cell leukemia is a lymphocytic leukemia that manifests as splenomegaly and pancytopenia. In patients with symptomatic hypersplenism, splenectomy is beneficial. It is associated with improved overall survival, likely because of the reduced risk of complications associated with pancytopenia.

Chronic lymphocytic leukemia (CLL) is treated with splenectomy only in patients with symptomatic splenomegaly or cytopenia resulting from hypersplenism. No increase in survival is seen; however, there is a substantial reduction in peripheral lymphocyte count and transfusion requirements.

Myeloproliferative Disease

Chronic myelogenous leukemia (CML) accounts for 30% of all adult leukemia. Splenectomy during the blastic or accelerated phase of the disease has been shown to improve quality of life and decrease transfusion requirements. Myelofibrosis is a rare disorder that is universally fatal, with mean survival time of 5 years. Splenectomy has a palliative role in reducing transfusion requirements and improving quality of life.

Primary (Nonlymphoid) Neoplasms

Angiosarcoma is the most common nonlymphoid malignant tumor of the spleen. These tumors grow rapidly and metastasize early and thus carry a poor prognosis. Splenectomy is indicated but rarely curative. Other exceedingly rare malignancies include fibrosarcoma, leiomyosarcoma, plasmacytoma, malignant fibrous histiocytoma, and vascular tumors, such as hemangiosarcoma and lymphangiosarcoma.

Metastatic Tumors

Metastatic involvement of the spleen from nonlymphoid malignant disease is rare and usually a manifestation of disseminated disease. Splenic metastases are usually seen in association with widespread visceral metastases. The infrequent involvement of the spleen may be a function of the immunologic role of the spleen and its ability to eliminate microscopic metastatic disease. Cancers known to metastasize to the spleen include breast, lung, melanoma, ovarian, endometrial, gastric, colonic, and prostate. Splenectomy is acceptable when thorough workup reveals solitary splenic metastases and the primary tumor is controlled. Splenectomy can also be justified in conjunction with an abdominal debulking procedure for ovarian carcinoma.

Benign

The discovery of benign splenic tumors has become more common as a result of improvements in CT technology and its widespread use. They are usually found incidentally and are seldom symptomatic. Hemangiomas are the most common benign tumors of the spleen. They are typically associated with hemangiomas of other intra-abdominal organs, particularly the liver. The associated risks include rupture and hemorrhage. These tumors do not require treatment unless they become symptomatic as a result of splenomegaly or they produce a consumptive coagulopathy, thrombocytopenia, microangiopathic anemia, or disseminated intravascular coagulation. There have been recent reports of treated hemangiomas with radiofrequency ablation, but this should only be considered in small tumors and only if symptomatic.

A tumor called littoral splenic angioma, described in 1991, is comprised of the sinus-lining cells of the spleen, also called littoral cells. These solid tumors are almost always asymptomatic and are diagnosed at pathology. They are vascular in origin and may be related to the integrity of the immune system. Interestingly, splenic littoral angiomas have been described in patients undergoing anti–tumor necrosing factor (TNF) alpha antibody therapy; a therapy commonly used for patients with inflammatory bowel disease and sarcoidosis.

Hamartomas of the spleen can be either cystic or solid. These lesions very rarely become symptomatic because of their size, and splenectomy is reserved only as a necessary diagnostic maneuver.

Lymphangiomas are benign cystic tumors that are rare and occasionally lead to hypersplenism. They are commonly associated with lymphangioma of the liver and lesions in other parts of the body, including the lung, skin, and bone. Splenectomy is only indicated to alleviate symptoms or confirm a diagnosis. Other benign tumors of the spleen include lipoma, angiomyolipoma, leiomyoma, hemangioendothelioma, and hemangiopericytoma.

Treatment

Splenectomy is accepted as the surgical procedure for nearly all tumors of the spleen that require treatment. Some small benign lesions might be amenable to partial splenectomy, but for malignant disease, splenectomy is the rule. Several series comparing splenectomy for benign and malignant tumors have shown that splenectomy can be safely performed laparoscopically for malignant disease with similar outcomes.

ABSCESSES

Splenic abscesses are rare, with reported incidence rates after intra-abdominal abscesses of less than 0.5%. In untreated patients, mortality rates can approach 100%; but with appropriate treatment, mortality rates are reduced to only 10% to 15%. Interestingly, recent reports document splenic rupture after intra-abdominal abscess, pelvic abscess, and splenic abscess (see subsequent discussion), which increases mortality.

Most abscesses arise from hematogenous spread from a distant primary septic focus, such as bacterial endocarditis, infected splenic arterial aneurysms, intra-abdominal infections including fecal peritonitis, diverticulitis, appendicitis, pyelonephritis, and direct introduction of bacteria into the bloodstream from intravenous drug use. They may also arise as a secondary infection in a splenic hematoma after a noninfectious embolic event or trauma. Recent reports have

documented splenic abscess after sleeve gastrectomy for bariatric surgery; so, with the increase in upper abdominal gastric surgery, more reports may be seen.

Finally, there can also be direct penetration of the splenic parenchyma from an adjacent intra-abdominal process, such as a perforated ulcer, pancreatitis, or colon cancer. Because of the increased incidence of human immunodeficiency virus (HIV) and more aggressive chemotherapy and immunosuppression for organ transplantation, immunodeficiency has become a more frequent risk factor.

Most patients present with fever, fatigue, abdominal pain, and leukocytosis. Only about half of patients have positive blood cultures. CT scan is the diagnostic procedure of choice; it shows a low-density lesion that does not enhance with intravenous (IV) contrast. The gram-positive aerobic organisms *Staphylococcus* and *Streptococcus* are the most common bacteria cultured. Gram-negative organisms like *Salmonella* are also seen, as is polymicrobial flora. Fungal organisms such as *Candida* and *Aspergillosis* represent approximately 8% of all cases and are more commonly found in patients with immunosuppression.

Splenic Rupture

Recent reports of splenic rupture have followed not only abscesses or infarcts but also colonoscopy. So, the presentation of a patient with severe abdominal pain, hypotension, and decreased hematocrit should suggest this diagnosis. These patients also present with nausea, emesis, and dizziness (Figure 2).

Splenic rupture after chemotherapy for hematologic disease has also been observed (Figure 3).

Splenic Infarct

Splenic infarction can occur after upper abdominal surgery such as pancreatectomy, bariatric surgery, splenic torsion (e.g. the wandering spleen), and sepsis. Spontaneous infarction has been associated with collagen vascular diseases, sarcoidosis, and, of course, chronic autoinfarction in sickle cell disease. Recently, a number of patients have been reported with acute splenic infarction after high-altitude travel (e.g., airplane); they are typically carriers of the sickle cell trait (Figure 4). Hypoxemia of altitude is believed to induce sickling and infarction. Although typically limited to only portions of the spleen and with a benign course, acute infarction as depicted can require surgery.

Treatment

Splenectomy is the definitive treatment for splenic abscesses. Treatment with IV antibiotics remains a cornerstone of treatment as well. Broad-spectrum antibiotics should be used once the diagnosis is made until the regimen can be tailored to specific culture data. Percutaneous aspiration can be used to direct antimicrobial therapy. Percutaneous drainage is increasing in popularity as a treatment option and is safe in carefully selected patients. Failure rates for percutaneous drainage range from 50% to 60%, and patients require lengthier hospital stays. It should be reserved for patients unable to tolerate surgery or as a temporizing measure for patients needing stabilization. Despite the rarity of these lesions, several series have shown that splenectomy can be done laparoscopically in this cohort of patients. The authors typically begin laparoscopically to perform an "intact" splenectomy, but many times the abscess is entered during surgery and easily drained with the laparoscopic suction. One can expect the patients to need intensive monitoring after surgery, both for infection and bleeding. Use of energy sources such as described earlier and argon beam electrocoagulation make surgery more straightforward.

Treatment of splenic rupture can also be performed laparoscopically; the authors' preference is with hand-port assistance. However, the open technique still gives the best exposure, control of vessels, lavage, and drainage.

When no tumor is present or a benign process is suspected, the spleen can be removed from a laparoscopic port with morcellation.

OVERWHELMING POSTSPLENECTOMY SEPSIS

Splenectomy increases a patient's risk for routine bacterial infection and, more importantly, overwhelming systemic sepsis usually associated with gram-positive encapsulated organisms. The incidence rate of overwhelming postsplenectomy sepsis (OPSS) is highest in children, as high as 4%, but adults are also considered to be at risk. The mortality rate of OPSS is approximately 50%. Vaccinations against *Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria* meningitis should be given 2 weeks before surgery. If this is not possible, vaccination should be delayed until 2 week after surgery. Given that the highest incidence of overwhelming postsplenectomy sepsis has been shown to be in the first year after splenectomy, some advocate providing low-dose prophylactic penicillin to patients at high risk in the first year after operation.

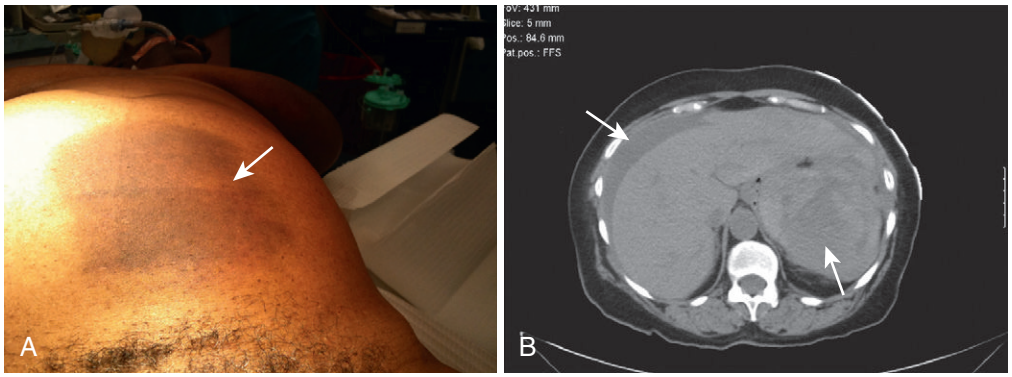

FIGURE 2 Splenic rupture after colonoscopy. This 55-year-old patient was seen 24 hours after colonoscopy with abdominal pain, hypotension, and decreased hematocrit values. **A,** She presented with a Cullen's sign; and **B,** computed tomographic scan showed ruptured spleen *(bottom arrow)* and hemoperitoneum *(top arrow)*. Open splenectomy was performed, and the patient was discharged from the hospital within 1 week. *(Photographs courtesy of Lisa Dresner, MD.)*

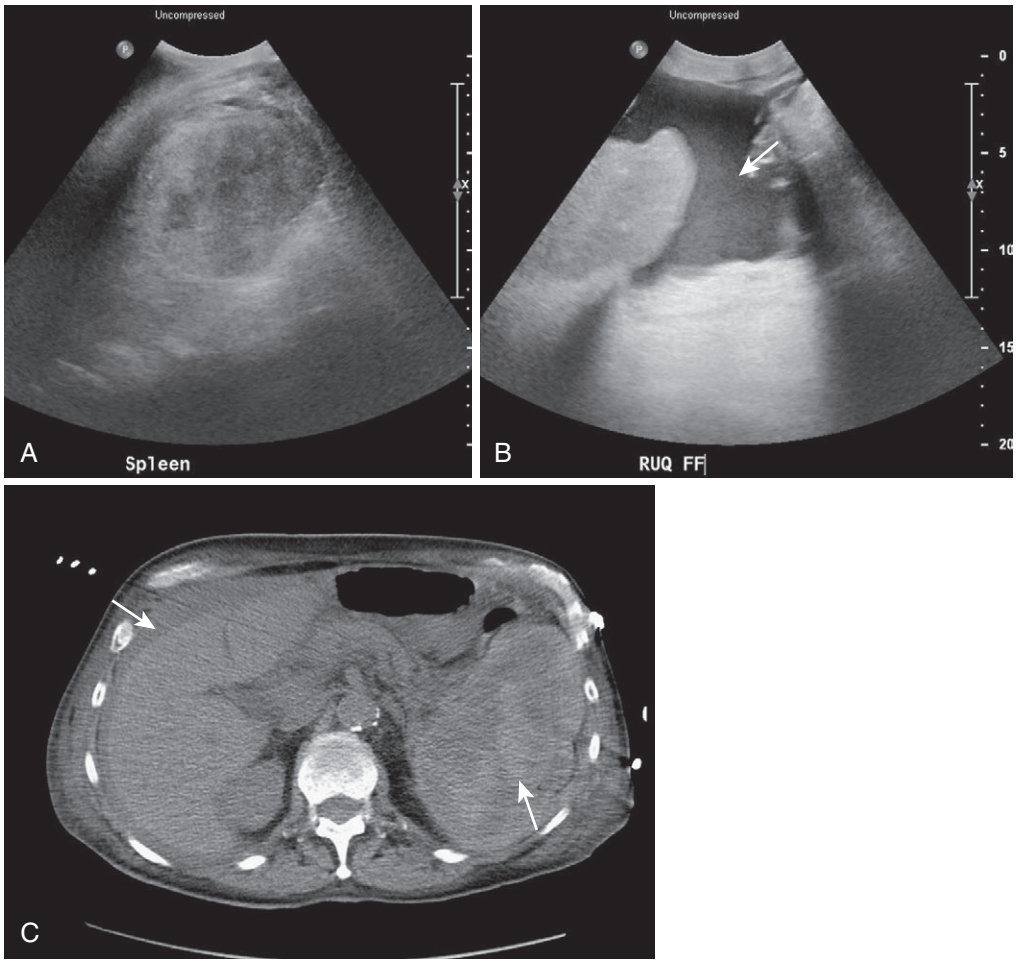

FIGURE 3 A 73-year-old patient presented with syncope, hypotension, and acute anemia 2 weeks after completing chemotherapy for appendiceal B-cell lymphoma. A computed tomographic (CT) scan 2 days before presentation was normal. After presentation to the emergency room, Focused Abdominal Sonography for Trauma (FAST) showed: **A,** splenic parenchymal disruption; and **B,** free fluid in the abdomen around the liver. **C,** CT scan showed the same. Emergency surgery confirmed ruptured spleen *(Photographs courtesy of Enrique Daza, MD.)*

Splenic Salvage Procedures: Therapeutic Options

Hadley K. H. Wesson, MD, MPH, and Kent A. Stevens, MD, MPH

The management of splenic injury in the setting of trauma has changed over the past five decades and continues to evolve as our understanding of therapeutic options improves. Since the 1960s, we have shifted from an era in which blunt splenic injuries in both adults and children were treated with splenectomy to an era in which nonoperative management (NOM) has become the dominant modality for splenic salvage.

The advantage of splenic salvage arises from concerns regarding risks associated with the asplenic state, including overwhelming post-splenectomy infection, a well-known but rare complication. While the focus of this chapter is on splenic salvage methods, including NOM, splenorrhaphy, and partial splenectomy, the role of definitive operative management with splenectomy in the hemodynamically unstable patient with splenic injury cannot be overemphasized.

NONOPERATIVE MANAGEMENT

Selective NOM of blunt splenic injuries in children has been practiced for more than four decades, first described in 1968 by Toronto's Hospital for Sick Children as an alternative to splenectomy in hemodynamically stable children. Despite the acceptance of this approach within the pediatric population, there was initial reluctance to adapt this to the adult population. Considerable advancements have since occurred. The American Association for the Surgery of Trauma developed the Organ Injury Scale for the spleen to aid in therapeutic and research decisions (Table 1), and computed tomographic (CT) sacn for blunt injury has become the standard of care. By the mid-1990s, NOM in the adult population had increased fivefold.

As NOM continued to develop as a mainstay option, surgeons sought to determine appropriate candidates for NOM. NOM was attempted for clinical conditions in which it was previously contraindicated, including hypotension responsive to fluid, high-grade splenic injury; neurologic impairment; a requirement for more than 2 units of blood; immunologic disease; and advanced age. While some conditions were associated with poor outcomes, others appeared acceptable. The need for a clear and standardized approach to NOM prompted the Eastern Association for the Surgery of Trauma (EAST) to generate evidence-based guidelines regarding NOM in 2003 and subsequently updated in 2011 (Table 2). As a result, today between 53% and 77% of patients with blunt splenic injury are managed nonoperatively.

Guidelines for Nonoperative Management

Patients with blunt splenic injuries must meet five criteria to be considered for NOM: (1) hemodynamic stability; (2) CT documentation and classification of the injury; (3) absence of intra-abdominal or retroperitoneal injuries mandating operative intervention; and (4) transfusion of fewer than 2 units of packed red blood cells (pRBC); and (5) be managed in a hospital facility that can provide continuous monitoring and serial exams. Exclusion criteria include patients in whom coagulopathy cannot be reversed and patients who must receive urgent anticoagulation therapy, such as in the setting of a vascular injury requiring anticoagulation.

The 2011 EAST guidelines use level II evidence to recommend that in a hemodynamically stable patient, the severity of the splenic injury (according to the grade of the injury or degree of hemoperitoneum), and age are not contraindications for NOM. The guidelines also state abdominal CT scan is the most reliable method to identify and assess the severity of the injury to the spleen in hemodynamically stable patients.

Approach to Nonoperative Management

An approach to management of splenic injuries is illustrated in Figure 1. The first step in deciding to pursue NOM is determined by the patient's hemodynamic stability. Thus it is important to establish standardized definitions and degrees of hemodynamic instability. In an effort to address this, the Western Trauma Association proposed a scoring system in 2006 to improve management and consistency of definitions of hemodynamic stability:

- *Grade 0*: No significant hypotension (systolic blood pressure < 90 mm Hg) or serious tachycardia (heart rate > 130 beats/minute)
- *Grade 1*: Hypotension or tachycardia by report but not reported in the emergency department
- *Grade 2*: Hypotension or tachycardia responsive to initial volume loading with no ongoing fluid or pRBC requirement
- *Grade 3*: Hypotension or tachycardia responsive to initial volume loads with modest ongoing fluid (<250 mL/hr) or pRBC transfusion
- *Grade 4*: Hypotension or tachycardia only responsive to more than 2 liters of volume loading and the need for vigorous ongoing fluid infusion (>250 mL/hr) and pRBC transfusion
- *Grade 5*: Hypotension unresponsive to fluid and pRBC transfusion

This scoring system can guide further management. For patients who are hemodynamically unstable on initial presentation, remain unstable despite fluid administration (e.g., grade IV or V), and have a positive result from a focused assessment with sonography for trauma (FAST) examination, emergent operative management and splenectomy are necessary. For patients whose FAST exam result was negative but who are hemodynamically unstable, intra-abdominal hemorrhage and operative intervention should be promptly initiated.

For hemodynamically stable adult patients with an isolated blunt splenic injury, NOM is currently the standard of care. NOM in adults is attempted in approximately 85% of all patients with blunt splenic injury. Failure rates are dependent on the grade of the injury and range from 8% to 38%. The optimal success rate of NOM is achieved when CT scanning is combined with serial clinical examinations. Patients should be actively observed with serial physical examinations, continuous monitored vital signs, and serial hemoglobin levels. During this period of active observation, if patients become hemodynamically unstable, need 2 or more units of blood, or develop peritonitis, emergent splenectomy is indicated. If the patient is stable, a repeat CT scan should be obtained. If the CT scan shows a larger hemoperitoneum or active bleeding, the patient should be taken to the operating room.

Role of Angioembolization

If the initial abdominal CT scan shows evidence of ongoing bleeding, splenic angiographic embolization (SAE) should be considered. SAE

TABLE 1: Organ injury scale for the spleen by the American Association for the Surgery of Trauma

Grade	Injury type	Description of injury
I	Hematoma	Subcapsular, nonexpanding, <10% surface area
	Laceration	Capsular tear, nonbleeding, <1 cm parenchymal depth
II	Hematoma	Subcapsular, nonexpanding, 10%–50% surface area; intraparenchymal, <5 cm in depth
	Laceration	Capsular tear, active bleeding, 1–3 cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma with active bleeding; intraparenchymal hematoma ≥ 5 cm or expanding
	Laceration	>3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar vascular injury with devascularized spleen

TABLE 2: Criteria for nonoperative management of blunt splenic injury

1. Hemodynamic stability
2. Documented computed tomographic classification of injury
3. Absence of additional injuries requiring operative intervention
4. Transfusion of fewer than 2 units of packed red blood cells

Source: East Associated for the Surgery of Trauma (EAST) AdHoc Committee on Practice Management Guideline Development. Non-operative management of blunt injury to the liver and spleen 2003. Available at: http://east.org.tpg.

is an adjunct in NOM. Based on level II evidence, EAST guidelines suggest SAE is appropriate in hemodynamically stable patients with CT scan findings of contrast extravasation, pseudoaneurysm or arteriovenous fistula, moderate hemoperitoneum, high-grade injury (grades IV–V), or persistent splenic bleeding..

A 2004 multicenter study by the Western Trauma Association showed the grade of splenic injury was the strongest predictor of successful SAE. More than 90% of patients with grade III splenic injuries and 80% of patients with grades IV and V splenic injuries were successfully managed with SAE. This is significantly higher than NOM success rates that did not use SAE: the 2000 EAST multi-institutional trial found observation alone (i.e. without SAE) had successful splenic salvage rates of only 80%, 66.7%, and 25% for grades III, IV, and V injuries, respectively.

While SAE can extend the application of NOM, the impact of SAE in the algorithmic approach to splenic trauma has not been well studied. Consensus has not been reached on either the indications for embolization or the optimal site (proximal vs segmental) of embolization. In theory, proximal (main) splenic artery embolization enables clot formation by decreasing distal flow into the parenchyma. Through selective distal coil embolization, a catheter is placed over a wire adjacent to the intraparenchymal vascular injuries, which are then embolized with Gelfoam (Pfizer, New York, NY) or a small coil. In practice, proximal embolization appears to be more common than distal embolization.

Complications associated with proximal and distal embolization are under investigation. Current studies show rebleeding following embolization ranges between 4.7% and 9.0%. Perfusion pressure to the spleen can also decrease, and this results in splenic ischemia. While hemostasis can be achieved this way, concerns about splenic function remain, and avoidance of surgical splenectomy may not result in the preservation of a functional spleen. Following proximal embolization, patients may face the same impaired immune response risks and infectious complications as those faced by patients who underwent splenectomy.

Progression of Care

The 2011 EAST Guidelines Update recommend that the need for follow up imaging be based on the patient's clinical status. Patients managed nonoperatively can be discharged in as early as 3 to 4 days. However, guidelines recommending the duration of hospitalization, duration the patient should remain NPO (nothing by mouth), duration of bed rest, initiation of deep venous thromboembolism prophylaxis, and resumption of normal activity have not been established. Surgeons' attitudes and practices regarding these issues have been surveyed. In 2005, 50% of polled EAST members recommended patients with grade I or II splenic injuries return to light normal activity in 2 weeks, while patients with higher-grade injuries wait at least 4 to 6 weeks.

Results of Nonoperative Management

NOM has been highly successful in hemodynamically stable patients. An EAST 2000 multicenter trial showed an 89% success rate of NOM without the use of SAE. More recent studies incorporating SAE as a standard of care show higher rates of success: a recent retrospective review of 398 patients found a 97% success rate of NOM that included SAE in those that qualified. Common causes of failure are bleeding in the first 96 hours, abscess formation, and splenic artery pseudoaneurysm.

OPERATIVE SPLENIC SALVAGE

When the patient's condition necessitates operative intervention, the surgeon should be aware of options to pursue splenectomy versus splenic salvage techniques. Operative splenic salvage should be approached cautiously. It should not be attempted in unstable patients undergoing damage control surgery or patients whose injuries warrant expeditious splenectomy, such as patients with severe head injury. In the author's experience, splenorrhaphy and partial splenectomy is relatively infrequent: in the past 5 years at the Virginia Commonwealth University Medical Center's level I trauma center of the 683 splenic injuries, 158 were managed operatively, of which 146 were managed with splenectomy, 12 were managed with splenorrhaphy, and none were managed with partial splenectomy.

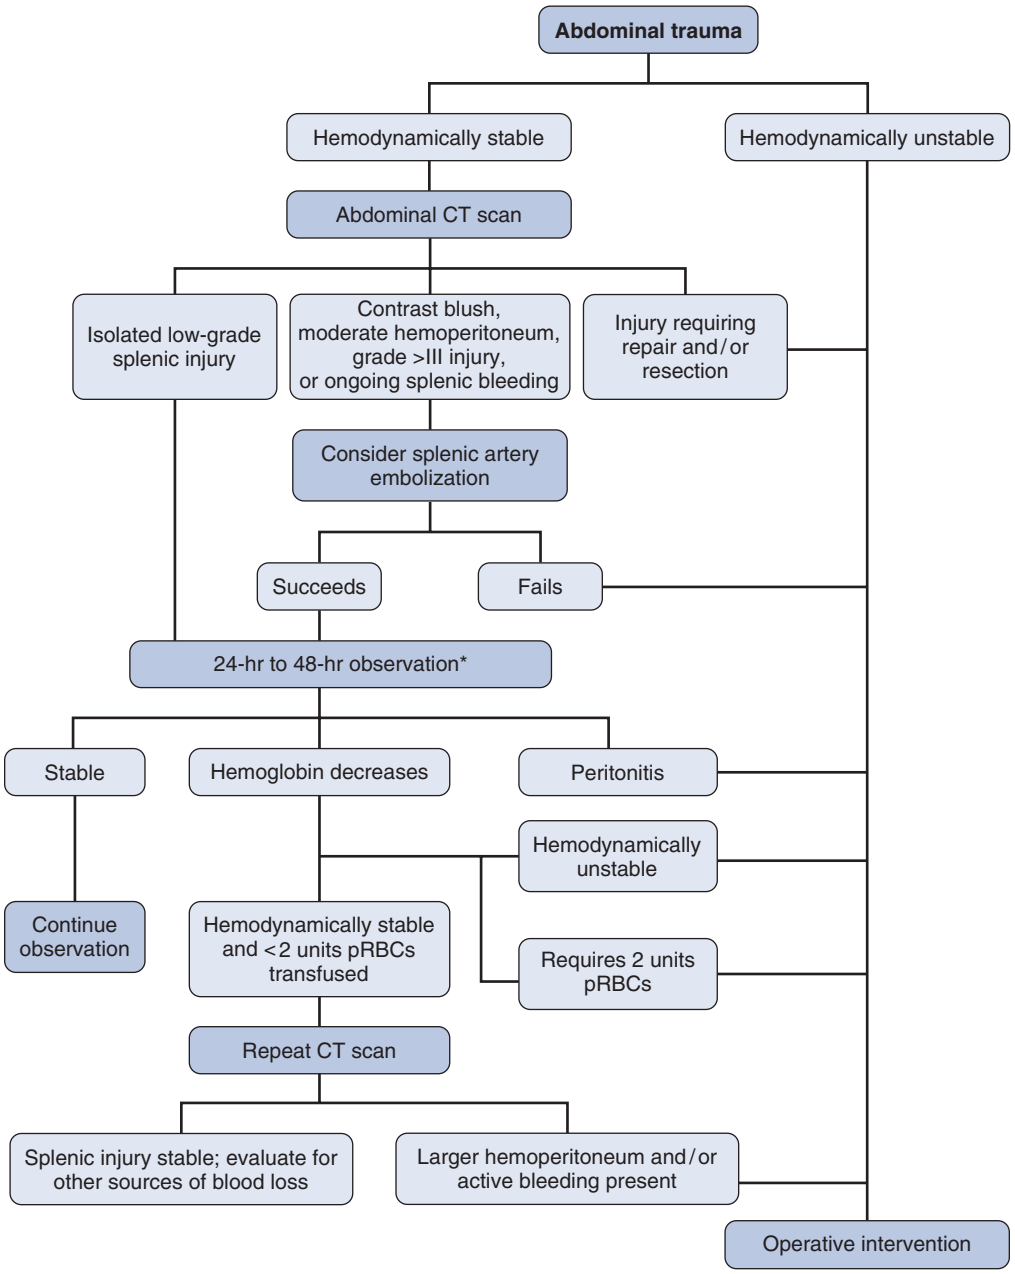

FIGURE 1 Algorithmic approach to the management of traumatic splenic injury. *CT,* Computed tomographic; *pRBCs,* packed red blood cells.

Operative management should be performed through a midline incision. The abdomen should be thoroughly examined to evaluate for other intra-abdominal injuries. To visualize the extent of splenic injury, adequate exposure and mobilization are mandatory. Dividing the avascular lienophrenic, lienorenal, and lienocolic ligaments allows the spleen to be mobilized from the retroperitoneum. The lesser sac is entered by removing the omentum from the left transverse colon. If the only injury is to the spleen and the patient is hemodynamically stable, splenic splenorrhaphy or partial splenectomy can be considered.

Splenic Splenorrhaphy

Small capsular tears may be managed with argon beam coagulation, an electrocoagulation system that achieves hemostasis using inert gas as a medium to conduct radiofrequency energy. Hemostasis can also be achieved using hemostatic agents such as microfibrillar collagen (Avitene; Davol, Cranston, RI), absorbable gelatin sponge (Gelfoam, Pfizer, New York, NY), or methylcellulose (Surgicel; Johnson & Johnson, New Brunswick, NJ). Deep lacerations can be repaired by placing horizontal mattress sutures using a 2-0 synthetic monofilament such as Prolene (Ethicon, Piscataway, NJ). Sutures can be placed either directly or over Dacron strips or pledgets (Invista Inc, Wichita, Kans) (Figure 2). Omentum can also be placed into the laceration to act as a hemostatic agent before approximating the defect with mattress sutures.

A technique that is occasionally applicable to patients with macerated splenic injuries not amenable to hemostatic agents or suture splenorrhaphy is to use a mesh wrap. Once the spleen is mobilized, a sheet of synthetic absorbable polyglycolic mesh is wrapped around

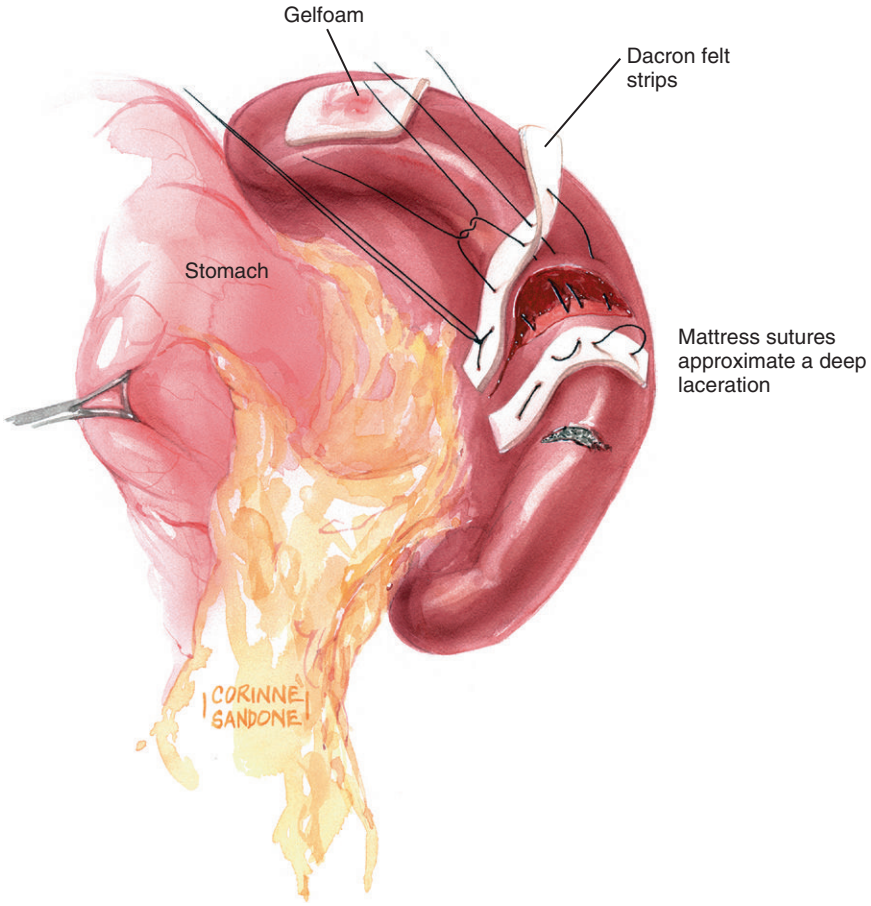

FIGURE 2 Horizontal mattress sutures with Dacron strips approximate the laceration. *(From Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *2nd ed, vol 2, 2013; used with permission from PMPH-USA, Shelton, Conn.)*

the spleen and gathered at the hilum, where a purse string suture is placed, thereby compressing the spleen to achieve hemostasis. Care should be taken to ensure the vasculature at the hilum is not compressed.

Partial Splenectomy

If the splenic laceration is more substantial and extends into the splenic hilum, maneuvers to control hemorrhage and preserve the spleen in its entirety may not be adequate. In such cases, a partial splenic resection can be performed by removing the nonsalvageable portion of the spleen. A partial splenectomy may be performed if ligating of a branch of the splenic artery results in significant hemostasis and at least half of the splenic parenchyma attached to an identifiable vessel is viable.

Manual compression of the spleen with a Mikulicz pad and/or temporarily cross-clamping the splenic hilum with a DeBakey bulldog clamp may be required to control the bleeding laceration. After the bleeding from the laceration has been controlled, the omentum can be divided anterior to the splenic hilum and the short gastrics ligated. By exposing the spleen, the extent of the splenic laceration and involvement of the splenic hilum can be assessed (Figure 3). The branch of the splenic artery feeding the lacerated pole is ligated and divided. The corresponding splenic vein branch is likewise ligated and divided (Figure 4). The residual splenic parenchyma is then divided with electrocautery, and the resected margin of the spleen can be oversewn using mattress sutures with Dacron stripes or omentum.

RECOMMENDATIONS

Careful selection, CT scan imaging, and serial clinical examinations are crucial to the successful NOM of patients with blunt splenic injuries. The use of angioembolization has furthered our ability to salvage a patient's spleen without operative intervention, and angioembolization should be used liberally when indicated and available.

Hernia

Inguinal Hernia

Shirin Towfigh, MD, and Leigh Neumayer, MD, MS

OVERVIEW

Inguinal hernia repair remains the most common general surgical procedure in the United States, with over 800,000 performed annually. It has a long history, and thus a wide variety of techniques have been described. The goals of inguinal hernia repair, however, remain the same for all techniques: to provide long-lasting, secure closure of the pelvic floor defect, reduce pain, and improve quality of life. In modern-day repair, recurrence after hernia repair has remained fairly low. A concerning trend is the increase in chronic pain seen after inguinal hernia repair. Though mesh implantation has been associated with this trend, most believe that chronic pain is a result of surgical technique, difficulty with identification of hernia anatomy, and other unknown patient factors. In this chapter, we review diagnosis of inguinal hernias among adults, common procedures for inguinal hernia repair and their expected outcomes, and the issue of chronic postinguinal herniorrhaphy pain.

DIAGNOSIS

Patients with inguinal hernias may present with complaints of a painless bulge, pain in the groin without a bulge, or some variation in between. It is very important to accurately document the preoperative symptoms and confirm that they are consistent with an inguinal hernia. Some patients may have other causes for their symptoms, such as epididymitis, testicular pain, or endometriosis. Symptoms from an inguinal hernia may include a burning or pinching sensation in the groin. The pain may radiate into the scrotum, labia, or vagina, down the leg, or around the back. They may have worsening pain with prolonged sitting, prolonged standing, bending, coughing, straining, getting out of a car, or toward the end of the day. Lying flat almost always results in improvement of their symptoms. Women may also report worse pain during their menses. Obstructive symptoms may include bloatedness, nausea, and vomiting.

Inguinal hernias are most commonly seen in men and are of the indirect type—that is, the result of a patent processus vaginalis. These hernias typically present with a bulge in the groin that may extend into the scrotum or labia. A less common variant, an interstitial hernia, dissects within the oblique muscle layers and presents with an oblong bulge extending superolaterally. Direct hernias are a result of weakness in the transversalis fascia and are more commonly seen in older males. Femoral hernias are rare and typically seen in women, as their pelvis is broad and the femoral space is wider. This compares to the narrow pelvis of males where the myoaponeurosis attaches at a different angle, resulting in downward forces merging onto a larger myopectineal orifice of Fruchaud (Figure 1).

Hernia development is considered to be due to genetic factors as well as acquired factors. Patients with inguinal hernias have been shown to have a higher proportion of immature type III collagen as compared to type I collagen. Patients with a family history of hernia are four times more likely to have an inguinal hernia. Medical diseases that have been associated with a higher risk of inguinal hernia include aneurysmal disease, other collagen disorders, hiatal hernia, and sleep apnea. In addition, it is commonly believed, though never scientifically proven, that increases in abdominal pressure contribute to the development of hernia. Such activities include straining due to constipation or prostatic hypertrophy, chronic cough or clearing of the throat, and heavy lifting as part of a daily job. Exercise has been shown to have a protective effect on hernia development. It is important to control for these risk factors preoperatively in order to improve outcomes after hernia repair.

Diagnosis of a hernia is based primarily on physical exam. The patient is examined in the standing position to allow for gravity to accentuate any findings. Standing alone may demonstrate a bulge, and attempts should be made to reduce it. In men, the examiner's digit is used to follow the spermatic cord cephalad into the inguinal canal by using the redundancy of the scrotal skin. There, the internal ring may be entered, and also the direct space can be examined for weakness. A cough or valsalva by the patient may be necessary if the initial exam is not diagnostic. The femoral space is examined by pressing medially in the groin just cephalad to the pubic bone. In women, the inguinal exam is often not as obvious, because many do not have a palpable bulge, defect, or reducible mass. If that is the case, the examiner may be able to elicit pain while pressing at the internal ring. This is suggestive of a hernia as the cause of the patient's pain, and further workup may be necessary. Femoral hernias, when palpable on examination, present as bulges below (caudad) the inguinal ligament. The bulge can be found just medial to the femoral pulse and frequently feels like a lipoma or lymph node. The differential diagnosis for a mass in this location must include femoral hernia.

If the exam is suggestive of a hernia, such as pain or mild fullness at the internal ring, without palpable mass or defect, and the history is also suggestive of a hernia, then radiologic studies may be considered before proceeding to surgery. These include ultrasound, herniogram, computed tomographic (CT) scan, or magentic resonance imaging (MRI). All of these studies can be performed in dynamic mode, with valsalva, to accentuate small hernias.

INGUINAL HERNIA REPAIR

Repair of the inguinal hernia should be timed to provide the most benefit to the patient and the least risk from the procedure. It was considered at one time that all inguinal hernias should be repaired

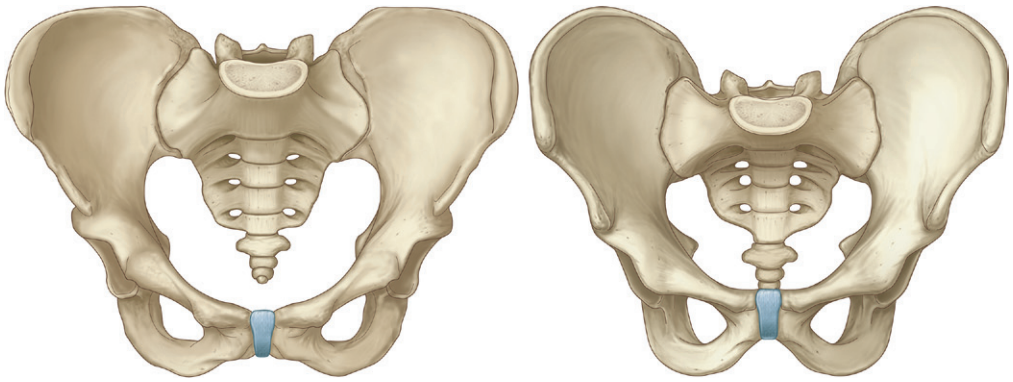

FIGURE 1 Female pelvis (left) and male pelvis (right). *(From Drake RL, Vogl AW, Mitchell AWM, et al:* Gray's atlas of anatomy, *Philadelphia, 2007, Churchill Livingstone.)*

to reduce the morbidity and mortality associated with potential incarceration or strangulation. Based on two prospective clinical trials in men with asymptomatic or minimally symptomatic inguinal hernias, the option of watchful waiting has been shown to be of low risk. In one trial, the risk of incarceration among patients randomized to the watchful waiting arm was calculated as 0.18% per year. No patient had a strangulated hernia during the trial period (2-4.5 years). In the second trial, only males age 55 and over were enrolled. Among this population, patients in the watchful waiting trial were more likely to suffer from a debilitating medical complication such as stroke or heart attack, thus rendering them poor candidates for elective inguinal hernia repair in the future. However, there were no hernia-related complications during the watchful waiting period. A commonly accepted practice now is to offer elective inguinal hernia repair to patients physically fit for surgery and to patients with symptomatic inguinal hernias. The timing of the repair is rarely urgent unless there is a known incarceration episode. In those at higher risk for perioperative complications or for minimally symptomatic patients not wishing to undergo repair at this time, watchful waiting is considered a safe option.

Femoral hernias, unlike other inguinal hernias, are associated with a much higher risk of incarceration or strangulation. One third of all femoral hernias are repaired emergently, compared to 6% of all inguinal hernias. Thus, repair is recommended for all patients with femoral hernias.

Tissue Repair

The technique of nonmesh or tissue repair dates back to ancient Egypt. Hundreds of techniques have been described since. Though mesh repair has become the standard in the United States, tissue repair remains the primary technique across the world and is growing in its application in the United States due to the increased concern with chronic pain. Tissue repair is considered to be superior to mesh repair in terms of chronic pain, though most studies show that acute postoperative pain and hernia recurrence are significantly worse when mesh is not used. Tissue repair is indicated for patients at risk for mesh infection, such as with a strangulated hernia requiring bowel resection. Also, it should be considered for patients at higher risk for chronic pain, such as women and those who present with a history of chronic pain.

The type of tissue repair and its outcome is dependent on technique and surgeon experience. No single technique is considered to be superior. The surgeon should be familiar with at least one or two techniques and perfect them in order to have the best outcome. All tissue repairs share a similar concept: closure of the defect and reinforcing the pelvic floor. A relaxing incision is often incorporated to reduce the tension on the repair. Repairs are performed with permanent suture.

The Marcy repair is a primary closure of the internal ring defect alone, without any further reinforcement of the pelvic floor. It is most often used for children because the recurrence rate is considered too high among adults.

The Bassini and McVay repairs involve opening the pelvic floor transversely and reducing all preperitoneal contents and the hernia sac back into the abdominal cavity. It is not necessary to resect the hernia sac if it can be successfully reduced. For the Bassini repair, one reapproximates the tissues by sewing the conjoint tendon to the inguinal ligament. For the McVay repair, the conjoint tendon is sutured to Cooper's ligament, thus patching the femoral space as well. Then, at the level of the femoral vein, a transition suture is used to continue the approximation from the conjoint tendon to the inguinal ligament. The suture line for both repairs starts medially at the anterior rectus fascia overlying the pubic tubercle and ends laterally at the internal ring. Suturing is in interrupted fashion using permanent suture. Care must be taken not to entrap the ilioinguinal, iliohypogastric, and genitofemoral nerve branches. The external oblique is then closed over this repair.

The Shouldice repair involves step-by-step layered closure of the pelvic floor. Pelvic floor dissection is similar to the Bassini and McVay (Figure 2, *A*). Classically, the cremasteric muscle is resected, including the genital branch of the genitofemoral nerve. For the hernia repair, starting medially at the pubic tubercle, the lower edge of transversalis fascia is sutured in running fashion to the underside of the upper edge, with partial thickness bites of the transversus abdominis and internal oblique (Figure 2, *B*). This continues laterally. At the internal ring, the proximal stump of cremasteric muscle enveloping the spermatic cord is included, and the suture line is reversed (Figure 2, *C*). In this second suture line, full-thickness bites of the upper edge of the transversalis fascia is sutured to the inguinal ligament below (Figure 2, *D*). Once completed medially, this suture end is tied to the tail of the first suture line. The third suture line begins laterally at the internal ring. The external oblique just above the inguinal ligament is sutured to partial-thickness bites of the internal oblique from the superior flap (Figure 2, *E*). This is continued medially toward the anterior rectus fascia overlying the pubic tubercle and reversed for the fourth and final suture line, which involves another layer of external oblique from the lower edge sewn to the internal oblique of the superior flap (Figure 2, *F*). To prevent ptosis of the testicle, the distal end of the cremasteric muscle stump is sutured to the anterior rectus fascia at the pubic tubercle or included in the external ring closure.

Mesh Repair

The gold standard in the United States involves implantation of mesh. It has been shown to provide a secure repair with little or no tension, as compared with tissue repair. Also, since most patients have

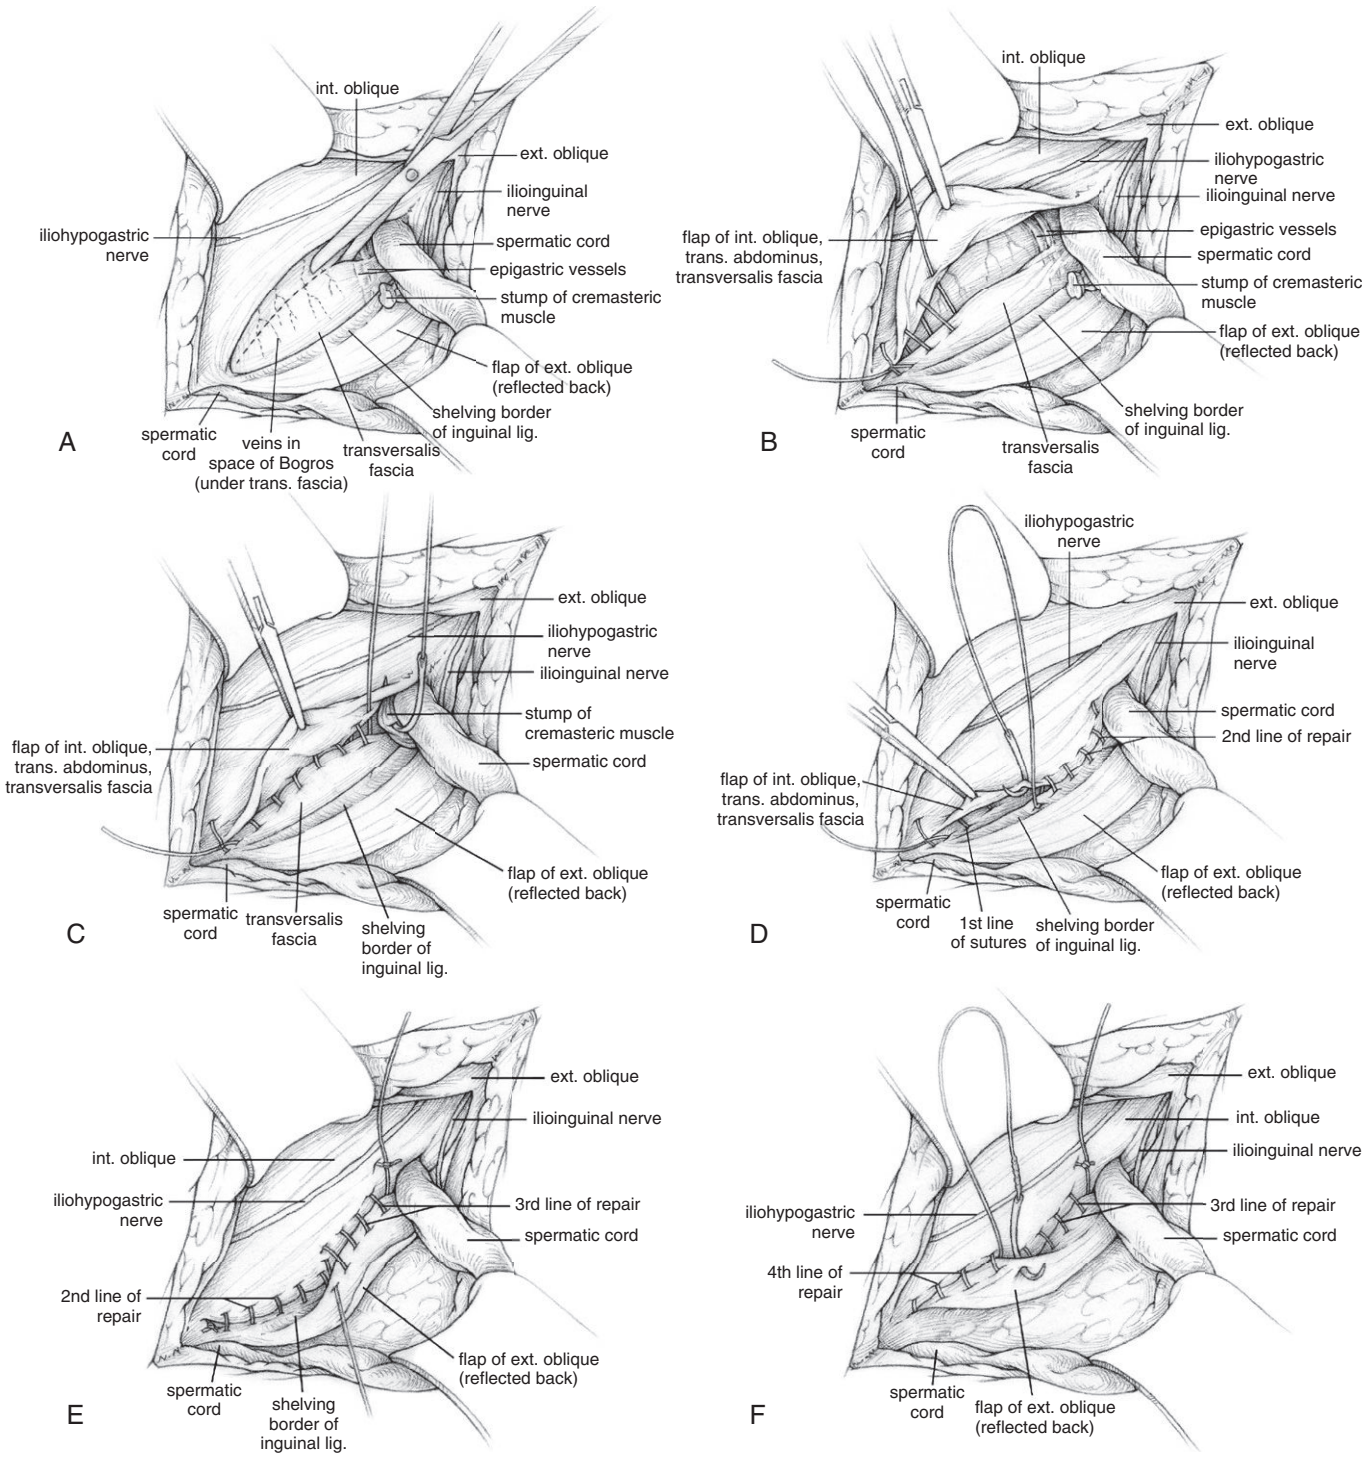

FIGURE 2 Shouldice hernia repair. **A,** Splitting of the transversalis fascia from the internal ring to the pubic crest as far as desired. **B,** First suture line continues to tack the lateral flap of transversalis fascia to the transversalis fascia lying medially beneath the rectus, transversus abdominis, and internal oblique muscles. **C,** Reconstruction of the internal ring incorporating transversalis fascia and the proximal stump of cremasteric muscle. **D,** Second suture line "carrying" the previously established medial flap of tissue to the curved or shelving edge of the inguinal ligament. **E,** The undersurface of the external oblique close to inguinal ligament is now in this third line of sutures being tacked over the internal oblique. **F,** The fourth line of sutures tacks more of the lower flap of the external oblique over the internal oblique. *(From Shouldice EB: The Shouldice repair for groin hernias,* Surgical Clinics of North America *83:1163–1187, 2003.)*

intrinsically weak pelvic floor tissue or may have a wide defect with absent tissue, the implant can augment the security of repair by bolstering the muscles or bridging the defect. Hernia recurrence rates using mesh implantation are typically under 5% nationally and are reported by experts to be less than 1%. This compares to recurrence after elective tissue repair, which may reach as high as 15% to 20%, depending on the patient characteristics and surgical technique performed. There are a multitude of hernia mesh biomaterials and techniques that have been developed. Outcomes are variable and dependent on surgeon technique and expertise. No single repair is considered to be superior. For the best outcome, it is important that the surgeon be informed about the risks and benefits of each implant and to know the correct surgical technique recommended for the chosen mesh biomaterial.

The onlay patch repair, reported by Lichtenstein and modified by Amid, is one of the most commonly performed inguinal hernia repairs with mesh. After the hernia sac and fat are reduced, flat mesh, 8 × 15 cm or 3 × 6 inches, is sutured in running fashion starting inferomedially at the anterior rectus fascia over the pubic tubercle and continuing along the ilioinguinal ligament, stopping at the internal ring. A few interrupted sutures are placed at the superior edge of the mesh. Care is taken to place sutures only in conjoint tendon and anterior rectus fascia, as the iliohypogastric nerve runs through the internal oblique muscle layer and can be entrapped if sutures are placed through this muscle. A lateral slit in the mesh accommodates the spermatic cord or round ligament. The round ligament can be sacrificed in most women, so a slit may not be necessary. In the Amid modification of this repair, the tails of the mesh are sutured to each other laterally at the level of the inguinal ligament, thus forming a three-dimensional tunnel for the recreated internal ring (Figure 3). This conforms to the contour of the pelvis and has lower risk of ring tightness as compared to the keyhole technique. The lateral tails of the mesh are tucked under the external oblique. For large indirect hernias, some advocate narrowing the internal ring with absorbable suture. For direct hernias, it is recommended to imbricate the redundant transversalis fascia, using absorbable sutures prior to placing the onlay patch.

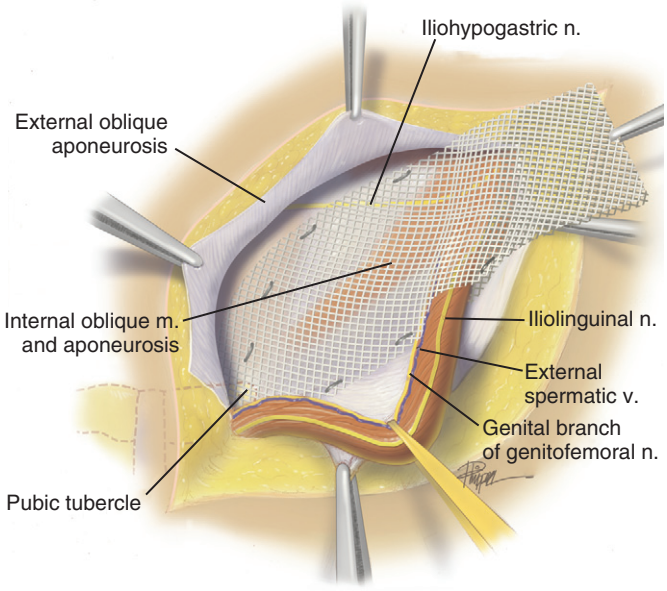

FIGURE 3 Amid modification of Lichtenstein open inguinal hernia repair with mesh. Mesh is sized to overlap with pubic tubercle, inguinal ligament, and conjoint tendon, typically 3 × 6 inches. Note the interrupted sutures or staples placed in conjoint tendon, with care not to entrap iliohypogastric nerve. Laterally, the tails of the mesh are secured to each other and the inguinal ligament with a single suture or staple. *(Image courtesy of PK Amid, MD.)*

The multi-institutional European TIMELI trial compared the traditional Lichtenstein repair with sutures to a similar repair spraying fibrin glue to anchor the mesh. Patients had body mass index (BMI) under 35 kg/m^2 and nonscrotal, nonincarcerated inguinal hernias. Results showed no significant difference in recurrence between the two groups (0.94% overall). The patients with fibrin glue had significantly lower moderate to severe pain or groin discomfort at 12 months (8.1% vs 14.8%). More experience is being gained with nonsuture techniques of mesh repair using tissue glue or implanting self-adhering mesh.

The mesh plug technique was introduced to reduce the amount of dissection necessary and thus reduce postoperative pain. Plugs are variable in their construction. They are typically placed through the defect after highly dissecting out the hernia sac and confirming wide retromuscular dissection free of retroperitoneal fat. Some plugs have an outer leaflet that can be positioned in this retromuscular space, essentially resulting in a small sublay repair. Other plugs are developed as a space occupying implant, thus requiring an onlay mesh repair with a second flat patch of mesh.

The sandwich repair, such as that pioneered by Gilbert, involves a two-layer mesh repair. The anterior leaflet of this mesh is placed as an onlay, similar to the Lichtenstein repair. It may or may not require suturing. Gilbert recommends only an anchoring stitch placed medially. The posterior leaflet of the mesh is placed in the retromuscular, preperitoneal space, providing a sublay repair. With this repair, it is important that the hernia sac is dissected highly and that the retromuscular preperitoneal space is widely dissected free of all fat and adhesions in order to accommodate this mesh.

Since mesh implantation induces an inflammatory process in the groin, chronic pain and postoperative swelling can be greater with this procedure than with tissue repair. Recent studies are suggesting a lower inflammatory response and less postoperative chronic pain and swelling with lightweight mesh biomaterials, defined as weighing less than 40 g/m^2. The recurrence rate of these products may be slightly higher than that of normal-weight mesh, also referred to as heavyweight mesh, defined as weighing 90 g/m^2 or greater. One study reports a 3% absolute increase in hernia recurrence rate when using lightweight mesh.

Laparoscopic repair is growing in popularity as more surgeons are gaining experience with the preperitoneal anatomy and the surgical technique. It has been associated with shorter recovery time and less postoperative pain. The learning curve is high and directly related to outcome. Expert surgeons with experience performing 250 or more laparoscopic cases can provide this repair to their patients with lower complication rates and lower recurrence rates as compared to the open repair. Laparoscopic repair involves dissection of the peritoneal sac and preperitoneal fat from the posterior abdominal wall and pelvic floor. The dissection can be performed totally extraperitoneally (TEP) or transabdominally with a preperitoneal dissection (TAPP). No single technique is considered superior, and the outcome is dependent on surgical technique and surgeon experience. It is important, however, that the surgeon performing the TEP technique also be facile with the TAPP technique, because conversion from TEP to TAPP may be necessary due to adhesions, scarring, large hernia, or other confounding factors.

The principles of laparoscopic technique include safely reducing the peritoneal hernia sac without injuring the external iliac vessels, bladder, or intraperitoneal organs. For this reason, most large scrotal hernias and some incarcerated hernias are not performed laparoscopically. The mesh is placed retromuscularly and extraperitoneally. It is important that the dissection be complete and wide, examining all three potential areas of hernia development in the myopectineal orifice: indirect, direct, and femoral spaces. Also, spermatic cord lipomas should be carefully dissected off prior to mesh placement. This may not be as evident during laparoscopic dissection as with an open dissection. The mesh size used is 10 × 15 cm or 4 × 6 inches.

For most indirect hernias, the mesh can be placed without fixation or with the use of tissue glue alone. For direct hernias, the mesh should provide wide overlap medially and be fixed with permanent fixation. When using a fixation device, care should be taken not to injure the bladder inferomedially; external iliac vessels, genitofemoral nerves, and lateral femoral cutaneous nerves inferolaterally; and the ilioinguinal and iliohypogastric nerves superolaterally.

For patients with large scrotal hernias, with loss of pelvic floor domain, or with bilateral inguinal hernias that are not amenable to laparoscopic repair, the Stoppa repair is a tension-free technique that can offer long-lasting repair. It is also known as a giant prosthetic reinforcement of the visceral sac. Essentially, it is a wide preperitoneal repair that involves implantation of a flat piece of mesh from left to right anterior superior iliac spine in the transverse dimension and from mid-anterior rectus muscle to sacrum in the longitudinal dimension. It can also be modified for unilateral hernias.

CHRONIC POSTINGUINAL HERNIORRHAPHY PAIN

Surgical techniques for inguinal hernia repair have advanced rapidly in the past few decades. With the introduction of mesh implantation in the 1980s, average hernia recurrence rates have dramatically reduced. Recurrence rates are now less than 5% overall and less than 1% as reported by most experts. Thus, most of the efforts toward advancement of hernia repair have been concentrated on developing techniques and biomaterials that reduce operating time, reduce surgical incision length and dissection, and reduce postoperative pain and recovery time.

We are now dealing with the phenomenon of chronic postinguinal herniorrhaphy groin pain, or inguinodynia. Chronic pain, defined as persistent pain lasting longer than 3 months postoperatively, is reported to be 15% to 33%. Three percent of patients suffer from severe debilitating pain. With over 800,000 inguinal hernia repairs performed annually in the United States, a large number of patients are suffering from pain due to their operation. A recent hernia database using the Caroline Comfort Scale for preoperative and postoperative evaluation of patients followed patients for up to 2 years postoperatively. Results showed that young patients and women are at highest risk for chronic pain. It is important to carefully evaluate the symptoms of all patients preoperatively, counsel patients about the risk of chronic pain as part of the informed consent process, and tailor the surgical plan and technique to meet the patient's specific needs.

The four main causes of chronic postoperative pain include hernia recurrence, mesh-related pain, nerve-related pain, and infection. Patients with chronic pain after hernia repair may suffer from one or a combination of these causes.

Hernia recurrence, if not obvious from exam and history, can be confirmed by radiologic studies if necessary. These patients typically complain of recurrence of their preoperative pain. Their pain may be activity-related. The pain is relieved when lying flat. Some may have new pain due to a missed femoral hernia or a new direct inguinal hernia. Repair of the recurrent hernia will treat this problem.

Patients with mesh-related pain may have pain due to a persistent inflammatory reaction to the mesh. In most patients, the inflammation associated with mesh resolves with time. In a small subset, the inflammatory reaction persists, resulting in swelling and chronic pain in the affected area. CT scan or MRI may show an abnormal inflammatory reaction in the groin that is not typical of postoperative changes after mesh repair. In most patients, antiinflammatory treatments such as ice packs, nonsteroidal antiinflammatory medications, or steroid injections may relieve their discomfort. In rare cases, the mesh must be removed.

A more common mesh-related complication is termed *meshoma*, and it is due to the folding or balling of mesh (Figure 4). This is perceived by the patient as a mass in the groin and can sometimes be felt on exam. The patient typically has pain with hip flexion. Activities such as sitting, driving, and bending are uncomfortable. It is not unusual for the patient to prefer to stand or to slouch back when sitting, with ipsilateral leg extended. Radiologic studies may confirm this diagnosis by showing a thickened pelvic floor or a foreign body mass with adjacent mass effect, such as distortion of the bladder. Removal of the mesh is the only treatment for this problem.

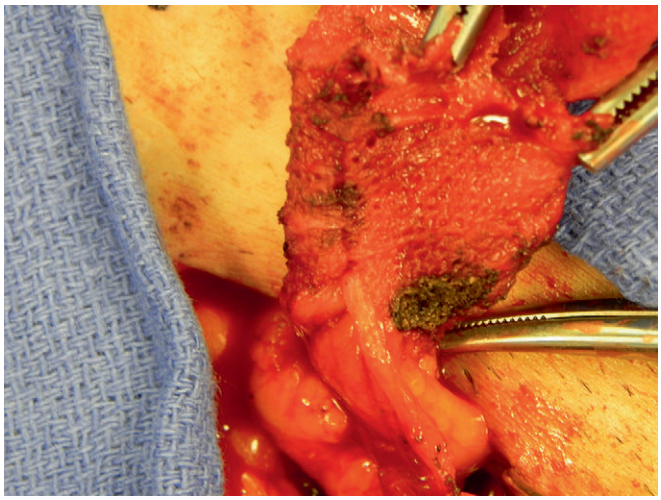

FIGURE 4 Meshoma (ball of mesh) folded, with ilioinguinal nerve entrapped within its fold (at 5:00 position).

Neuropathic pain may be due to direct nerve injury at the time of hernia surgery, ingrowth of the mesh into a nerve, entrapment of the nerve by suture, fixation material, scar tissue or a fold in the mesh (see Figure 4), or impingement on the nerve from the mass effect of a meshoma. These patients typically have a burning pain or electrical shooting sensation in the dermatome of the affected nerve. Any external pressure from belts, jeans, or underpants causes discomfort. Diagnostic testing includes a local nerve block. Treatment may include serial nerve blocks, topical lidocaine patch, nerve ablation, or neurectomy. The mesh may or may not need to be removed.

An active infection of the mesh will present with purulent drainage from the wound or a fluid collection around mesh implant. In some patients, their mesh can be seeded from bacteremia, such as tooth infection. They may present with a chronic infection, resulting in pain and intermittent swelling in the groin. They may also have associated constitutional symptoms such as fever, night sweats, fatigue, or joint pain. Radiologic study may show an inflammatory reaction, thickening of the soft tissue, or a fluid collection with or without gas. Antibiotics alone will improve their symptoms. In most cases, mesh removal is necessary.

Regardless of the cause of the chronic pain, it is important that the surgeon address this issue in a timely manner. Urologists and pain management specialists may also be consulted to help address the patient's needs. Early treatment of the cause of chronic pain provides the best outcome.

Recurrent Inguinal Hernia

Robert Moesinger, MD

INTRODUCTION

Inguinal hernia repair is the most frequently performed operation by general surgeons. An inguinal hernia is present in 4 to 5 million Americans (prevalence rate, 1.5%). The lifetime risk of inguinal hernia is approximately 27% for men and 3% for women. At least 770,000 inguinal hernia repairs are performed in the United States annually. The recurrence rate is relatively low but difficult to pin down because it is nearly impossible to truly follow these patients long term. Many large series of inguinal herniorrhaphy cases show recurrence rates of 1% to 3%. The true lifetime recurrence rate is probably around 5%, but it may be higher. On the basis of that rate, it should be safe to assume that 30,000 to 40,000 inguinal hernia repairs for recurrence are performed annually in the United States. The rate of recurrence after a second inguinal repair is definitely higher and may approach 10%.

Recurrent inguinal hernia, particularly an early recurrence, is frustrating for both surgeon and patient. The inevitable thought that "something went wrong" is present and can be difficult to explain. At the time of repair of the initial hernia, it is important to explain to patients that hernia recurrence is a possibility at any point in their lives.

PREVENTION

Obviously, prevention of recurrence wherever possible is ideal. Classic surgical teaching emphasizes careful handling of tissue and avoiding tension as key aspects of a durable repair. The advent of tension-free repairs, initially via open techniques and now also with laparoscopic techniques, with synthetic mesh to buttress the inguinal floor has clearly improved recurrence rates compared with classic sutured repairs (Bassini's, McVay's, etc). Whether an open anterior repair is superior to a laparoscopic posterior repair remains controversial, and in terms of recurrence rates, the repairs are probably equivalent.

Multiple risk factors for poor healing can lead to hernia recurrence. Diabetes mellitus, wound infection, vascular disease, connective tissue disorders, ascites, and immunosuppression are all implicated in poor wound healing and hernia recurrence. Some evidence shows that family history of recurrent hernia can predispose a patient to recurrence, suggesting genetic wound-healing problems. Obesity is an important risk factor for hernia recurrence because it puts increased tension on the repair. Glucocorticoids clearly interfere with wound healing by suppressing the inflammatory response. Wherever possible, risk factors should be identified and minimized before elective hernia repair. For example, patients with chronic renal failure who are treated with peritoneal dialysis can be converted to temporary hemodialysis for hernia repair and the early postoperative period. Tapering of glucocorticoids, better diabetes control, and other methods may help obtain a more durable repair.

Smoking is a particularly important risk factor in hernia recurrence. Smoking clearly interferes with collagen synthesis and alters extracellular matrix proteins. Smoking also causes tissue ischemia. Perhaps the worst effect of smoking is the smoker's cough. The Valsalva maneuver associated with coughing creates a large amount of tension on the abdominal wall, and with a smoker's cough, this tension is applied constantly to the fascia every day that the patient continues to smoke.

Technical problems that can result in hernia recurrence include: (1) failure to notice an indirect hernia when a direct hernia is repaired or inadequate dissection and reduction of an indirect sac, (2) failure to notice a direct hernia when an indirect hernia is repaired, (3) excessive tension on the suture line of a sutured primary repair, (4) failure to adequately reinforce the inguinal canal at its most inferomedial portion, leading to the classic medial recurrence, near the pubic tubercle, and (5) failure to seat the mesh correctly during a laparoscopic repair, allowing recurrence through the unprotected portion of the inguinal floor.

ANATOMY

Recurrent hernias are most common direct hernias through the transversalis fascia, which is the floor of the inguinal canal. The classic recurrence seen in the era of open suture repair is in the inferomedial portion of the inguinal floor near the pubic tubercle. This can still happen with mesh repair, if the mesh is not seated and secured into the pubic tubercle. However, recurrences at many places in the inguinal floor have been seen, including quite laterally, near the internal ring, lateral to the edge of a previous mesh repair, and even lateral to the iliofemoral vessels.

In a recurrent hernia, particularly after multiple recurrences, exact anatomic structures can become nonexistent, and even the spermatic cord may be unrecognizable. In these cases, intraoperative palpation usually reveals the defect in the inguinal floor that requires repair. If the patient is awake, having the patient bear down or cough can help pinpoint a defect. In particularly perplexing cases, laparoscopy can be used to directly visualize the inguinal region and find elusive defects.

DIAGNOSIS

Like primary hernias, the hallmark of recurrent inguinal hernia is a bulge in the groin, usually over the pubic tubercle and often

extending down into the scrotum. The degree of symptoms varies from none to severe. Distinguishing recurrent hernia from chronic inguinodynia is important. As more patients undergo groin surgery for hernias, it has become very clear that a certain number will develop chronic groin pain. This is often described as a "twinge" or "an electric shock" that begins in or near the scar and goes onto the lateral scrotum or medial thigh. It is often triggered by certain movements or activities. The frequency can vary from occasional to multiple times a day. It is often very aggravating, but it is not associated with a bulge on the affected side. Its cause is sometimes difficult to determine. Some patients clearly develop pain from an ilioinguinal neuroma or entrapment, and in others, the pain is secondary to chronic groin strain.

Physical examination in these patients reveals no evidence of a hernia, but often a trigger point can be identified that reproduces the pain when it is palpated. These patients should have a hernia excluded with imaging, and then a variety of medical therapies can be helpful. Fortunately, this chronic inguinodynia often resolves over time; reassuring the patient that there is no recurrence and that nothing is seriously wrong is often adequate therapy. The first therapy of choice after exclusion of hernia is injection of the trigger point with a mixture of 9 mL of 0.25% bupivacaine and 1 mL (40 mg) of depo-methylprednisolone. This injection provides long-term relief surprisingly often and can be repeated as needed, or referral for a more permanent nerve block can be made. Neuromodulators like gabapentin (Neurontin, Pfizer, New York, NY) or amitriptyline can be helpful. Some patients, particularly those with complicated worker's compensation issues, benefit from referral to a chronic pain specialist. In some cases, groin exploration with section of the ilioinguinal nerve can provide good pain relief, but this is generally a last resort.

Imaging of the groin in cases where the diagnosis of recurrence is unclear can be helpful. Computed tomographic scan can show a defect in the fascia or a knuckle of bowel or fat in the inguinal canal. Ultrasound scan is useful, but sensitivity varies with experience and skill of the ultrasonographer. Ultrasound scan of the groin with the patient supine, then standing, and then during a Valsalva maneuver can show evidence of very small defects in patients with groin pain but no obvious bulge.

The most accurate (and most invasive) imaging is diagnostic laparoscopy, which has been used in particularly perplexing cases and frustrated patients to definitively rule in or out an abdominal wall defect. This has the advantage of allowing one to look at the entire abdominal wall; if found, the hernia can be fixed at the time of laparoscopy. This is a great tool in patients who are difficult to examine, like the obese patient.

PATIENT PREPARATION

As with all surgery, adequate patient preparation helps to obtain a superior result. The surgeon needs to look for causes of the recurrence and try to eliminate risk factors where possible. Smokers should be strongly encouraged to quit before repair of recurrent hernia. Male patients need to be told that there is a higher risk of damage to cord structures during recurrent repair than during primary repair with resultant testicular atrophy. The likelihood of damage to the ilioinguinal nerve is also much higher during recurrent repair. Perhaps the most important point of discussion is informing patients that the risk of another recurrence after the second repair is not trivial, even if an excellent technical result is achieved. For these reasons, the author does not try to convince the hesitant patient with an asymptomatic recurrence to have another repair. Waiting until the patient is symptomatic, or the hernia exhibits a substantial growth rate, is acceptable and safe, particularly in elderly patients. Good studies show that the rate of strangulation of inguinal hernia is less than 1% per year.

ANESTHESIA

General, regional, and local anesthesia with sedation are all acceptable for recurrent hernia repair. The patient, when awake, is able to cough to help locate a defect and to ensure it is adequately closed. Laparoscopic repair inevitably requires general anesthesia. Large recurrences should probably not be attempted with local anesthesia because it usually proves inadequate.

REPAIR OPTIONS

Emergent

Fortunately, recurrent groin hernias rarely present as an emergency. Even when the hernia is incarcerated, the neck of the hernia is usually generous and strangulation is extremely unusual. Acutely incarcerated hernias often spontaneously reduce at the induction of anesthesia. They can then be repaired normally. These patients need to be closely watched after surgery to ensure that there is no resultant damage to the bowel. Alternatively, transinguinal laparoscopy has been performed to look at the bowel and ensure its viability after it has spontaneously reduced from incarceration.

True strangulated hernias require resection of the affected bowel, and this is usually done via a laparotomy incision, often in addition to the groin incision. There is no role for synthetic mesh in this situation. The hernia defect can be loosely "closed" from the inside to prevent reincarceration with definitive repair at some future time if necessary.

Laparoscopic

Laparoscopic inguinal hernia repair is almost as common as open hernia repair (40% vs 55% in population-based studies) for primary and recurrent inguinal hernias, although advantages and disadvantages compared with open repair remain a subject of ongoing study. Many laparoscopic approaches are now used, the most common of which is probably the laparoscopic total extraperitoneal (TEP) hernia repair. Other approaches include a single port variant of the TEP repair and laparoscopic transabdominal preperitoneal repair (TAPP). Advantages include the ability to repair both sides or to examine the contralateral side during a primary repair. A laparoscopic approach allows the surgeon to avoid going through the scar tissue and altered anatomy of a previous anterior approach. A physical advantage is suggested for preperitoneal mesh, which is pushed *into* the defect when the patient strains as opposed to being pushed *away* from the defect as is the case with an anteriorly placed mesh. Laparoscopic repair may be of particular benefit in recurrent inguinal hernias for these reasons. Many studies have compared open and laparoscopic approaches, but none have shown such clear benefits as to lead to the abandonment of the other approach; for now, and probably the foreseeable future, surgeons should use the technique with which they feel most comfortable.

Stoppa Procedure

The Stoppa procedure, or giant prosthetic reinforcement of the visceral sac, has been described by a number of authors. Essentially, a large mesh is placed in the preperitoneal space, replacing the transversalis fascia in containing the abdominal viscera. It may be the ideal approach for large, multiply recurrent groin hernias or groin hernias with multiple defects in which the transversalis fascia has become so shredded that traditional repair is hopeless. This procedure is well

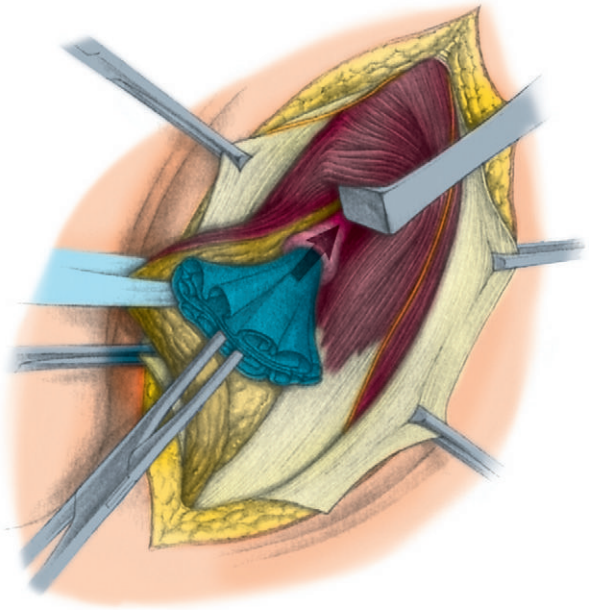

FIGURE 1 Placement of a prefolded mesh plug into a patulent internal ring.

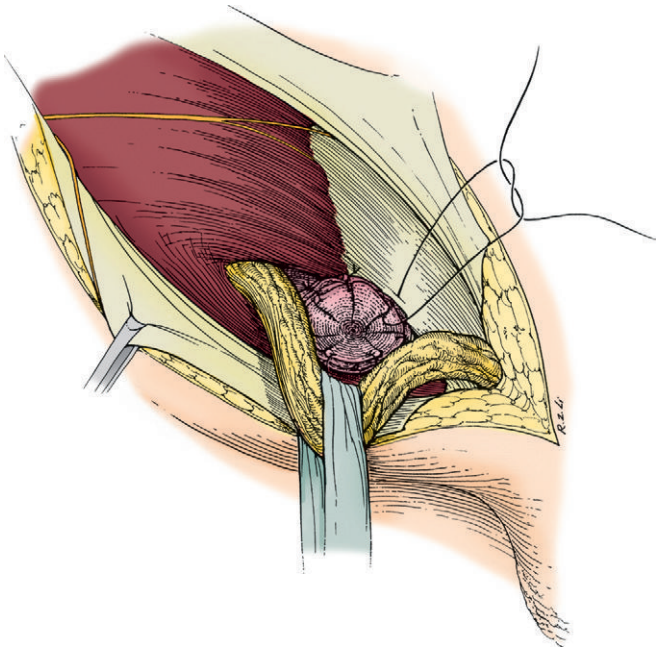

FIGURE 2 Mesh plug in position in a direct defect. Although the spermatic cord is shown retracted away from the defect, often the spermatic cord is scarred down or unidentifiable and a meticulous dissection of the spermatic cord is not necessary.

described and illustrated by Drs. Wantz and Fischer in the seventh edition of *Current Surgical Therapy* and is not replicated here.

Plug and Patch

The vast majority of recurrent groin hernias are relatively small discrete defects, either in the inguinal floor itself or as part of a loose internal ring. The edges are usually readily palpable from an anterior approach, and except for the defect, the remaining inguinal tissue is competent. Plugging and patching these defects is an easily learned technique with near universal application that requires minimal dissection and results in a tension-free repair.

Local, regional, or general anesthesia is effective. An incision is made through the previous scar. The subcutaneous tissue is divided until the aponeurosis of the external oblique is found. Although the anatomy is always distorted from previous repair, usually the external oblique is recognizable and is opened parallel to its fibers along the length of the incision. Sometimes the spermatic cord is identifiable. If it can be done easily, it should be mobilized as in primary repair. However, if it is scarred in, then no attempt to mobilize it should be made. If the patient is awake, the patient can cough to identify the hernia defect. These defects are also palpable. An indirect sac, if found, can be dissected away from the cord if it is not difficult. If it is tightly adherent, then it should be divided, allowing the distal sac to stay open in the wound. The proximal sac is then ligated at the internal ring as in primary repair. Extensive dissection of a tightly adherent sac injures the venous plexus of the testicle and can lead to testicular swelling and then atrophy. Blunt finger dissection of the preperitoneal tissue away from the sides of the defect is usually adequate to prepare the defect for repair, and little formal dissection is required. If previously placed mesh is encountered, it should generally be left undisturbed because removing it is usually difficult and traumatic. An appropriately sized synthetic plug is inserted into the defect and sutured in place. This can be through a direct defect or through a loose internal ring for an indirect recurrence (Figures 1 and 2). Then, a mesh patch is used as an overlay over the defect, securing the plug in place and reinforcing the inguinal floor (Figure 3). It is secured to the inguinal ligament and conjoint tendon where

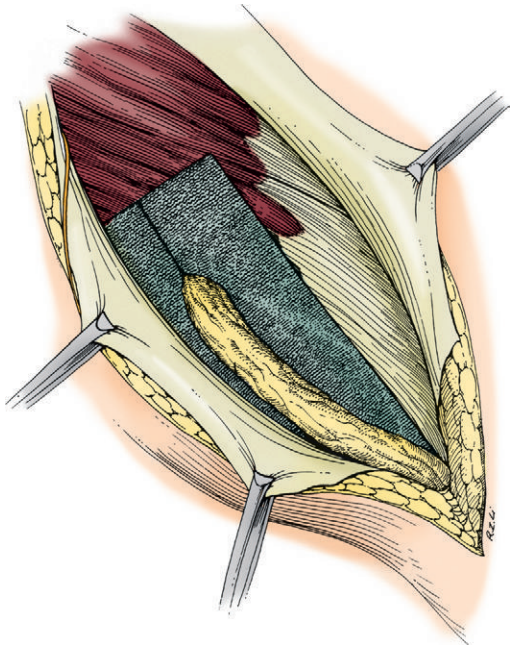

FIGURE 3 Onlay patch in position in the inguinal canal.

identifiable. Otherwise, it is secured to any good solid tissue. In an inguinal floor with no identifiable anatomy, the laparoscopic tacker has been used to secure the mesh to the pubic tubercle and to any solid shelves of tissue found. Some meshes are designed with tiny barbs to hold themselves in place, requiring little if any further fixing in place. The awake patient can be instructed to cough before the wound is closed.

After surgery, patients are instructed that they cannot drive until they no longer take narcotics. They should not lift anything heavier

than 10 to 15 lbs for 2 to 3 weeks, after which, if they are doing well, they are instructed to begin normal activity as they are able.

COMPLICATIONS

Complications of recurrent hernia repair are essentially the same as for primary repair. Recurrence is the most troublesome complication, but large series of patients suggest that the recurrence rate is not more than 10%. Chronic groin pain can also be a problem as discussed previously. Hematomas and seromas are more common after recurrent hernia repair. Testicular swelling and atrophy are also more common after recurrent hernia repair, particularly after aggressive dissection of a hernia sac from the cord structures, which is to be avoided. Infectious complications are fortunately rare. Superficial wound infection, stitch abscess, and cellulitis can occur. They are treated with opening of the wound or antibiotics as indicated. Removal of the mesh is virtually never necessary.

SUMMARY

Recurrent groin hernia is a common problem. A number of strategies exist for fixing these hernias; the best strategy is usually the one with which the surgeon is most comfortable. Anterior open placement of mesh and laparoscopic techniques are both safe and effective for recurrent inguinal hernia repair. Gentle handling of the tissues, the avoidance of tension, and appropriate reinforcement of hernia defects and patient preparation are the key principles in repairing recurrent hernias.

Incisional, Epigastric, and Umbilical Hernias

Paul G. Curcillo II, MD, FACS

INCISIONAL HERNIAS (VENTRAL HERNIAS)

The term *ventral hernia* is often used to describe incisional hernias. In fact, a ventral hernia is any defect within the anterior abdominal wall. Incisional hernias make up only a portion of all the hernias that can occur from the xyphoid process to the pubic bone and between the most lateral aspects of the oblique muscles.

Unlike all other hernias that surgeons evaluate and repair, incisional hernias are unique in that surgeons contribute to the source and cause of the disease. In this regard, attention should always be given to appropriate closure because prevention is always better than treatment. Of all surgical incisions, 10% to 15% will develop a hernia in time. In patients developing a wound infection, this rate can double. In view of that, attention to detail with adequate fascial stitches, appropriate suture to tissue length, and complete aseptic technique is the best way to reduce this disease. Internal or external retention sutures in patients with risk factors for hernia development (obesity, diabetes, immunosuppression, advanced age) often prevent hernias as well.

The discussion of incisional hernias also requires attention to other ventral hernias: namely, umbilical and epigastric hernias. Repair techniques are similar, but often, if such hernias are present before a patient's first surgery, they can predispose the patient to development of an incisional hernia after surgery.

Because nearly 150,000 patients a year undergo repair of ventral hernias, this number would be expected to decrease as repair techniques improve and more laparoscopic procedures are developed. However, this decrease has not yet materialized. When one considers that two of the most common surgical procedures performed are cholecystectomy and hysterectomy/oophorectomy, hernia occurrence rate would have been expected to decreased since 1990 with the advent of laparoscopy. The fact that it has not actually proves that it is still the midline incision that has the highest rate of hernia occurrence. Cholecystectomy routinely involves a right upper quadrant incision, and gynecologic procedures generally were performed through Pfannenstiel incisions. Incisions in both these regions rarely result in hernia formation. In fact, midline incisions account for almost 90% of all incisional hernias. With regard to the anatomy, a discussion of the other two topics of this chapter shows why incisional hernias can also be caused by underlying patient anatomy if not identified and included in primary closure of the initial wound.

UMBILICAL HERNIAS

Umbilical hernias are most often detected and repaired in children. However, in some patients, umbilical hernias, both known and undetected, continue to occur into adulthood. An important aspect of diagnosing and treating an umbilical hernia in adults is to determine how it has developed. In an adult who has had one in his or her entire life, assessment and repair are relatively straightforward. However, in the adult with a new-onset umbilical hernia, then anything that can increase intra-abdominal pressure needs to be considered as a potential causative agent. New-onset increasing constipation, difficulty with urination, and chronic cough can not only lead to the development of a new hernia but also stress the repair postoperatively and need to be addressed. After ruling out cancer of the colon or urinary tract, physicians need to consider the stress postoperatively that will continue and thus be placed on the repair. The age-old

primary closure or "tensioned" repair becomes a much less viable option.

Any patient undergoing a midline or even a laparoscopic incision needs to be assessed for umbilical hernia. Such hernias should always be noted preoperatively or, at the very least, before the incision, so that closure can incorporate the repair of the native hernia. A common hernia is an umbilical hernia after laparoscopy. When it is repaired laparoscopically, closure is often made from the umbilical port, and a hernia is noted just above it that was clearly stretched from the tension of the wound closure. A small, unappreciated defect can develop postoperatively into a larger defect that could have been prevented. Equally as common is the umbilical hernia that develops at the top of a low midline incision from pelvic surgery that is not included in the closure.

EPIGASTRIC HERNIA

One of the most confusing areas for both diagnosis and repair of ventral hernias is the epigastrium. This area from the xyphoid process down to the umbilicus is often an area of weakness from the separation of the right and left rectus muscles (diastasis recti). The separation of the muscle with the fascial envelope left intact produces the classic appearance of a hernial bulge, but no true defect hole is present. It manifests during isolated contraction of the rectus muscles rather than increased intra-abdominal pressure such as during cough or a Valsalva maneuver as with a hernia. This is best demonstrated by having the patient lie back and then sit up on the examination table. During *inclining* and *reclining* (Figure 1), the bulge appears and promptly resolves once the recti are relaxed. This separation is often a cosmetic concern but does not need to be repaired. However, once a true defect, or a break in the fascial integrity, occurs, an epigastric hernia has developed. This usually manifests as a bulge or protrusion in the midepigastrium surrounded by the diastasis recti and is most often properitoneal fat or a portion of the falciform ligament. This repair now needs to be more extensive than simple closure of the defect because the lateral tissue will be too weak to hold the sutures and may result in a recurrence.

Like an umbilical hernia, an epigastric hernia should be noted preoperatively in a patient about to undergo a midline incision. Closure from the planned surgery must account for the weakened tissue that will be grasped with every placement of the suture, as well as the perforating effect of needle punctures too closely placed. Failure to account for this weakness will certainly result in an incisional hernia with time.

The most important aspect of treating incisional hernias is often to prevent them and plan wound closure appropriately.

APPROACH TO THE REPAIR OF VENTRAL HERNIAS

To Repair or Not to Repair

The first question in evaluating a patient with a ventral hernia is whether it should be repaired. The traditional teaching was to "repair every hernia." Certainly an incarcerated hernia needs to be addressed in a timely manner, and few authorities would argue against repair. The decision is more involved with regard to elective evaluation and consideration for repair.

Box 1 lists the indications for repair of hernias. In patients with small hernias, or those simply referred because they were found on routine examination or computed tomographic scan, observation with follow-up is an option. Particularly in patients with other comorbid conditions, repairing a hernia is not without complications. If a hernia does not grow with time, then routine office follow-up can be a safe option in a compliant patient. An important aspect of this is the size of the hernial defect and the size of the hernial sac. A large-mouthed hernia that spontaneously reduces can be monitored, whereas a small defect with a larger sac raises the concern of eventual incarceration. Naturally, any report that a hernia has become firm or is not reducing should raise concern and prompt repair.

The patients' concerns also need to be a consideration in the evaluative and planning process. Many patients are concerned about the appearance. Not only is repairing hernias from a cosmetic standpoint acceptable but also the final appearance and outcome must be considered as surgeons plan the approach and technique.

Techniques of Hernia Repair

All hernia repairs can be classified into two categories: *tensioned* and *tension-free.* It is important to remember that simply placing a piece of mesh does not necessarily make a repair tension-free, nor is a laparoscopic repair necessarily a tension-free repair (Table 1).

BOX 1: Indications for hernia repair

Expanding hernia
Loss of abdominal domain
Cosmesis
Thinning of soft tissue and skin on anterior abdominal wall
Nonhealing wound on scar

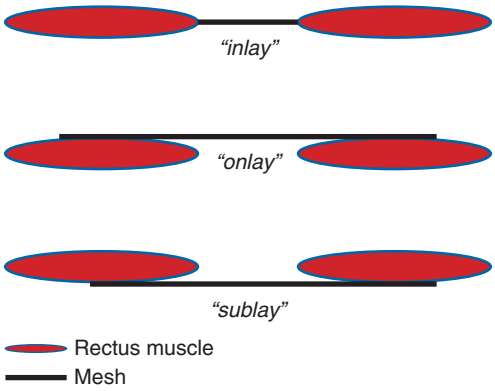

FIGURE 2 Mesh positions.

Tensioned Repair

The primary repair is rarely ever performed except for small hernias because defects greater than 2.5 or 3 cm repaired primarily have a high recurrence rate. A surgeon should keep in mind that although a primary repair is perhaps slightly more painful and somewhat more restrictive postoperatively than a mesh repair, it eliminates the need to place a foreign body. For a young patient with a small umbilical hernia or perhaps a small trocar hernia, primary repair should still be offered as a first choice. Should the hernia recur, then mesh can be offered. However, the presence of the diastasis recti should always be determined before repair because the recurrence rate can dramatically increase if the muscle is close to the actual defect. This scenario is often best approached with a mesh repair. The same holds true for epigastric hernias.

Tension-Free Repairs

Perhaps one of the most important steps in understanding the best way to repair a hernia was the development of laparoscopic inguinal hernia repair. As laparoscopists turned the camera to the pelvis and inguinal region and saw an opportunity to repair inguinal hernias from within, one of the early stumbling blocks was attempting to form, cut, and shape the mesh for the defect. Before this, most meshes were placed in an inlay manner (Figure 2). However, difficulties in planning the mesh shape and size extracorporeally and in trimming the mesh intracorporeally led to the concept of simply placing a piece of mesh larger than the defect with a wide overlap. In addition, and probably of most importance, the mesh was being placed in a sublay position (see Figure 2). This allowed for wide coverage of the area with decreased tension. In the likely event of continued intra-abdominal pressure from constipation, urinary difficulties, or chronic cough, the hydrostatic pressure would be directed towards the mesh against the abdominal wall and fascia; thus the mesh would be secured to the wall around the defect rather than protruding into the wound. For virtually all hernias repaired in a tension-free technique, both laparoscopically and with open surgery (i.e., with mesh plugs), a piece of mesh is cut larger than the defect and placed posterior to the defect. Recurrence of hernias has clearly decreased with this concept applied.

Mesh

For hernia repairs with mesh, a wide variety of mesh types and combinations are available (Box 2). Synthetics (both reactive and nonreactive), coated meshes, and biologic materials are all used in hernia surgery. A surgeon needs to be knowledgeable of all the types and be able to apply them where and when appropriate. The ideal mesh placed within the abdomen would be completely inert on the bowel side to prevent adhesions and completely reactive on the abdominal wall side to promote tissue ingrowth. An ideal biologic mesh would promote formation of new fascia; the current development simply of new scar tissue can lead to the "pseudo"-hernia observed when the defect is still present, but is now simply spanned by scar tissue and sac, rather that sac and fatty tissue. Although a defect may not be present to allow bowel to incarcerate, patients may not understand that the development of laxity is not a recurrence, and they may wish to have it revised.

BOX 2: Mesh types and coatings

Type

Nonreactive
Expanded polytetrafluoroethylene (ePTFE)

Reactive
Polypropylene
Polyester

Biologic
Porcine dermis
Bovine dermis
Human cadavaric
Porcine intestine

Coatings
Hyaluronic acid
Omega fatty acids
Modified polysaccharides
Collagen
Cellulose
Titanium

In simple cases with minimal adhesions, coated mesh or polytetrafluoroethylene (PTFE)–based meshes may help prevent adherence to the bowel and omentum. However, regardless of the mesh type used, if extensive adhesiolysis is necessary to expose the defect, then the inflammatory response that ensues will lead to adhesion with virtually any mesh placed. In these cases, combined PTFE/polypropylene or coated meshes offer some relief. Although adhesions will still develop, lysing them on reoperation if necessary is often easier than with polypropylene-only or biologic meshes placed intra-abdominally.

Combined Approach

A hernia surgeon needs to be facile in all aspects of surgery. Not every hernia can be repaired with the same method. Although it seemed as though the 1990s were giving rise to repairing all hernias laparoscopically, it soon become evident that laparoscopic repair was sometimes

not appropriate. The decision can often be made preoperatively; however, the plan can change once the defect is visualized. Most hernias should be approached laparoscopically, albeit if only as an initial step. First, the laparoscopic approach allows better visualization not only of the defect but also of the entire area to assess whether there are any other defects along the incision, whether the defect is isolated or within a large lax area, and whether the diastasis recti will ultimately affect the repair. Furthermore, adhesiolysis is often best performed laparoscopically. In patients with extensive adhesions, even if the repair is open with muscle flaps and mesh, a laparoscopic adhesiolysis allows most of the surgery to be performed without opening of the wound. Thus less exposure of the primary wound minimizes the chance of wound and, ultimately, mesh infection. In some cases, once the adhesiolysis is complete, it may become evident that a laparoscopic mesh placement would be the *wrong* repair (Box 3).

BOX 3: Contraindications to laparoscopic ventral hernia repair

Large defect
- Mesh not large enough
- No lateral space to allow 3-cm to 5-cm overlap beyond defect

Skin thinning
- Loss of tissue below skin = loss of protection for mesh

Infection
Fistula
Concurrent contamination

Laparoscopic Repair

Hernia repair has been altered by the current changes and evolution of laparoscopic surgery. Although fewer than 50% of ventral hernias are repaired laparoscopically, surgeons are showing a trend to using even less invasive techniques. Reduced port techniques introduced in 2002 limit the approach to only two trocars. Along with the single-port access repairs, with only one port site, these advanced procedures have offered the benefit of limiting not only postoperative pain and scarring but also the number of potential hernia sites in the future. Repairs have also been completed using natural orifice transluminal endoscopic surgery (NOTES) approaches; with instruments and mesh place Transvaginally completely avoiding cutaneous incisions in an attempt to limit scarring. Regardless of the approach, the concept and techniques are identical for all minimally invasive approaches.

A safe entry laparoscopically is always the first step (Figure 3). In a patient with an umbilical hernia, a separate access site is necessary. A subxyphoid position or lateral abdominal wall entry in the open technique is often the safest approach. Trocars need to be placed widely enough in the abdominal wall and with enough distance so that the surgeon can see the entire defect, as well as position the tacking devices along the outer rim of the mesh at least 3 to 5 cm from the defect edge. Once entry is obtained, additional trocars are placed to proceed with the adhesiolysis. Sharp and blunt dissection and energy dissection are acceptable methods if the same techniques and care are taken laparoscopically that would be taken with open surgery. Instruments that are sharp or hot should never be out of view and should avoid touching other instruments during activation. Failure to be vigilant in this regard can result in missed bowel injuries. An injury to the bowel during laparoscopic dissection can be

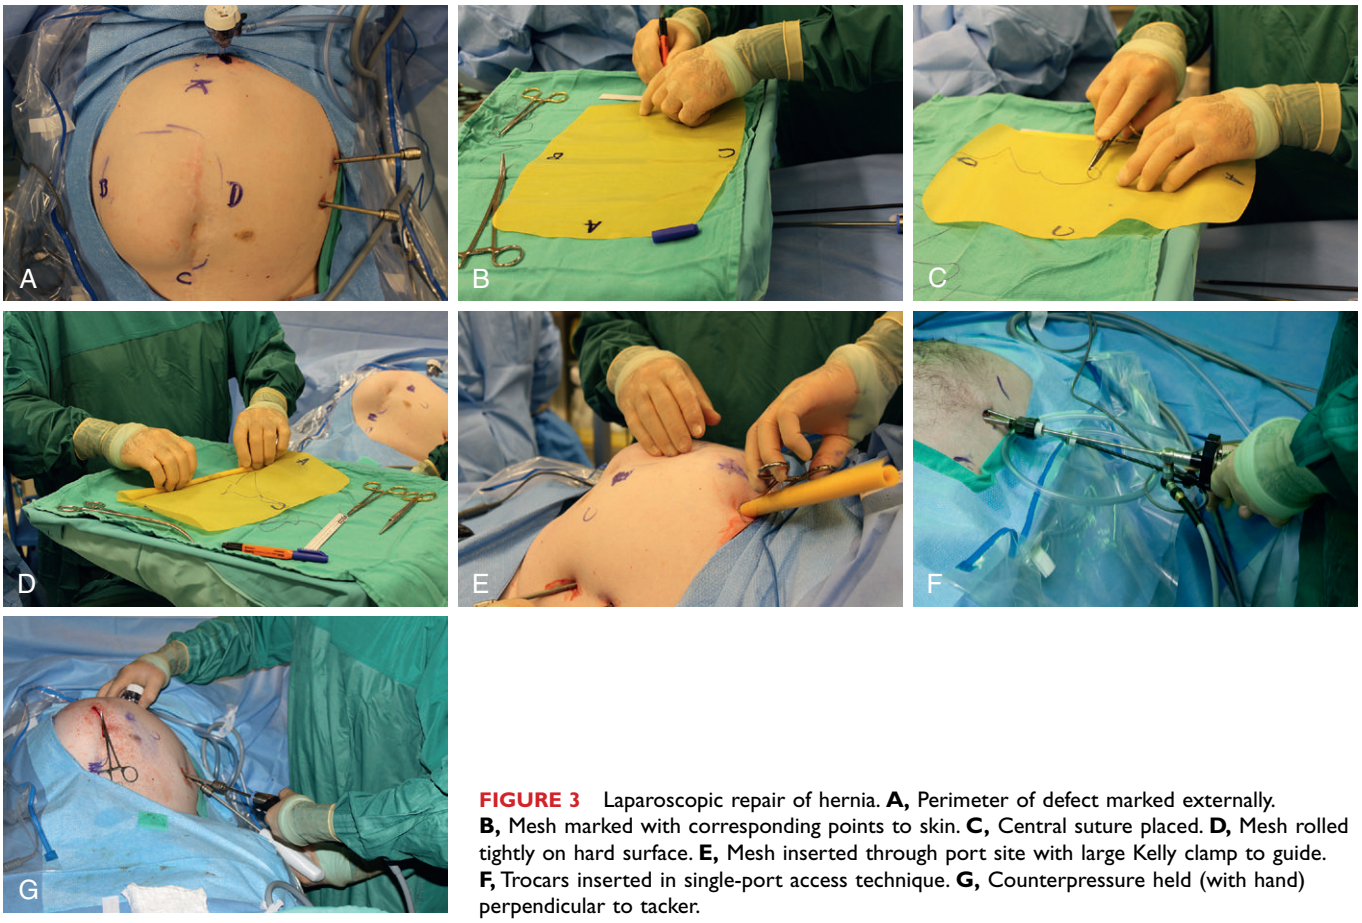

FIGURE 3 Laparoscopic repair of hernia. **A,** Perimeter of defect marked externally. **B,** Mesh marked with corresponding points to skin. **C,** Central suture placed. **D,** Mesh rolled tightly on hard surface. **E,** Mesh inserted through port site with large Kelly clamp to guide. **F,** Trocars inserted in single-port access technique. **G,** Counterpressure held (with hand) perpendicular to tacker.

repaired just as with open surgery. As with open surgery, a bowel injury may manifest itself postoperatively; therefore, with extensive adhesiolysis, the patient should be monitored closely after surgery.

Once the adhesiolysis is complete, the entire defect or incision, or both, should be visualized. If a laparoscopic placement of mesh is appropriate, then the defect should be measured. A thin ruler can be inserted, with counter pressure placed on the abdominal wall, and marked while the edge of the defect is observed from within. Once the defect size is measured, the mesh size can be determined. A 3-cm to 5-cm overlap in all directions is recommended in order to ensure wide coverage and allow for migration that may occur. The use of polypropylene meshes can minimize migration, but some still occurs with time. In general, simply adding 6 to 10 cm to the defect size helps guide the decision as to which size of the precut meshes to be applied. It is good practice to choose a size larger than estimated, to ensure wide overlap. Not only does the defect need to be widely covered with overlap, but also any laxity of the abdominal wall and musculature, such as diastasis recti, needs to be covered. This is one of the clear benefits of the laparoscopic approach for exposure of the defect from within.

The mesh can then be inserted directly through the trocar site or through a large trocar. The mesh should be centered on the defect with either a centrally placed suture or with the use of instrumentation to a position correlating with the marks on the abdominal wall.

The mesh can be secured with either tacks or transfascial sutures. If a reactive mesh with tissue ingrowth is utilized, tacks generally suffice. Both absorbable and nonabsorbable tacks are acceptable. Tacks should be placed every 2 to 3 cm around the perimeter and then a "double crown" technique utilized with the tacks placed around the outer edge of the fascial defect. If the mesh used does not have tissue ingrowth, then transfascial suture are advised at least at four points and nonabsorable tacks are recommended.

The author and colleagues always attempt to pull the mesh off the abdominal wall at the end of the procedure. Our philosophy is that if we can pull the mesh off, it is not secure. Tugging on the mesh to move the abdominal wall externally demonstrates enough force to determine whether the tacks and mesh are secure.

On exsufflation, the mesh is observed to ensure it does not crimp or fold. Once the abdomen is reexplored and proven to have no injuries, the trocars are removed and wounds closed. The patient is placed in an abdominal binder to decompress the hernia sac, which is not removed. Virtually all patients develop seromas in the sac as the mesh adheres. On examination at 1 week, seromas are usually not yet present. At approximately 2 weeks, the seroma is palpable, indicating that the reactive mesh has adhered to the underlying wall, and the fluid created by the sac can no longer extravasate into the abdomen. The abdominal binder is worn 24 hours a day, except during showers, and can help prevent and minimize the seroma. If one does develop, it can generally be monitored and will be resorbed with time. Occasional aspiration may be necessary if a seroma clinically becomes symptomatic. It is best to wait 2 to 3 months to ensure that the mesh has scarred to minimize the possibility of infection.

Open Repair/Abdominal Wall Reconstruction

In some patients, although the laparoscopic approach to perform the adhesiolysis is the first step, an open repair (Figure 4) may be necessary. A large sac may have to be excised, the patient may have extensive scarring or old mesh that needs to be excised, or the hernia size may be too large for adequate placement of a piece of mesh. In many cases, reapproximation of fascia may be necessary. With the exception of small primary hernias, tissue-to-tissue primary closure is rarely adequate to prevent a high rate of recurrence. As a result, a number of methods have been developed to bring fascial edges together, with focus on decreasing the tension. Component separation or advancement flaps of the overlying muscle can be used.

A benefit to this type of repair is tissue-to-tissue reapproximation in which the bowel and abdominal contents come into contact only with peritoneum and the mesh can be placed on the outer side of the defect. Although not in a sublay position, the mesh in this repair serves to reinforce the primary repair. The laterally placed sutures create a "suspension bridge" across the primary closure, absorbing some of the tension. In addition, should the tissue-to-tissue closure

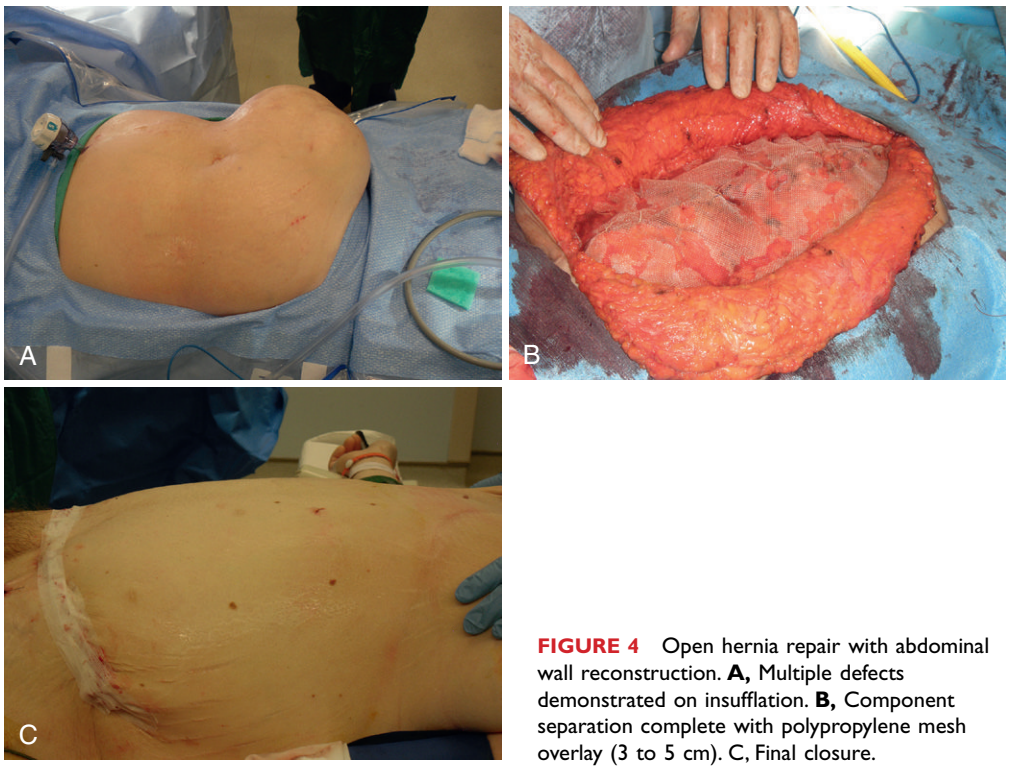

FIGURE 4 Open hernia repair with abdominal wall reconstruction. **A,** Multiple defects demonstrated on insufflation. **B,** Component separation complete with polypropylene mesh overlay (3 to 5 cm). C, Final closure.

develop a defect with time, the reinforcing mesh atop acts as a barrier to hernia formation and does not expand as does a hernia sac. Of more importance is that plain polypropylene can be used to promote tissue ingrowth on both sides because it is not in contact with the abdominal contents.

In this technique, once the defect is cleaned and identified, the fascial edges need to be grasped with Kocher clamps and pulled toward the contralateral side. The fatty tissue overlying the rectus sheath and external oblique muscle is then raised in the avascular plane. This maneuver alone allows the fascial edge to advance across midline. Depending on the size of the defect and the amount of fascia present from prior surgeries, the distance to the lateral side of the abdominal wall may be a few centimeters, or it may track back to the level of the pelvic brim. A similar release on the contralateral side brings the other side across midline as well.

On occasion, a releasing incision needs to be made along the lateral edge of the rectus muscle fascia for very large hernias, although this often times leads to replacing the midline hernia with lateral laxities. In general, the relaxing incisions are not necessary. If the fascia from each side can be brought approximately 3 to 4 cm across midline with good overlap, the relaxing incision is not necessary.

Reapproximation is performed with a running long-term absorbable suture, with several interrupted absorbable sutures placed along the incision. Care should be taken during the closure to monitor the peak inspiratory pressures the PIP and to ensure that they do not increase by more than 25%. Although an abdominal compartment syndrome is rare, an increase in the PIP would be an early indicator.

A piece of polypropylene mesh is placed over the incision with 5-cm overlap in all directions, including top and bottom portions of the incision. Absorbable sutures are placed in a mattress fashion laterally around the perimeter and across the midline incision. Closed-suction drains are placed in the dead space, and the wound is closed. Excess skin and soft tissue can often be excised to eliminate the old scar and offer clean fat planes to close. As in the laparoscopic procedure, an abdominal binder is placed.

In the rare patient in whom the defect is too large to close primarily, the defect may have to be spanned by a piece of mesh. A coated or dual-layer mesh is preferred for the same reasons mentioned previously. The sublay position is the best position, and this is one of the few situations where a sublay mesh should be placed in the open technique. A wide defect allows good exposure and visualization of the mesh before closure. In smaller hernias that can be repaired laparoscopically, sublay mesh is harder to place, and there is generally one corner portion that is not visualized at the end and often causes a problem with bowel entrapment or recurrent hernia (Figure 5).

FOLLOW-UP

In general, patients are seen by the surgeon the first 2 weeks to evaluate seromas and drains. Binders are maintained for 4 to 6 weeks, and then their use is tapered off with time. Longer applications of the binder are common with open repairs. Activity is unrestricted for laparoscopic repairs and restricted to no heavy lifting or strenuous activity for open repairs.

CONCLUSION

Hernia repair has always been a common surgical procedure. Since 2000, it has developed into its own field for complex and difficult hernias. However, hernia repairs still make up a fair portion of most general surgeons' practice. With the trend toward laparoscopy and abdominal wall reconstructions, surgeons need to be facile in both so that they can adapt the surgery to the patient and be versatile in their ability to change plans in the operating room if necessary. With small, simple hernias, a laparoscopic procedure should be attempted first. Unlike most other laparoscopic surgeries, however, ventral hernias are approached differently surgeons are working "up" toward the abdominal wall, and around the entire abdominal area and often times in opposition to the camera. Easier cases will pave the way for repair of more difficult cases, and mesh applications will expand. Adhesiolysis may also become easier than open surgery as skill develops. In the current environment, a hernia surgeon needs to be versed in both laparoscopy and open procedures.

The Management of Semilunar Line, Lumbar, and Obturator Herniation

John Paige, MD

INTRODUCTION

Semilunar line, lumbar, and obturator hernias all share common features that make their diagnosis and management challenging. First, they comprise a small percentage of all forms of herniation, and, as such, they are encountered rarely during a surgeon's career. Second, they are often difficult to diagnose on physical examination because most of these defects do not extend through all layers of the overlying musculature. As a consequence, these hernias are often encountered by the surgeon in the emergency setting after incarceration or strangulation of their contents, limiting therapeutic options and increasing both morbidity and mortality. Additionally, all three types of hernias can result in a so-called Richter's herniation (i.e., partial entrapment of a portion of an involved organ or tissue through the defect), altering presentation and making diagnosis even more challenging. Finally, eponyms for particular types of these hernias abound, requiring surgeons to have an intimate knowledge of the anatomic borders and location associated with each one (Table 1).

Computed tomographic (CT) scanning has become the preferred modality for the preoperative diagnosis of these uncommon hernias because it is useful in characterizing both the defect itself as well as the contents within the hernia sac (Figure 1). Ultrasonography (US) can also be useful as a rapid means of evaluation in the emergent setting; it should not, however, delay operative exploration in patients with peritonitis. Both open and minimally invasive surgical (MIS) repairs have been described for each type of hernia, and primary as well as tension-free options exist. In general, synthetic prostheses should be avoided in the presence of strangulation or contamination, and the approach undertaken should be based on the clinical situation and the surgeon's experience and expertise with the technique chosen. As with many aspects of general surgery, successful diagnosis and management of these challenging hernias require a high index of suspicious, a clear understanding of the surgical anatomy, and familiarity with several options for repair.

SEMILUNAR LINE (SPIGELIAN) HERNIATION

The linea semilunaris, or linea Spigeli, extends from the tip of the ninth cartilage to the pubic spine and serves as the lateral border of the aponeurotic zone in which Spigelian hernias form (Figure 2). This zone is bordered medially by the lateral edge of the rectus abdominis muscles, and it is widest in the so-called Spigelian hernia belt, a zone extending 6 cm above the anterior superior iliac interspinal plane. In this region, the arcuate line, or line of Douglas, marks the caudal end of the posterior aponeurotic sheath of the rectus muscles; its intersection with the semilunar line creates a weak point. Ninety percent of semilunar line hernias form within this belt, protruding through various layers of the abdominal wall musculature, depending on their relation to the arcuate line (Figure 3). In addition

TABLE 1: Anatomic borders, incidence, and demographic characteristics of some uncommon abdominal wall and pelvic floor hernias

Anatomic location of herniation	Eponym	Anatomic borders of defect	Incidence, demographics
Semilunar line	Spigelian hernia	Within the aponeurosis of transverse abdominal muscle between the lateral edge of the rectus abdominis and the linea semilunaris	1%-2% of all hernias Female predominance Left > right
Lumbar			<2% of all hernias Left > right
Superior triangle	Grynfelt hernia	Base: twelfth rib Medial border: erector spinae muscle Lateral border: internal oblique muscle	Most common location for herniation Short, obese individuals
Inferior triangle	Petit hernia	Base: iliac crest Medial border: latissimus dorsi muscle Lateral border: external oblique muscle	Less common location for herniation Women with wide hips
Obturator	N/A	Superolateral: obturator groove of pubic bone Inferior: free edge of obturator membrane; internal and external obturator muscles	<1% of all hernias Thin, old women (female predominance) Right > left

to spontaneous creation, iatrogenic herniation is possible when surgical drains or laparoscopic ports are placed within this vulnerable aponeurotic zone between the semilunar line and the lateral edge of the rectus muscles, especially in the area of weakness along the hernia belt. Care, therefore, should be taken when choosing the location for these devices.

Abdominal pain is a common presenting symptom of semilunar line hernias. Such pain is exacerbated by increases in intra-abdominal pressure and relieved with rest. On physical exam, a lump may be palpable in the appropriate aponeurotic zone; it can increase in size with patient Valsalva and disappear spontaneously when the patient lies supine. Such spontaneous reduction of the hernia can lead to diagnostic difficulties because CT of the patient in the supine position might not reveal a hernia sac. Hence, diagnostic laparoscopy may be required to confirm the presence of a hernia if CT or US studies are equivocal. Defects tend to be small in size and oval in shape, and, consequently, incarceration of contents commonly occurs. Often, diagnosis is made upon operative exploration for obstructive symptoms.

Given the high rate of incarceration, repair is indicated for all diagnosed semilunar line hernias. Contraindications to operative intervention are limited to those situations in which patient comorbidities preclude general anesthesia. Examples include recent myocardial infarction, severe pulmonary disease, and severe coagulopathy. An open approach should be undertaken in emergent cases or when laparoscopy is contraindicated (e.g., portal hypertension with coagulopathy). In cases involving complete obstruction or frank peritonitis, open exploration should be undertaken expeditiously after the initiation of appropriate resuscitative measures.

Open repair typically consists of anterior hernioplasty with or without prosthesis (Figure 4). If a mass is present, a skin incision is made over it and carried down through the aponeurosis of the external oblique in cases when it is not penetrated. When a mass is not present or in cases of diagnostic uncertainty, a midline incision should be made. For incarcerated hernias, a medial incision of a small, constricting ring extending to the rectus abdominis will aid in the reduction of sac contents. The sac should be opened to inspect its contents after its complete dissection from surrounding tissues. It is reduced in toto or excised. Following reduction, the peritoneal surface of the adjacent semilunar line should be palpated for additional defects because multiple hernias can exist. Small defects can be repaired primarily with reapproximation of the transversis abdominis and internal oblique aponeuroses using nonabsorbable suture. In cases of larger orifices, multiple defects, thin or weak aponeuroses, or recurrence, tension-free repair should be undertaken using a synthetic mesh (e.g., polypropylene or expanded polytetrafluoroethylene [ePTFE]); it should be placed in an extraperitoneal underlay position and secured with interrupted nonabsorbable sutures. The repair is then reinforced anteriorly by primary closure of the external oblique aponeurosis; skin closure completes the procedure.

MIS options for repair of semilunar line herniation do exist. In general, they are variations of MIS incisional and inguinal hernia repair techniques applied to the setting of a Spigelian hernia and, as such, follow the same principles for exposure, dissection, and mesh placement and fixation. The intraperitoneal onlay mesh (IPOM) repair follows the same steps as a laparoscopic ventral hernia repair. Access is obtained via direct exposure and opening of the fascia with port placement and insufflation (i.e., the Hasson technique) or with Veress needle insufflation with port placement via direct visualization. A combination of 5 and 10 mm ports is placed intraperitoneally according to the principle of triangulation of instruments with the laparoscope (Figure 5). The abdomen is then explored, the hernia defect identified, contents are reduced via gentle traction, and an approximately 3-cm to 5-cm circumferential area cleared around the edges of the defect(s). Mesh is then placed into the abdomen after placing four interrupted sutures in the cardinal locations and rolling the mesh. Typically, a composite synthetic mesh with an antiadhesive layer is chosen to promote scarring to the abdominal wall and decrease adhesion formation to intra-abdominal organs; ePTFE can also be employed. Authors have advocated rolling the mesh in the form of a scroll to assist with securing it to the anterior abdominal wall by unrolling each side sequentially. The mesh is initially secured to the abdominal wall via the four interrupted transabdominal sutures. Following this maneuver, fixation tacks are placed circumferentially around the mesh in one or two rows. Further

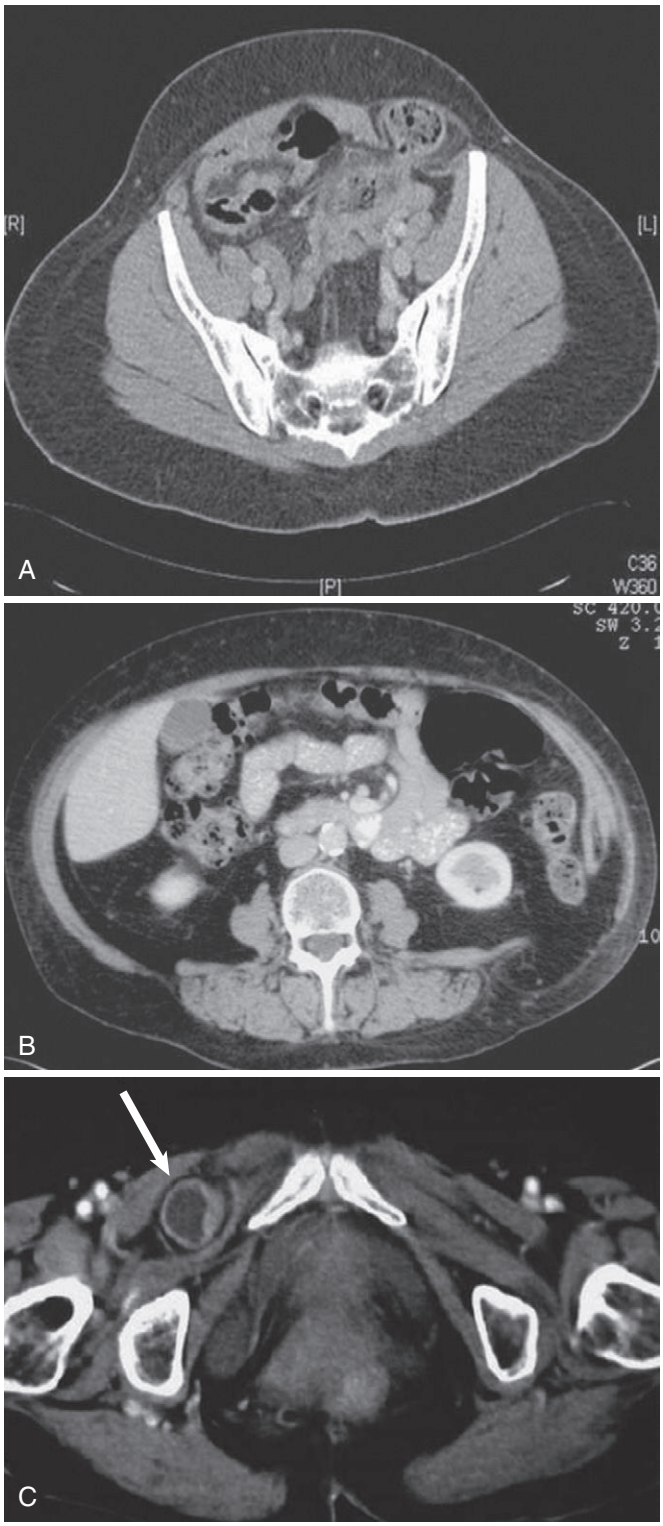

FIGURE 1 **A,** Computed tomographic (CT) scan of the abdomen demonstrats a left-sided Spigelian hernia containing sigmoid colon. **B,** CT scan reveals the presence of a left Petit hernia involving extraperitoneal fat and partially descending colon. **C,** CT scan demonstrates a right-sided obturator hernia revealing a fluid-filled mass located between the pectineus and the right external obturator muscles. (**A** *From Sheu EG, Smink DS, Brooks DC: Spigelian hernia. transabdominal sutures are then placed at 4- to 6-cm intervals. Mesh should overlap the defect by 3 to 5 cm from all edges. Fascial closure of all 10-mm port defects is then undertaken, and the procedure is completed.

In addition to the IPOM technique, both total extraperitoneal (TEP) and transabdominal preperitoneal (TAPP) repairs have been described for semilunar line hernias. The TEP repair requires the creation of a preperitoneal workspace using a balloon pump. Its advantage is the placement of mesh preperitoneally, preventing intra-abdominal adhesion formation. It requires midline placement of ports; mesh is secured with tacks. The TAPP repair creates a preperitoneal flap intra-abdominally. Mesh is placed and secured using tacks and sutures (i.e., transabdominal or intra-abdominal). The flap is sutured close, covering the mesh and protecting the intra-abdominal contents from contact with it. Both of these repairs can be technically more challenging, given the preperitoneal placement of the mesh. They require a 3-cm to 5-cm overlay over the defect and can employ synthetic mesh alone (i.e., without an antiadhesive layer composite).

As already mentioned, the decision regarding the approach for repair depends on multiple factors. A randomized controlled trial comparing open versus MIS repair of elective Spigelian hernias demonstrated an advantage for the MIS approach in terms of hospital length of stay and morbidity. It did not show an advantage, however, regarding recurrence rates or mortality. Current recommendations advocate MIS repair, preferably via TEP, in elective cases when such expertise is available. Laparoscopy is also advocated in cases where the diagnosis is in doubt or if another intraperitoneal procedure is being contemplated. Anterior hernioplasty is reserved for more complicated cases (i.e., strangulation) or in the setting of recurrence.

Complications related to repair are similar to those encountered for other types of ventral hernia repair, including bowel injury, bleeding, mesh migration/shrinkage, infection, and recurrence. Thankfully, recurrence rates are rather low, owing to the layered closure of open repairs. One recent review found only a 0.7% rate among over 800 repairs.

LUMBAR HERNIATION

Lumbar hernias can be congenital or acquired. Acquired hernias are by far the most common, approaching 80% of all lumbar hernias. Primary acquired hernias occur spontaneously and are commonly found in the superior lumbar triangle (i.e., Grynfelt hernias). Secondary acquired hernias arise following surgical incision (e.g., from denervation after retroperitoneal aortic aneurysm repair), infection (i.e., after lumbar abscess), or trauma (e.g., deceleration and sheering after a motor vehicle crash); they are not typically confined to an anatomically defined region in the lumbar area. Age over 60 years, hard labor (i.e., heavy lifting), conditions causing increased intra-abdominal pressure, and morbid obesity are all recognized risk factors for lumbar herniation.

Lumbar hernias typically present as a painless mass or protrusion in the lumbar region that may increase in size with straining. Associated back pain and/or vague abdominal symptoms may be present.

Contents can contain either extraperitoneal fat or intraperitoneal structures. In severe cases, whole organs such as the kidney and/or spleen may be involved. Additionally, sliding hernias can occur. Incarceration is present in approximately a quarter of cases, and strangulation can approach 20%. Given such rates, many authors recommend repair when the diagnosis of lumbar hernia is made. In the case of superior lumbar triangle hernias, the latissimus dorsi muscle covers the defect anteriorly, making clinical diagnosis more difficult. For inferior lumbar triangle hernias, no overlying muscular layer is present. CT and US are the preferred modalities for delineation and diagnosis of lumbar hernias.

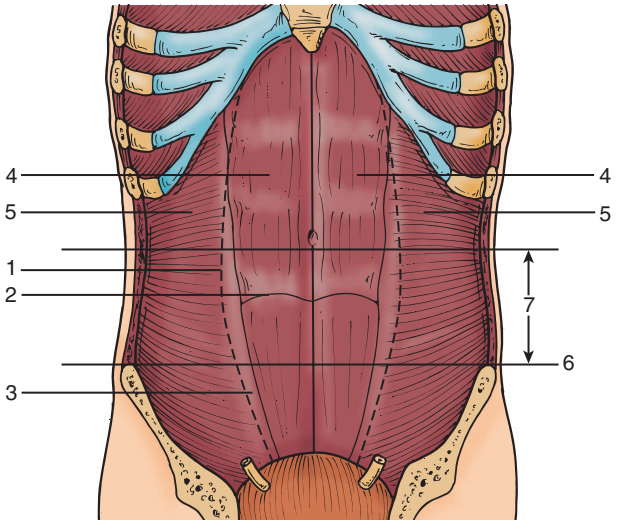

FIGURE 2 Posterior view of the abdominal wall. (1) Semilunar line of Spiegel. (2) Semicircular line of Douglas. (3) Spigelian aponeurosis. (4) Posterior rectus sheath. (5) Transversus abdominis muscle. (6) Interspinal line connecting the anterior superior iliac spines, forming the caudal border of the (7) Spigelian belt, where the majority of Spigelian hernias occur within the Spigelian aponeurosis. *(From Sheu EG, Smink DS, Brooks DC: Spigelian hernia. In Jones DB, editor: Mastery techniques in surgery: hernia, Philadelphia, 2013, Wolters Kluwer/Lippincott, Williams & Wilkins, pp 385–392.)*

Open repair is conducted with the patient in a prone position. An incision is made over the hernia defect with exposure of the sac and defect. The sac is then dissected free from surrounding structures. Small defects (i.e., those less than 2.5 cm in diameter) may be repaired primarily with nonabsorbable sutures. Musculoaponeurotic flaps can also be used to cover larger defects. In general, however, tension-free repair using synthetic mesh is preferred for most defects (Figure 6). Mesh should overlap the edge of the defect by 3 to 5 cm. It is secured to surrounding structures using interrupted nonabsorbable sutures and then covered by reapproximating overlying muscle. If mesh remains exposed after such reapproximation, a rotational fascial or musculoaponeurotic flap can be fashioned for coverage, especially for inferior lumbar triangle defects. Otherwise, a second layer of mesh can be placed. Recently, a sutureless meshplasty repair has been described in which mesh is placed over the defect without fixation and loosely covered by overlying tissue.

MIS repairs consist of transabdominal or retroextraperitoneal approaches. The patient is typically positioned in a semilateral position in order to allow repositioning in the supine or true lateral position as needed (Figure 7). For the transabdominal approach, a periumbilical port is placed and pneumoperitoneum established. Additional ports are then placed based on the size and location of the hernia. Typically a supraumbilical and infraumbilical port in the midline is sufficient. The hernia is exposed after mobilization of the ipsilateral colon and kidney as needed. The contents are then gently reduced, and the defect is dissected free from surrounding tissue. Synthetic or composite mesh is then placed and secured with tacks and transabdominal sutures. Some authors have advocated the placement of bone anchors to the iliac crest and/or an encircling suture around the twelfth rib to secure the mesh. The extraperitoneal approach involves the creation of a workspace within the

retroperitoneum with reduction of the hernia sac and mesh repair of the defect.

Although randomized trials are lacking, longitudinal prospective studies have demonstrated an advantage in MIS repair of lumbar hernias in terms of overall cost, pain control, and return to normal activity. Recurrence rates for repair can approach 15%. Diffuse hernias, large defects, local morbidity, and muscle atrophy increase the risk of recurrence. Moreno-Egea and colleagues have recently suggested an algorithm for repair of acquired lumbar hernias based on type. Primary hernias should be repaired either via an open or laparoscopic approach based on surgeon expertise. Secondary hernias arising from trauma should undergo laparoscopic repair if chronic, open repair via laparotomy if acute. Finally, postincisional hernias should undergo laparoscopic repair if less than 10 cm in size and open double mesh repair if greater than 15 cm. Those hernias ranging from 10 to 15 cm in size should undergo laparoscopic versus open repair based on the degree of muscular atrophy present.

OBTURATOR HERNIATION

Although obturator herniation accounts for only 0.2% to 1.6% of all small bowel obstructions, 90% of patients presenting with an obturator hernia have signs and symptoms of small bowel obstruction (i.e., nausea, vomiting, crampy abdominal pain). Oftentimes, patients report previous attacks with spontaneous resolution. Known as the "little old lady" hernia, it occurs predominantly in older, thin women with concomitant illness. Risk factors include multiparity, malnutrition, chronic illness, and conditions associated with increased abdominal pressure. Gangrenous bowel can be present on exploration in up to 50% of cases, resulting in high perioperative morbidity and mortality. Hence, all obturator hernias should be repaired once diagnosed. Additionally, because bilaterality can occur, exploration of the obturator region opposite the hernia should be undertaken at the time of repair.

Herniation can follow the path of the anterior or posterior branch of the obturator nerve (Figure 8). Its compression by the sac contents leads to its irritation and associated medial thigh pain radiating to behind the knee and into the hip. The pain is relieved with hip flexion and exacerbated with extension, abduction, or medial rotation of the thigh, the so-called Howship-Romberg sign. Some authors consider its presence as pathognomonic for obturator herniation. In some cases, a tender mass is present in the upper inner thigh or felt anterolaterally on rectal examination. Ecchymosis in the femoral triangle below the inguinal ligament can also be present. In cases of bowel necrosis and perforation, patients will have frank peritonitis.

CT remains the diagnostic modality of choice in patients who do not require immediate operative intervention. It has high sensitivity and accuracy. US of the inguinal region and inner thigh is a fast, inexpensive way to diagnose an incarcerated obturator hernia in the emergency department, but it should not delay surgery. In certain situations, plain radiograph can reveal intraluminal air overlying the obturator canal or at the level of the superior pubic ramus, suggesting the presence of an obturator hernia. Herniography (i.e., placement of iodinated contrast within the peritoneal cavity) is effective in diagnosing obturator herniation without incarceration. Finally, laparoscopy has been advocated in cases of obstruction to assist with diagnosis. Repair can then be undertaken via open or laparoscopic means based on findings and/or the presence of contamination.

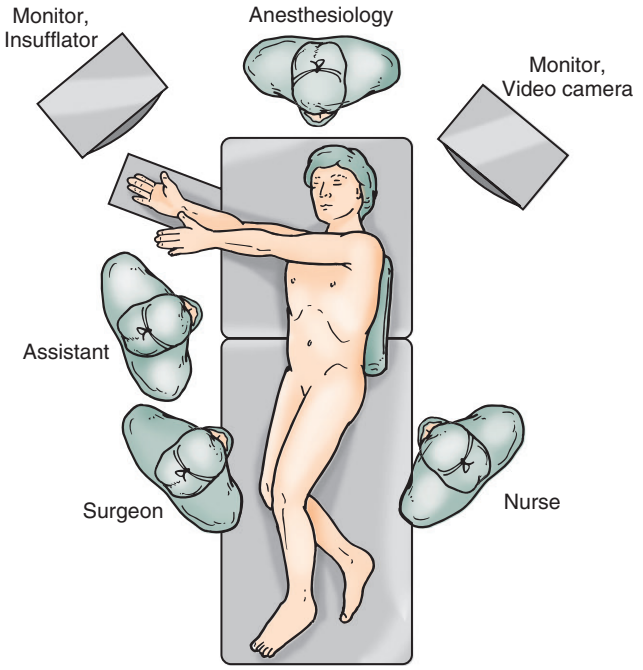

FIGURE 7 Patient position for laparoscopic left lumbar hernia repair. The patient is placed at a 45-degree angle from the horizontal. A rolled blanket is used as a posterior wedge. *(From Arca MJ, Heniford BT, Pokorny R, et al: Laparoscopic repair of lumbar hernias,* J Am Coll Surg *187:147–152, 1998.)*

Depending on the patient presentation, open repair can be via a transabdominal or extraabdominal approach. Laparotomy via lower midline incision should be undertaken in cases of peritonitis, diagnostic uncertainty, complete intestinal obstruction, suspected gangrenous bowel, or deteriorating clinical condition. The patient should be placed in the Trendelenburg position to assist with exposure. Gentle dorsal and medial traction is used to reduce incarcerated bowel. In cases in which such a maneuver is unsuccessful, the deep ring of the obturator canal can be incised in a downward and medial direction at its lower margin because 50% of the time the nerve and vessels will be lateral to the sac. Care must be taken, however, because they can lie anterior, medial, or posterior in the remaining cases. Hip flexion and adduction after finger stretching of the obturator canal can assist with reduction as well. In extreme cases, a counter incision medial to the femoral vein is required with disinsertion of the pectineus muscle in order to reduce the hernia. After reduction, any necrotic bowel should be resected. The hernia sac itself should be inverted and excised. This maneuver decreases the rate of recurrence. Small defects can be repaired with interrupted or purse-string closure. Larger defects require tissue flaps in the setting of strangulation or contamination. Periosteum, muscle aponeurosis, costal cartilage, round ligament, uterus, ovary, and bladder have all been used; bioprostheses are an alternative.

Extraabdominal open repair is indicated when the preoperative diagnosis of an obturator hernia has been made and contamination is not anticipated. The obturator approach is useful when a palpable mass can be felt. It involves an incision over the mass with division of the fascia lata, retraction of the pectineus and adductor longus muscles, reduction of the hernia sac, and closure of the defect. Preperitoneal exposure of an obturator hernia can also be undertaken via an inguinal, suprapubic, or lower midline incision (Figure 9). The midline approach has the advantage of allowing exploration of the obturator region opposite to the hernia. When strangulation or contamination is not present, synthetic mesh repair can be employed for large defects.

MIS repair is generally recommended in the setting of elective repair, although some authors have advocated its use in the presence

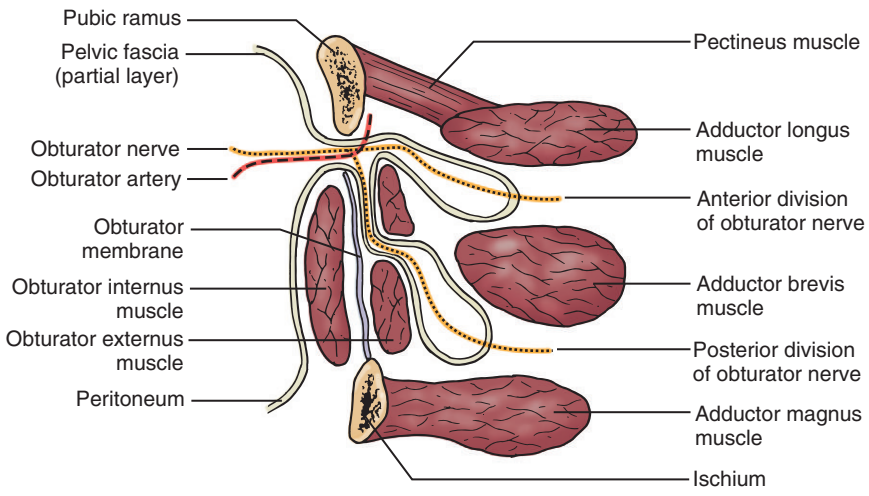

FIGURE 8 Herniation can follow the path of the anterior or posterior branch of the obturator nerve. *(From Stamatiou D, Skandalakis LJ, Zoras O, Mirilas P: Obturator hernia revisited: surgical anatomy, embryology, diagnosis, and technique of repair,* Am Surg *77:1147–1156, 2011.)*

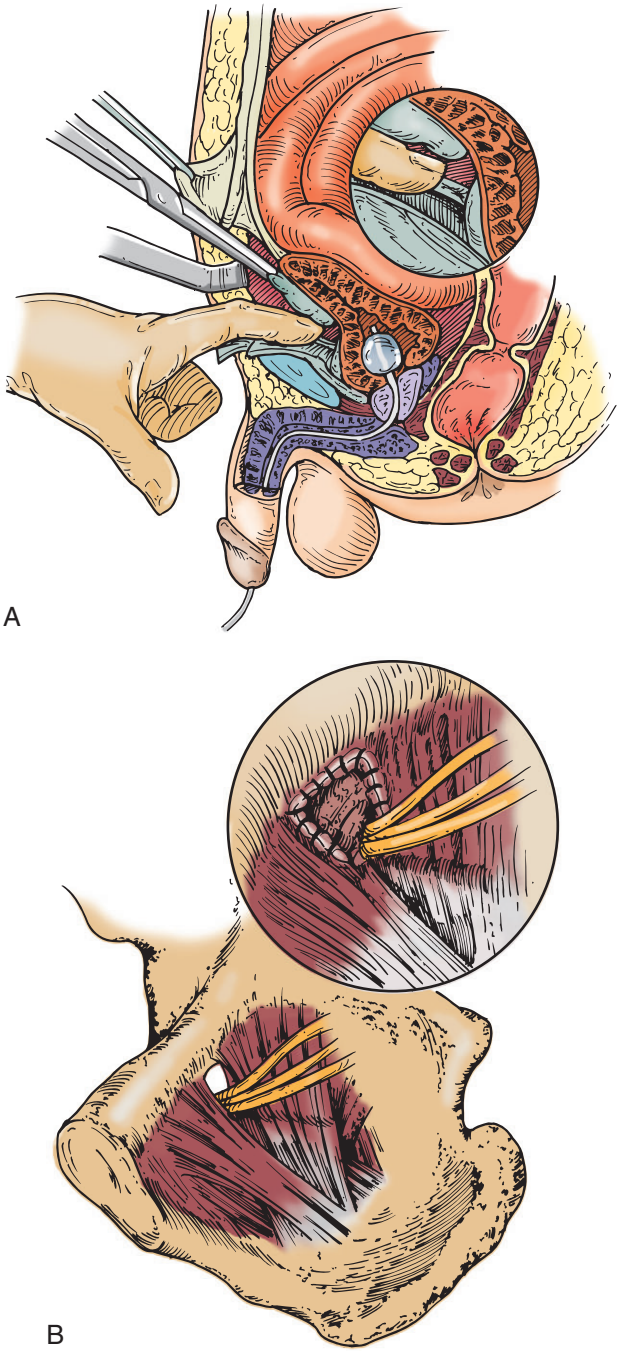

FIGURE 9 **A,** Exploration of the retropubic space. *Inset:* Identification of the structures that pass through the obturator canal. **B,** A relatively large defect of the obturator canal. *Inset:* Closure with the use of mesh. *(Originally from Skandalakis LJ, Gadacz TB, Mansberger AR, et al:* Modern hernia repair: the embryological and anatomical basis of surgery, *New York, 1996, Parthenon Publishing Group, pp 286–296, with permission. of obstruction without evidence of bowel necrosis, ischemia, or contamination. TAPP and TEP approaches have been described and are similar in technique as for inguinal hernia repair. For the TAPP approach, the obturator space is exposed via a parietal peritoneal incision and flap creation. In the TEP approach, the preperitoneal fat overlying Cooper's ligament must be swept away with medial retraction of the bladder. Both approaches allow for easy exploration of the opposite obturator space, concomitant repair of inguinal or femoral hernias, and better visualization. The TAPP approach also allows for close inspection of the bowel to rule out necrosis, but care must be taken to completely close the peritoneal flap to prevent contact of mesh with intra-abdominal contents. Additionally, mesh must adequately cover the obturator opening. As with Spigelian and lumbar hernias, MIS repair of obturator hernias results in shorter lengths of stay, less pain, and less morbidity (i.e., fewer pulmonary complications and lower postoperative ileus rates in the case of obturator hernias).

Postoperative morbidity rates for obturator hernia repair can approach 40% given the high rates of gangrenous bowel and peritonitis on presentation. Complications described in the literature include sepsis, pneumonia, wound infection, mesh migration, fistulae, small bowel obstruction, urinary tract infection, pulmonary embolism, myocardial infarction, and congestive heart failure. Mortality can range from 12% to 70%. As a result, intensive care is often required in the postoperative period, especially following emergent presentations. Recurrence rates are fortunately low, occurring less than 10% of the time following repairs.

SUMMARY

Management of semilunar line, lumbar, and obturator herniation remains a challenge for the practicing surgeon given their uncommon nature, unusual anatomy, and high risk of incarceration. CT and US are useful modalities for diagnosing and delineating these hernias that can be difficult to identify on physical exam. Repair of these hernias is indicated when they are discovered because incarceration and strangulation of contents are not infrequent events. Fortunately, surgical options include multiple open and MIS approaches with or without the use of prosthesis. Management is guided by the clinical situation, surgeon experience, and anatomic considerations.

Athletic Pubalgia: The "Sports Hernia"

Bruce Ramshaw, MD, FACS, and
Issa Mirmehdi, MD

INTRODUCTION

The diagnosis and management of a sports hernia, or athletic pubalgia, is a complex undertaking. Even the terminology to describe the condition has been controversial, primarily because the most commonly used term, *sports hernia*, is not an accurate description of the underlying disease for most cases. For most patients who are diagnosed with a sports hernia, no true hernia defect is present. The management can be a long and frustrating process, and the decision to proceed with more aggressive treatment, including surgery, can be complex. The basic strategies and techniques for surgical management also vary, and although most patients do well with surgical management from those surgeons who are experienced treating this condition, regardless of the technique, there are also failures with all approaches. This chapter discusses the background, diagnosis, and management of a sports hernia, and it presents a concept for learning and improving care for treating complex conditions such as sports hernias.

BACKGROUND

Sports hernia or athletic pubalgia is defined as chronic groin pain (lasting more than 6 to 8 weeks without improvement or the patient not able to return to normal activities) in an individual who frequently engages in athletic and/or strenuous activity. It is diagnosed in the absence of a palpable hernia and when other causes of inguinal pain are excluded. Due to the lack of a visible or palpable hernia defect, this syndrome has not been well understood by many general surgeons. Only recently, perhaps due to the increasing media coverage about professional athletes whose careers have been interrupted or ended as a result of this condition, attempts to better understand the complex nature of sports hernia have been made. Although this condition has been popularized by the experience of professional athletes with this condition, it also affects athletes in college and high school, as well as recreational athletes and people who perform other strenuous activities.

In 1980, Gilmore (Gilmore OJ, 1991) recognized chronic groin pain in professional athletes, mostly soccer players, and undertook to surgically repair the disruption. This condition was subsequently referred to as Gilmore's groin. A similar condition was also reported in Europe and Australia. Many investigators have described the chronic lower abdominal and groin pain in professional athletes as a syndrome secondary to muscular injury or incipient inguinal hernias. In 1991, Taylor and colleagues (Taylor D, et al., 1991) concluded that while the majority of groin pain in athletes was caused by muscle strains, inguinal hernias, or subclinical abdominal wall defects without herniation, in a smaller subset of cases there was no palpable hernia or any other cause of groin pain. Following the terminology used in the European literature, they referred to this condition as *pubalgia*.

ANATOMY, PATHOPHYSIOLOGY, AND DIFFERENTIAL DIAGNOSIS

Etiology

Gilmore identified torn external oblique aponeurosis, torn conjoint tendon, and dehiscence between the torn conjoint tendon and inguinal ligament as the underlying causes of chronic groin pain. Meyers and colleagues (Meyers W, 2007) suggested that hyperextension injury with the pivot point being the anterior pelvis or pubis symphysis is the most likely etiology of sports hernia. Tendons of the rectus abdominis and adductor longus insert on the pubis symphysis so they pull against each other. This anatomic apparatus, when combined with sport activities that involve rapid pelvic movements such as hyperextension, can potentially injure weaker abdominal wall muscles. This group has documented over 20 distinct anatomic defects from magnetic resonance imaging (MRI) results with surgical recommendations based on each abnormality.

A different perspective on the mechanism of sports hernia focuses on the notion that the syndrome is an incipient hernia, with the defect being in the transversalis fascia comprising the posterior wall of the inguinal canal. Polglase and colleagues found substantial derangement in the posterior wall of the inguinal canal in 61 out of 72 professional athletes, mostly Australian Rules football players who presented with chronic groin pain and underwent surgical exploration of the inguinal canal.

While a general consensus on the complex nature of sports hernia is yet to be established, a third viewpoint combines both mechanisms of muscle tear and incipient hernia and categorizes this condition as one component of a broader pattern of "groin disruption injury." According to this school of thought, sports hernia is an occult or incipient direct hernia, which is derived from pelvic instability. This underlying mechanism also gives rise to other groin syndromes such as osteitis pubis, conjoint tendinopathy and/or tear, adductor tendinopathy and/or tear, and nerve entrapment and/or irritation of the variety of nerves in the groin and pelvic area.

People at Risk

A sports hernia is more likely to occur in athletes who engage in sports that require sudden turns and pelvic movements and/or those that require the athlete to push hard against resistance. It is thought that the highest prevalence occurs in athletes who are professional soccer players, ice hockey players, and football players, respectively. Men are more frequently affected than women. However, there seems to be an increase in the number of female athletes experiencing chronic groin pain as more women engage in competitive sports. It has also been postulated that gender-specific anatomic variation may play a role in predisposing male athletes, more than female athletes, to developing chronic groin pain. Brophy and colleagues demonstrated that male soccer players tend to generate a greater activation of the iliacus muscle in the kicking limb, and this difference may contribute to a higher susceptibility to developing sports hernia. Other risk factors include limb length discrepancy, poor pelvic muscle balance, reduced hip range of motion, and pelvic instability.

Presentation and Differential Diagnosis

Patients with sports hernia present with lower abdominal pain on exertion. Most can recall a distinct injury during exertion prior to the onset of the pain. The pain is usually located in the inguinal region around the insertion point of rectus abdominis muscle on the pubis or along the course of the ilioinguinal nerve. Most patients

experience unilateral pain, although in some athletes, their symptoms begin with unilateral pain and subsequently progress to bilateral pain. The pain may also radiate to the lower abdomen, perineum, scrotum, or thigh. At rest, there is usually minimal or no pain. Valsalva maneuvers such as coughing or bearing down may sometimes reproduce the pain. Also, adduction against resistance can exacerbate the pain in some patients. The majority of these patients report that their groin pain preceded their adduction pain. Patients will experience these symptoms for many months, and some present having suffered from their pain for more than 1 year. At the time of presentation, the majority of athletes have stopped competitive physical activity, or they are limited in their ability to compete.

On physical examination, a localized tenderness can be elicited near the rectus abdominis insertion above the pubic tubercle on the affected side or on both sides, depending on the course of the pain progression. This finding is more pronounced during resisted sit-up. Additional findings may include inguinal canal tenderness or tenderness at the hip adductor origin. A pain along the adductor longus tendon on the affected side may also be elicited on forceful adduction. Occasionally, a cough impulse can be palpated at the rectus abdominis origin when the patient is standing. It is uncommon to palpate a cough impulse at the external inguinal ring. A thorough physical exam should generally rule out inguinal hernia.

The different diagnosis for groin pain without a hernia bulge can be extensive (Figure 1). The patient can have more than one condition, including inguinal (direct and/or indirect), femoral, obturator, or other more rare hernias in the groin and pelvic region. A lipoma of the spermatic cord may also be present. For most sports hernias, however, the patient is otherwise healthy, and the duration of the pain, the location of the pain, and the activities that bring on the pain will differentiate a sports hernia from other conditions.

Diagnostic Approach

Sports hernia is primarily diagnosed by history and physical examination. Most data in the literature indicate that imaging studies have relatively poor diagnostic value. However, they can be helpful to rule out other causes of groin pain and may identify specific musculoskeletal injuries causing pain in some cases.

MRI is an imaging modality that can occasionally provide helpful data in diagnosing sports hernia, particularly when the underlying mechanism is muscle or tendon tear. Yet, its reported sensitivity can vary greatly, likely due to the experience of the radiologist reading the film and to the many false positives that may occur when injuries are identified but are not actually causing the symptoms. MRI may also be helpful to rule out osteitis pubis, occult stress or avulsion fracture, and other etiologies of groin pain.

Another imaging technique that may be helpful in diagnosing sports hernia in the setting of inguinal canal posterior wall defect is dynamic ultrasonography. In this technique, the probe is placed on the medial aspect of the inguinal region, first along the plane of the inguinal canal and then perpendicular to the initial position. At each position, the patient is asked to cough or bear down, and if a defect is present, ballooning of the posterior wall of the inguinal canal will be present.

Computed tomographic (CT) scan or plain radiograph are usually normal in patients with sports hernia. They may, however, provide information to rule out bony fractures or other causes of pain.

MANAGEMENT

Nonsurgical

Most cases of groin pain in athletes will resolve with conservative management strategies. When pain does not resolve after 6- to 16-week period of rest and conservative management strategies, surgery is often the most definitive management for patients with a sports hernia. Conservative management includes rest, core strengthening exercises, stretching, and antiinflammatory medications. The initial rest period is usually 1 to 4 weeks, and during this period, the athlete may receive steroids or platelet-rich plasma injections to the rectus abdominis, adductor longus origin, or both. If injections are not desired, the patient may receive a short course of oral steroids, which is quickly tapered. At the end of the 4-week period, a functional trial of an athletic regimen appropriate for the athlete's sport is performed to evaluate the patient's response to the conservative management. Core strengthening exercises may emphasize the development of a strong single-limb stance and pelvic rotation exercises against resistance. Some of the works listed in Suggested Readings describe in more detail the prophylactic and conservative physical training exercises and strategies to prevent and manage sports hernias nonoperatively.

Surgical

There are a variety of surgical approaches based on the philosophies about the causes and the documented pathologies found for patients with a sports hernia. We present the laparoscopic approach first, and then the various open methods are described.

Laparoscopic Approach

The concept behind a laparoscopic approach for sports hernia is to reinforce the groin from the inside or behind the groin to block intra-abdominal pressure and allow healing of any musculoskeletal injury. This approach may be most helpful for patients with groin weakness and occult hernias, which might contribute to the patient's symptoms. Although a total extraperitoneal approach is used typically, a transabdominal approach may be used in patients with atypical pain or two different types of pain for which a diagnostic laparoscopy may be indicated.

The technique involves exposure of the entire myopectineal orifice, including reduction of any preperitoneal fat from the indirect space (lipoma of the cord), the femoral space, or obturator foramen. Other rare hernias of the groin may also be visualized and reduced. The most common finding during a laparoscopic approach is a weak transversalis over the direct space. Occasionally actual tears can be visualized. A mesh is used to cover the entire myopectineal orifice and provides a barrier to intra-abdominal pressure that may contribute to the lack of healing of the groin. This would also cover any true hernia defect. The type of mesh used may be extremely important. Chronic groin pain after mesh hernia repair can be a devastating complication. Our hernia program has evaluated hundreds of mesh explants, and for the patient with a sports hernia, we now offer a variety of alternatives to the standard heavyweight polypropylene mesh. The wider-pore, lightweight polypropylene mesh has become a popular option. There are also other polymers, such as polyester, which is relatively hydrophilic, and nonwoven polypropylene and coated polypropylene, both of which may result in less inflammation and better biocompatibility. Today, long-term resorbable meshes (synthetic and biologic) are available that can provide the necessary support for the groin during healing and recovery and will resorb over many months or years to leave no permanent material in the groin. We provide patients with these options with the most current information available so they can make their own decision. A polyester mesh and a long-term resorbable synthetic mesh used for sports hernia repair are shown in Figures 2 and 3. Fixation of mesh may include no fixation, absorbable tack fixation, or glue fixation. Although permanent tack or staple fixation might be used, this may increase postoperative pain.

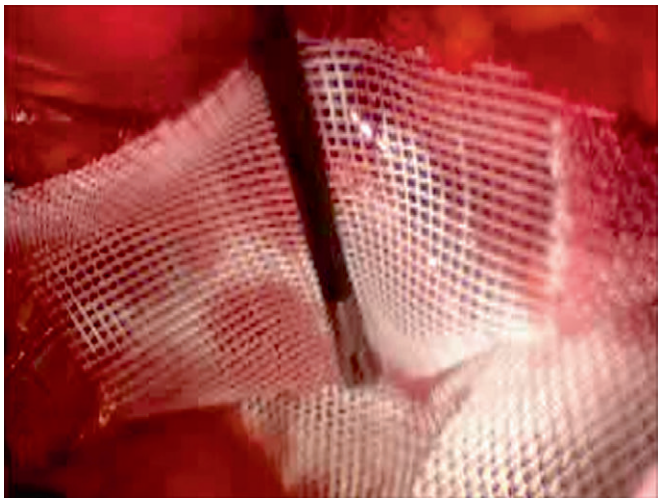

FIGURE 2 A polyester mesh used for laparoscopic sports hernia repair of the right groin.

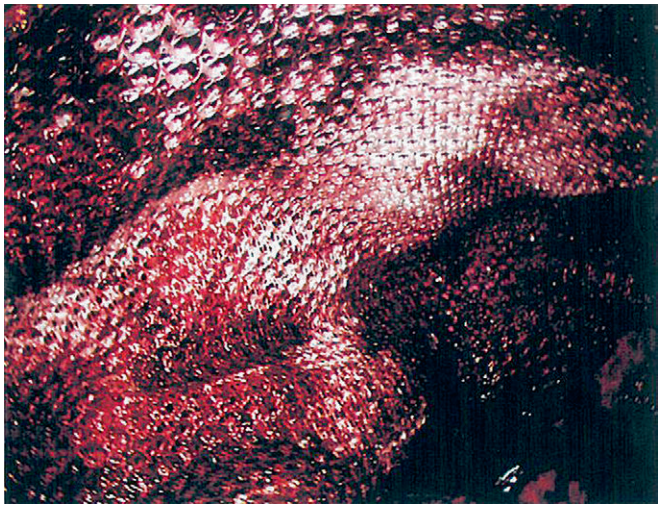

FIGURE 3 A long-term resorbable mesh used for laparoscopic sports hernia repair of the left groin.

Open Mesh Approach

Similar to the laparoscopic approach, the focus of an open mesh placement is to reinforce the floor of the groin to allow for groin stability and musculoskeletal healing. A lightweight polypropylene mesh is typically used and placed similar to a Lichtenstein approach for inguinal hernia repair. Other mesh alternatives described for the laparoscopic approach could also be utilized. One advantage of the open mesh approach is the opportunity to divide the genital branch of the genitofemoral, the ilioinguinal, and/or the iliohypogastric nerves if they are observed to be entrapped in scar tissue or in the tissue disruption caused by musculoskeletal injury. Alternatively, a neurolysis may be performed if a scar tissue release appears appropriate.

Open Nonmesh Approaches

A variety of open nonmesh approaches have been described. One approach popularized by Muschaweck (Muschaweck U, 2010) is presented as an open "minimal repair" technique. The procedure involves a repair of the posterior inguinal floor with two running sutures, including lateralization of the rectus muscle with the second suture. Selectively, the genital branch may be divided if it is impinged by the scar or damaged tissue. The internal ring is reinforced with a buttress of internal oblique muscle to protect the pampiniform plexus.

Myers has presented a more targeted approach to repair of the groin with a variety of techniques utilized, depending on the finding on the MRI and at surgery. General descriptions of these approaches include a variety of repair, release, and excision procedures that may include the reconstruction of the rectus abdominis to the pubis and a selective adductor tenotomy as indicated by the radiographic, clinical, and surgical findings. An adductor tenotomy may include a partial release of the fibers approximately 1 to 2 cm from its attachment to the pubis. Transection with or without reattachment of the adductor longus has also been described.

Postoperative Course

In general, the postoperative recovery is quicker with the less invasive approaches. The laparoscopic approach is the least invasive and has the quickest recovery, with the open reconstructive approaches often requiring the longest recovery. Many factors, however, can impact recovery. The degree of preoperative pain; the nature of the athletic activity; and the decisions of the athletic trainer, athlete, team owner, coach, and so on all may play a role in the timing of return to full activity. In general, athletes may return to light activity in the first 1 to 2 weeks and may try their regular training regimen within 1 to 4 weeks. After appropriate strength, endurance, and flexibility are obtained, return to full competition is appropriate. For very high-level athletes, appropriate game conditions may be simulated to test the appropriateness of a return to full competition.

Clinical Quality Improvement

As mentioned, when performed by surgeons with experience treating sports hernias, all of the procedures described achieve a relatively high rate of success in returning an athlete to his or her sport. However, all of these techniques have failures as well. This demonstrates the reality that a sports hernia, like most problems in health care, is a complex medical problem. For complex problems, a one-size-fits-all solution will not work for every patient. In addition, the most aggressive, costly treatment cannot be used for every patient due to wasteful use of limited resources. The ideal situation would be to learn which patient subpopulations would be best treated with nonsurgical approaches, which would be best treated with minimally invasive approaches, and which would require the most aggressive or costly approaches requiring the longest recovery.

A relatively new science is now being applied to health care that can begin to determine the appropriate indications for the various presentations of complex medical problems such as the sports hernia. Complex adaptive systems science concepts have produced the principles of continuous learning and clinical quality improvement (CQI) in health care. The first step in applying CQI is to define the dynamic processes of care for the entire cycle of care for a specific complex medical problem. In this case, the processes of care would be defined for an athlete from the time of the initial symptom of groin pain until the ability to return to full competitive activity with no future incidence of groin pain. All appropriate treatment options would be included in the dynamic care processes, and the outcomes measures that determine the value of care would be determined and documented. These outcomes measures would include the costs for the entire cycle of care; the quality of the outcomes measure, such as the relief of pain symptoms after treatment; and the patient's and family's experiences with their care. By defining and documenting the care processes and measuring the outcomes that determine the

value of care, we can then use these results to provide feedback to improve the processes of care iteratively over time. With more and more data and experience, this will allow for a better understanding of what the best value of care will be for what type of patient.

Another element of complex adaptive systems science applied to health care is the emergence of care communities on the Internet for guidance in caring for complex medical problems such as sports hernias. Through websites, blogs, chat rooms, and other communication methods, more and more people experiencing the symptoms of sports hernias are sharing their stories and experiences with symptoms and treatments. For complex medical problems, these groups and this body of information have been a relatively untapped resource as we strive to improve the value of care for sports hernias and other complex medical problems.

SUMMARY

Sports hernias are complex problems that can be very frustrating for athletes suffering from pain and the inability to return to an activity they enjoy. This is usually a quality of life issue, but for high-level athletes, this can also be a serious economic problem as well. More information about this problem is coming forth, both in the traditional medical literature as well as through emerging care communities on the Internet. As with any complex medical problem, we must apply new scientific thinking to better understand which patients will receive the most value from the variety of surgical and nonsurgical treatment options available and to develop innovative strategies to attempt to prevent this condition and to continuously improve the value of care for this group of patients.

Abdominal Wall Reconstruction

Anthony P. Tufaro, DDS, MD, FACS, and Kurtis A. Campbell, MD, FACS

The need for complicated reconstruction of the abdominal wall is a growing problem in many hospitals large and small. Improvement in trauma care, oncologic surgery, and critical care of surgical patients has led to a host of new problems. Survival of these patients has demanded a comprehensive approach to reconstruction and rehabilitation of the devastated abdominal wall. The problem list that needs to be reviewed includes enterocutaneous fistulas, loss of domain, loss of soft tissue coverage, chronic infection and colonization, deconditioning of the patient, and long-term disability. The trunk is surrounded by a very well designed multilayered wall that first and foremost protects the solid and hollow viscera from injury. The wall, made up of skin, fat, fascia, muscle, and peritoneum must be impervious to water, flexible, resistant to trauma of all kinds, and capable of expanding, contracting, and helping resist infection from the inside environment as well as the outside world. Any attempt at reconstruction of the abdominal wall must take all of these things into consideration and try to incorporate as many of them as possible into the new construct.

ANATOMY

The composite nature of the abdominal wall demands that a number of specialized tissues must work in concert to maintain normal function.

Skin and Adipose Tissue

The skin is the first line of defense for the deeper structures. The skin is the primary barrier to infection, and is vital for fluid control and temperature regulation (Figure 1). The loss of abdominal wall skin may be the result of thermal injury, avulsive trauma, oncologic resection, and necrotizing soft tissue infections and chronic wounds associated with unstable soft tissue coverage. Perhaps the most common cause of skin "loss" seen in patients requiring reconstruction is a relative loss. If we take the patient who suffers an abdominal

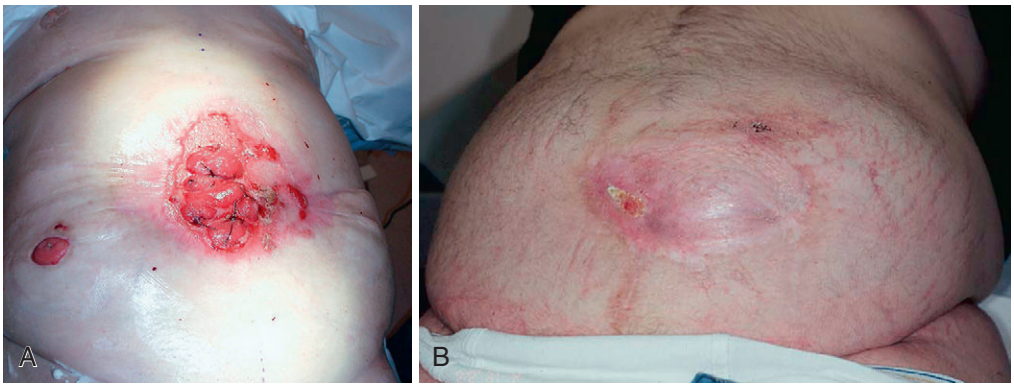

FIGURE 1 **A,** A devastated abdominal wall with small bowel fistulae. The problem is complicated by the loss of stable skin and soft tissue coverage. **B,** Unstable skin coverage associated with skin graft on bowel and chronic draining wound.

catastrophe of any etiology, subject them to 6, 8, or even 10 hours of surgery or more, administer many liters of colloid and crystalloid fluids, and then attempt to close this multilayered structure over the viscera, we quickly see that it becomes an impossibility. The management of the open abdomen is now a relatively common problem. The longer-term problem of skin retraction and fibrosis is a challenge that can be quite vexing. If the deeper structures can be advanced over the viscera, and fascia and muscle are intact, then the problem can be solved with a split-thickness skin graft on a healthy bed. Fluid loss, infection, the need for complex dressing changes, and disability will be cured in short order. The subcutaneous fat has a protective function in that it offers padding and thermal protection. The loss of the fat layer will not be of great consequence in the short term. However, the skin graft will be tighter and can restrict the movement of the underlying muscles. The skin graft without the fat layer will not be able to move freely and will be fixed to the muscles, fascia, or both. There will be a cosmetic depression at the site of fat loss. If the fascia and muscle are closed over abdominal cavity contents, hernias should not be an acute problem.

The cosmetic and some of the functional problems of skin grafts, which some patients find unacceptable once their major medical issues have been solved, can be addressed with secondary procedures such as excision of all or part of the graft and closure of the defect created with advancement of adjacent skin and subcutaneous fat. Tissue expanders can be placed in an effort to increase the available lipocutaneous coverage to attain a primary closure after excision of the skin graft.

Fascia

Fascia is an important component of the multilayered nature of the abdominal wall. The abdominal wall musculature functions within the tough fibrous envelope of the fascia. The fascia of the rectus sheath is formed mainly by the aponeuroses of the external oblique, internal oblique, and transversus abdominis muscles. The aponeuroses join to form the linea semilunaris at the lateral edge of the rectus and pass anterior and posterior to the rectus abdominis muscles. The posterior rectus sheath ends at the arcuate line, which is often described as being found 2 cm cranial to a horizontal line drawn between the anterior superior iliac spines. The fascial sheaths meet and intersect in the midline at the linea alba, which runs from the xiphoid process to the pubic symphysis. This concept of paired lateral muscle groups exerting forces on and across paired vertical muscles and fixed together in the midline is important in understanding the concepts of loss of domain, functional shortening of muscles, and reconstruction failures.

Fascia is a difficult material to replace. Fascial grafts from the legs (fascia lata) were used extensively in the past. With the advent of freely available, large sheets of acellular dermis, both allograft and xenograft, the need for the morbidity of harvesting fascia from the legs has almost been eliminated. These acellular dermal matrices act as a biologic substitute. A true loss of fascia is fairly unusual. This is primarily seen when fascia is directly excised, as seen in tumor resection such as desmoids and sarcomas, or necrotizing soft tissue infections. The majority of cases of fascial loss are actually relative losses due to retraction of the fascial edge secondary to the unopposed action of the lateral muscles. The layered lateral muscular wall inserts at the linea semilunaris and will exert a lateral vector on the rectus muscle when the linea alba closure fails in the midline. This midline hernia will assume a "C" shape with the rectus muscles fixed at the xiphoid and pubic symphysis. The muscles will not function as efficiently at their new shorter working length. There will be fibrosis of the muscle, scarring of the soft tissue, and a relative lack of fascia in the midline. As more and more viscera exits through the hernia, a loss of domain will develop with a resultant inability to return the viscera back into the abdominal cavity and close muscle and fascia over the top (Figure 2). The release of the lateral fascia and musculature, via a component separation will allow the rectus fascia and muscles to be brought together in the midline.

Muscles

The paired muscle groups of the abdominal wall are designed to work together for the most efficient functioning. As discussed in the previous section, when a group of muscles is allowed to function independent of the stabilizing action of its mirrored group, dysfunction and lack of coordinated movement ensue. A true loss of muscle tissue is most commonly seen in the case of tumor resection or soft tissue infection requiring débridement (Figure 3). The dynamic action of the muscle is not easily replaced. The gap left by the loss of muscle tissue can be closed using any prosthetic material of choice; however, this will be a static patch replacing a dynamic structure. Replacement of muscle tissue with dynamic muscle tissue would require a free tissue transfer with motor nerve repair. This is not practical and is not done.

Peritoneum

The peritoneum represents a unique serous membrane that lines the abdominal cavity and is reflected over the contained viscera. In its undamaged state, it allows the viscera to glide freely against the wall of the abdominal cavity and the adjacent viscera with the least possible friction. Violation of the peritoneum can and does lead to adhesions of the viscera to adjacent structures. This is exacerbated by acute and chronic inflammation, as is often seen in patients requiring abdominal wall reconstruction. There is no practical way to reconstruct the peritoneum when there is a relative loss of this tissue, as in the case of the open abdomen or the large ventral hernia with a loss of domain. The important point is that this specialized tissue

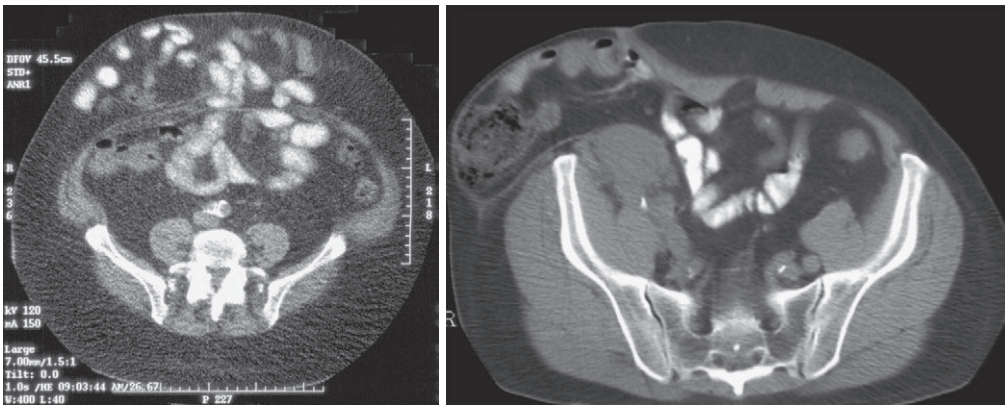

FIGURE 2 Large ventral hernia with loss of domain.

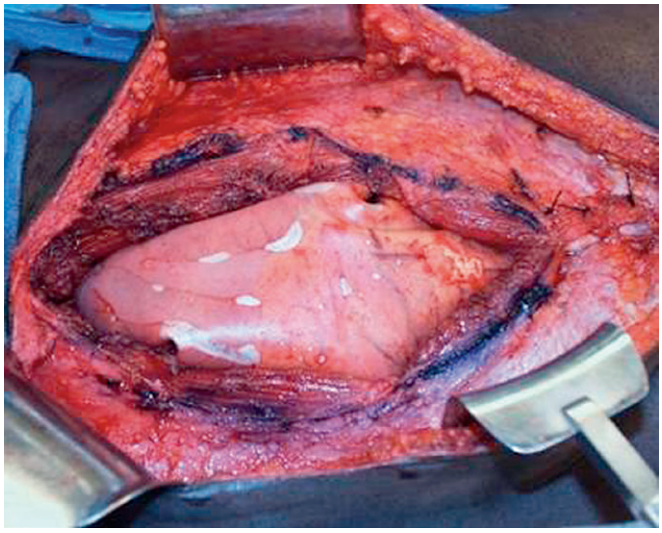

FIGURE 3 Defect of abdominal wall following tumor resection. Resection of rectus abdominis muscle and associated fascia.

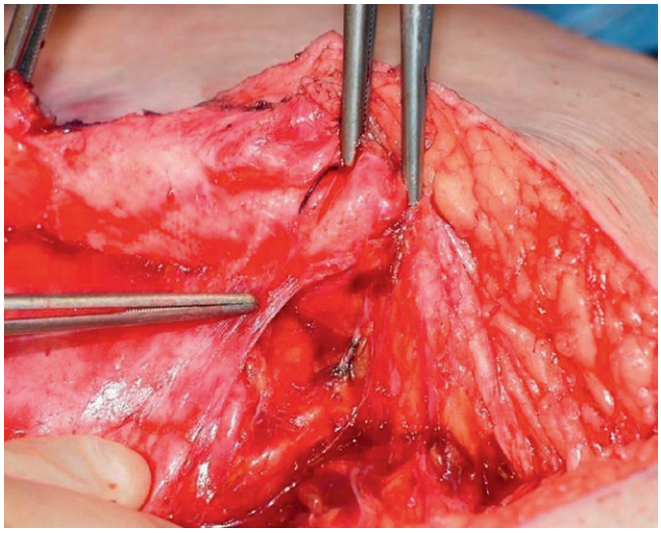

FIGURE 4 Adhesions secondary to prosthetic mesh placed in contact with viscera.

protects the delicate abdominal viscera. Any reconstruction must address this, and care must be taken so that materials that may be in contact with the viscera cause a minimum of inflammation. Prosthetic materials such as polypropylene cause inflammation, adhesions, and fistulae if placed in direct contact with the bowel (Figure 4). It is our policy always to obtain biologic tissue coverage over the viscera prior to placing any prosthetic mesh. This can be autologous or allogeneic.

PATIENT EVALUATION

The patient who presents for abdominal wall reconstruction often presents with multiple problems that must be addressed if there is any hope of reasonable long-term outcome that includes durable anatomic reconstruction, restoration of thoracoabdominal dynamics to allow high levels of activity, and satisfactory quality of life. The etiology of the defect is important. Is the patient an otherwise healthy young individual who sustained a gunshot wound or a morbidly obese patient who underwent an oncologic surgical procedure and went on to have an open abdomen with skin graft on the bowel? The initial evaluation should include a computed tomographic scan with oral and possibly intravenous contrast. Problems such as fistulae, abscesses, stoma issues, and history of obstruction will need to be addressed either before or at the time of the definitive reconstruction. Something as ubiquitous as cholelithiasis must be considered prior to final reconstruction. A thorough understanding of the problem list is an absolute requirement for success. Begin with evaluating what is missing and why, starting in a layered fashion. Is there a skin defect, actual or relative? Can the myofascial layer be advanced to close the hernia? Is the bowel in continuity? These things should be understood prior to entering the operating room.

APPROACH TO REPAIR

The term *abdominal wall reconstruction* usually implies multiple problems that need to be addressed. Often there is a large defect of the myofascial component with unstable skin coverage. The myofascial deficits may be secondary to resection or retraction and scarring. The major question to be asked is can the native tissue be closed over the viscera? Attempting to obtain a primary fascial closure in the face of a large composite defect can almost ensure recurrence of the hernia. The closure of the tissues under excessive tension leads to necrosis at the suture line, increased intra-abdominal pressures, and recurrence with a larger defect. In many cases of relatively smaller defects, the skin and subcutaneous tissue can be elevated off of the fascia for the full length of the midline incision. Care must be taken in the face of stomas and multiple parallel and/or crossing incisions. By separating the lipocutaneous layer from the myofascial layer,

the components can now move independently of each other. Often, previously placed prosthetic materials are the source of ongoing problems of infection and unstable skin coverage (Figure 5). This prosthetic material will need to be removed.

Fascial Closure

If undermining and separation of the skin and subcutaneous fat from the myofascial layer does not allow for fascial closure without tension, a thorough understanding of all the available options will need to be reviewed.

Freeing of the skin and fat from the fascia will allow for evaluation of the abdominal wall areas at risk. Care must be taken when undermining the lipocutaneous layer. The aggressive elevation of the tissue can compromise the vascular supply to large areas of the abdominal wall. Approach perforating vessels carefully and preserve as many as possible. Areas of attenuated fascia or previously unidentified hernias can be addressed at the time of reconstruction. Lysis of intra-abdominal adhesions is also an important factor in getting the fascia closed. The deep surface of the abdominal wall musculature must be evaluated for defects, foreign material, and adhesions. The fascial edges are then approximated without tension. As much of the cranial and caudal fascia as possible is closed. The retraction of the fascia is maximal in the center of the C-shaped defect. This area is best addressed with a biologic "inset" (Figure 6). This will replace the viscera back into the peritoneal cavity with a "no tension" fascial closure.

The list of choices of implant material for the fascial patch grows longer every day. An understanding of some basic principles is important. We can consider the choices to be broken into two main divisions: biologic and synthetic. The biologic implants can be autologous, but, as mentioned earlier, the widely available allografts render autologous choices somewhat unimportant. The use of a biologic implant is advisable in contaminated fields. Many patients who present for reconstruction have open infected wounds and chronic bacterial colonization. Patients who will require bowel resection, stoma revision, or have large enterotomies at the time of reconstruction should be managed with a biologic of choice. We place our biologic inset at the time of the initial reconstruction and obtain stable soft tissue coverage (skin and subcutaneous fat) over the abdominal wall. The implant is fixed to the native fascia with interrupted mattress sutures set back about 2 cm from the edge of the defect. This ensures that if one suture fails, there is not a total loss of integrity of the construct. We do not consider the biologic implant to render long-term stability; failure is often seen at the interface of the inset with the native tissue. Furthermore, the concept of a static implant material fixed to dynamic abdominal wall musculature is a problem that is not solved by using a biologic implant alone. The patient is advised to have a planned return to the operating room in 3 to 4 months. At that time, the now stable soft tissue is opened, and a sheet of polypropylene mesh is used to cover the biologic implant and fixed to the fascia of the anterior abdominal wall across the entire area at risk. In cases when there is no significant contamination, the biologic implant will be placed and then a sheet of polypropylene mesh is placed over the abdominal wall. The mesh is quilted in place with multiple sutures (Figure 7). The mesh is also quilted to the biologic implant. The quilting ensures rapid soft tissue ingrowth to stabilize the two materials and decreases the chance of fluid accumulation between the mesh, the native tissues, and the biologic implant. The idea of wide coverage with mesh and fixation to stable structures outside the area at risk allows for a transfer of lateral forces from the midline to the mesh and thus the entire abdominal wall. Often the lipocutaneous flaps will be sutured to the mesh, again in an effort to encourage rapid tissue ingrowth and eliminate the possibility of large fluid accumulations. Multiple large closed suction drains are used.

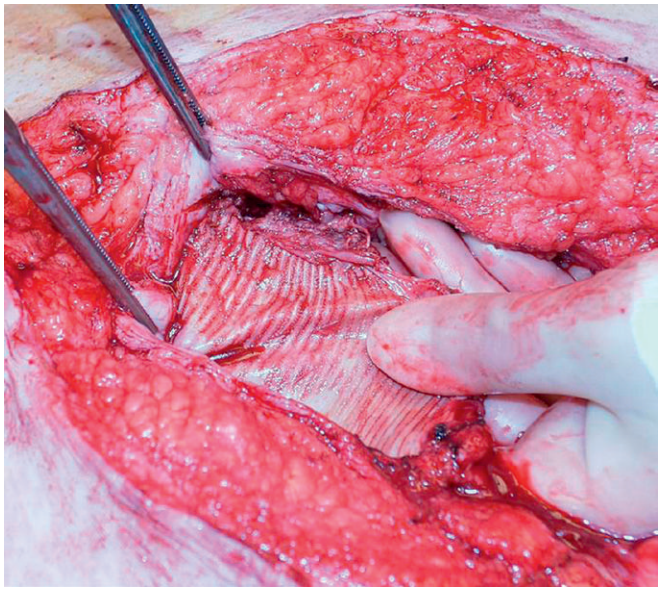

FIGURE 5 Multiple layers of prosthetic material with chronic draining wound.

Fascial Defects

The inability to close the fascia is not an uncommon situation. The retraction of the fascia can be addressed with an inset of acellular dermis as described previously. The other widely used option is the use of component separation. A lateral release of the external oblique should not be mistaken for a component separation. Ramirez and

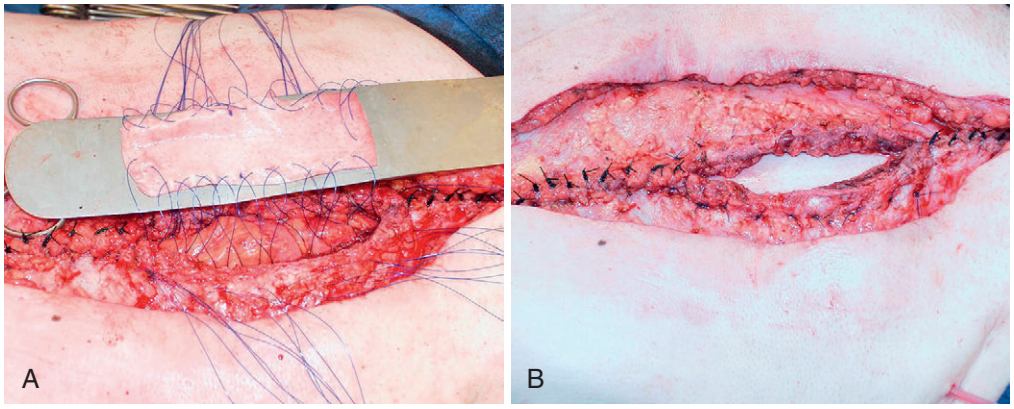

FIGURE 6 **A,** Placing sutures for acellular dermal inset. **B,** Acellular dermal inset in position.

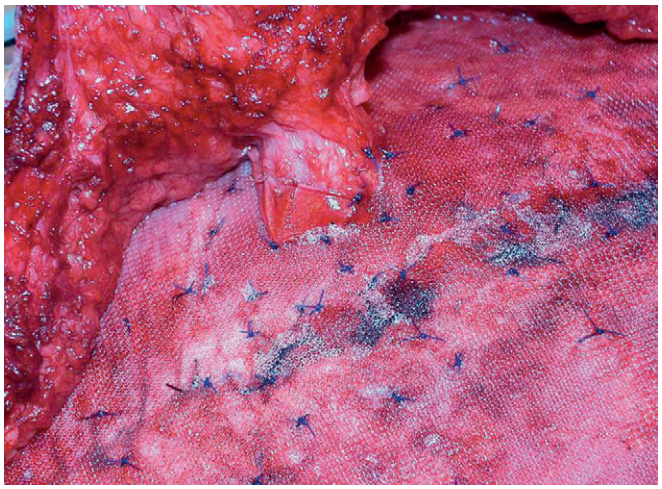

FIGURE 7 Quilted mesh onlay.

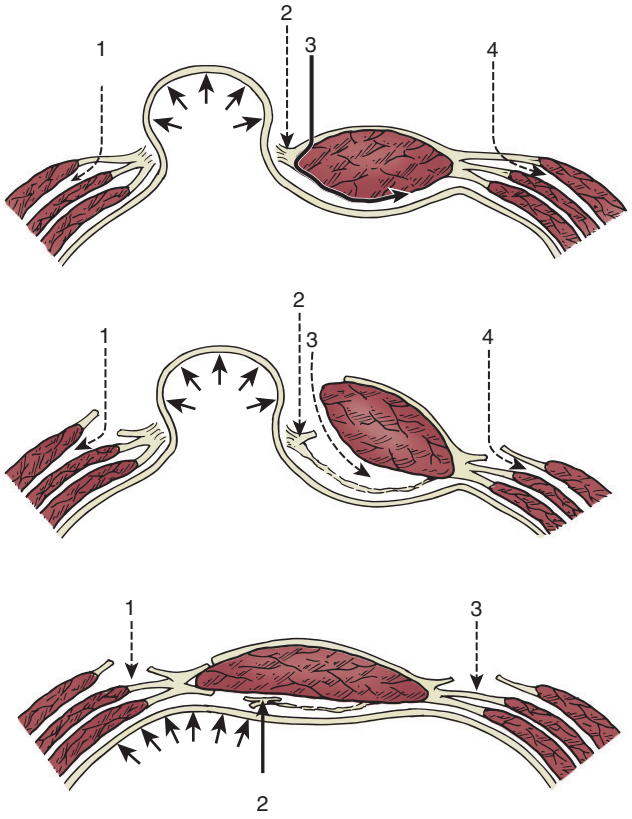

FIGURE 8 Component separation. *1,* Separation of the external oblique muscle from the underlying internal oblique. *2,* The internal oblique muscle is adherent to the transversus abdominis muscle. *3,* The rectus can be easily separated from the posterior rectus sheath. *4,* The anterior rectus sheath is adherent to the rectus muscle at the tendinous inscriptions above the umbilicus. The segmental neurovascular bundle of the rectus muscle travels in the deep surface of the internal oblique muscle, between this and the transversus muscle not at its lateral margin but at a variable distance (10-25 mm) from the margin close to the axis formed by the deep superior and inferior epigastric arteries. The external oblique muscle alone can be advanced toward the midline 2 cm in the upper and lower third, and 4 cm in the middle third in the midline around the waistline. Each rectus muscle with the overlying rectus sheath can be advanced 3, 5, and 3 cm, respectively, in the upper, middle, and lower thirds. For this advancement to occur, the muscle has to be removed from its encasement in the posterior rectus sheath. The rectus muscle with the overlying rectus sheath and its attached internal oblique and transversus muscles can be advanced 5 cm in the epigastrium, 10 cm at the waistline, and 3 cm in the suprapubic region. *(From Ramirez OM, Ruas E, Dellon AL: "Components separation" method for closure of abdominal-wall defects: an anatomic and clinical study,* Plast Reconstr Surg *86:519, 1990.)*

colleagues first described the technique of component separation with their landmark publication in 1990. Multiple variations on the original technique have been tried, but the original description still appears to be the most widely used and effective (Figure 8). The basic technique is predicated by the fact that the external oblique muscle can be separated from the internal oblique muscle in a relatively avascular plane. Once the external oblique is released, the rectus abdominis muscle can be separated from the posterior rectus sheath. The muscle will be held in place to the anterior sheath by the muscular inscriptions. The external oblique fascia is carefully separated from the linea semilunaris just lateral to its insertion into that structure. Careful dissection will release the external oblique muscle and its restricting fascia from the internal oblique and transversus abdominis muscles. They will remain attached to the linea semilunaris. The entire composite construct of muscle and fascia can be moved to the midline. With the release of the external oblique muscle and fascia, the rectus muscle and fascia can be moved medially 10 cm at the waistline. Because the muscle and fascia are fixed to the ribs cranially and the pubic symphysis caudally, one can expect to achieve 5 cm of medial movement in the epigastrium and 3 cm in the suprapubic area. In our experience, the component separation can get significant midline defects closed; however, there is a price to be paid. The procedure can lead to significant lateral "bulges," particularly in larger patients. We will onlay polypropylene mesh out past the medial edge of the now released external oblique. The mesh is then fixed across the abdominal wall from xiphoid to pubic symphysis with a quilting technique. In cases of gross contamination, we would obtain biologic closure over the patient's viscera using the component separation and close the skin/fat flaps over large closed suction drains. The plan would be for the patient to come back in 3 to 4 months when we would place a large mesh onlay to ensure the stability of the reconstruction.

In cases of a lateral fascial defect such as in tumor resection, necrotizing infection, or avulsive wound, the feasibility of using component separation alone is reduced. In these cases, the peritoneal defect is reconstructed with acellular dermis sutured with interrupted mattress sutures placed 1 to 2 cm back from the edge of the defect. This material will maintain the viscera in the abdominal cavity and separate it from the polypropylene mesh onlay. The mesh will be applied widely and fixed to stable structures such as the anterior superior iliac spine, pubic symphysis, inguinal ligament, and/or ribs. The mesh will be quilted in place for the previously mentioned reasons. By fixing the mesh to stable structures and quilting it in place, we are able to transfer the forces across the entire construct and decrease stress at the interface of the construct with native tissue (Figure 9).

PROSTHETIC MATERIALS

The choices of prosthetic materials that can be used in abdominal wall reconstruction essentially fall into two categories: synthetic and biologic. The history associated with synthetic materials extends back over 100 years to 1903 with the first reported use of a silver wire mesh. This material fell from favor quickly due to erosion, fragmentation of material, and secondary infection. Thereafter, both polyvinyl and nylon products were used. However, these were found to have unacceptable high levels of tissue reactivity and increased infection rates as well. Polypropylene was first used in this medical application

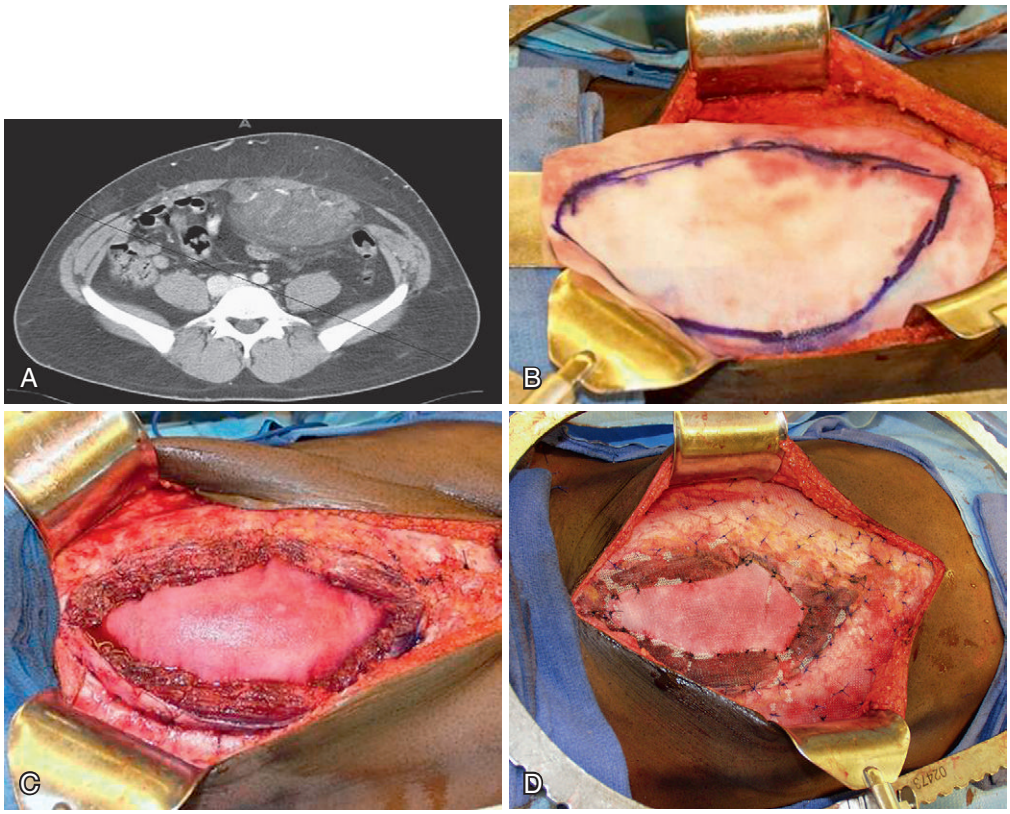

FIGURE 9 **A,** Large abdominal wall soft tissue tumor. **B,** Acellular dermal inset being trimmed to size. **C,** "Patch" sutured in place. **D,** Quilted mesh onlay for reinforcement.

in 1959. Subsequent to that, other materials such as polytetrafluoroethylene (PTFE) have been produced and used. In addition, absorbable synthetic materials, including polyglactin 910 and polyglycolic acid, have been developed and used.

Synthetic Materials

Polypropylene mesh products have been used extensively in abdominal wall reconstruction. This material results in significant tissue ingrowth and fibroblast proliferation. The typical remodeling that occurs due to the reduction of cellular content and corresponding increased production of extracellular matrix is in fact inhibited to a great extent by implantation of artificial meshes. The balance between neosynthesis and protease-mediated degradation of extracellular matrix surrounding these implanted materials remains shifted toward neosynthesis. These are important concepts in that cellular migration and cell proliferation are the basic growth factor–dependent mechanisms of wound healing. Transforming growth factor beta 1 (TGF-β 1) appears to play a prominent role in wound healing and is known as a powerful growth factor for mesenchymal cells and a growth inhibitor of epithelial cells. Low levels of TGF-β 1 terminate growth inhibition and correspondingly result in an increase in the proliferation of fibroblasts. Fibroblasts play a significant role in the formation of defective tissue in wound healing. The synthetic hernia meshes have now evolved to include lighter weight meshes, which likely offer several advantages, including increased abdominal wall compliance, reduced inflammatory reactivity, and subsequent improvement in tissue incorporation.

Sheet-like synthetic products such as PTFE have been used as well. These have been shown to reduce intra-abdominal adhesions. These laminar products are associated with decreased tissue incorporation and increased risk of seroma. This may be due to the micropore nature of these sheet-like products, which results in resistance to the passive movement of fluid through the material. The incidence of seroma may be linked to increased risk of infection as well as increased likelihood of chronic pain, in that the host inflammatory response to the implanted material may contribute to the formation of the seroma. In keeping with this, PTFE products have been shown to have a tendency to encapsulate with little tendency to integrate into the host abdominal wall. With this lack of integration into the native tissue, there is a tendency toward insufficient anchorage of the material to the underlying or adjacent fascia, leading to failure of the repair. We therefore do not recommend the use of these materials to achieve a durable long-term outcome.

Absorbable Materials

The use of absorbable products has little application in the durable reconstruction of large abdominal wall defects. They may play a role when there is no identifiable method of achieving a biologic reconstruction of a large myofascial defect over which a macroporous mesh product can then be applied to achieve a durable reconstruction. It is our preference, however, to use bioprosthetic products in that particular application.

Bioprosthetics

Many bioprosthetic products are available. In broad categories these fall into either autologous tissue versus acellular dermal products, which are available as both allograft and xenograft products. The use of autologous materials such as tensor fascia lata has been essentially replaced by the widespread availability and ease of use and handling of the off-the-shelf acellular products. Varying products have specific material processing characteristics and reported advantages. The choice, however, should be based on the surgeon's experience and familiarity with a specific product. We have used these products many times to achieve restoration of the myofascial component of

the abdominal wall when the patient's native tissue cannot be reapproximated in an acceptable fashion. Their use as a reinforcing material to address the reconstruction of the entirety of the abdominal wall may be cost prohibitive, at the present time, given the relatively low-cost, favorable material handling characteristics and known excellent tissue incorporation of other synthetic macroporous products.

CONCLUSIONS

Large abdominal wall defects may represent seemingly simple surgical problems, which are, in fact, quite complex. The techniques are simple, but the approach requires careful forethought and attention to detail to afford the patient the best possible outcome, which will be durable and lead to normal function and a high quality of life. The fact that the recurrence rates for recurrent hernias approaches 50% in patients who are at high risk should be proof enough that the management is not simple at all. The surgeon must make a comprehensive problem list at the outset. These are not challenges that are amenable to the quick fix. The execution of the operative plan must be carried out with an understanding of the causes of failure.

The procedures and details presented in this chapter are the culmination of our experience in the management of almost 500 complex abdominal wall reconstructions. We have analyzed our successes and, more important, our failures. Following the steps outlined here will help to ensure predictable outcomes and long-term success.

The Management of Benign Breast Disease

Lisa Jacobs, MD, and Rosemarie Hardin, MD

Benign breast disease accounts for a significant number of referrals to a breast surgeon and a source of substantial anxiety for patients. These conditions include mastalgia, nipple discharge, palpable solid masses and cysts, fibrocystic disease, and infections. These conditions must be appropriately managed to provide patients with the necessary care to either cure the disease or provide symptomatic relief to make them manageable. It is important to be able to discern when a coexisting suspicious pathology develops and when further imaging and biopsy are indicated.

EVALUATION OF BENIGN BREAST COMPLAINTS

The evaluation of benign breast complaints begins with a focused history and clinical breast examination. The history should include a detailed assessment of the symptoms, aggravating and alleviating factors, duration of symptoms, and presence of associated symptoms. The goal of documenting this history is not only to ascertain pertinent information to appropriately diagnose the patient's condition but also to help guide the selection of diagnostic testing that will have the most yield, especially with regard to the age of the patient. Furthermore, this information helps identify patients who are at high risk for development of breast cancer in the future and are candidates for screening. Clinicians must maintain clinical suspicion of atypical findings because patients with seemingly benign presentations could harbor findings suggestive of malignancy, and, of course, some patients with benign disease may be at risk for later development of breast cancer.

Detailed documentation of the history is followed by a thorough bilateral breast examination, including examination of regional lymph node basins. The physical examination should begin with visual inspection for asymmetries, skin or nipple changes, nipple inversion, breast edema, and breast erythema. This is followed by superficial and deep palpation in an orderly manner to carefully examine all quadrants of the breast, including the axillary tail. It is useful to ascertain whether any nipple discharge is present and to characterize it in terms of color and location, especially if it involves a single duct or multiple ducts and if a trigger point can be identified.

Diagnostic imaging is selected on the basis of clinical suspicion of the underlying cause of a patient's symptoms and includes the same studies available for evaluation of a patient with suspected breast cancer, including mammography, ultrasonography, and magnetic resonance imaging (MRI), all of which can be used with biopsy to help establish the diagnosis. It is important to consider the age of the patient as well. In a young patient with dense parenchyma who presents with typical benign symptoms suggestive of a cyst or fibroadenoma, an ultrasound study may prove more useful than mammography, which would be less sensitive with dense parenchyma. As with patients suspected of having breast cancer, negative results of imaging should not deter the recommendation of aspiration or biopsy of suspect palpable abnormalities detected on physical examination.

On occasion, imaging findings are abnormal but no changes are found on physical examination. In these cases, biopsy may be required if there are features suspect or indeterminate for malignancy. Abnormalities that can be visualized with ultrasonography should be subjected to ultrasonography-guided biopsy because this is the most comfortable positioning for the patient. If abnormalities are visible only by mammography, a stereotactic biopsy must be considered. For abnormalities identified only on MRI, MRI-guided biopsy is the only option. If the target lesion is deep in the breast along the chest wall or in a superficial location close to the nipple, or if the patient cannot tolerate the positioning for an image-guided biopsy, then a needle-localized surgical excisional biopsy may be warranted.

BREAST MASSES

Palpable breast masses are one of the most common complaints. In premenopausal women, most breast masses are benign, especially when they have been present over several months to years. However, any suspect palpable breast mass necessitates additional imaging and diagnostic biopsy. Palpable abnormalities could represent dense breast parenchyma with fibrocystic changes, cysts, lipomas, or fibroadenomas. On the basis of the initial history and physical examination findings, the differential diagnosis is usually evident. If a lesion is suspected to be cystic in nature, this can be confirmed on ultrasonography, and a cyst aspiration can be attempted. If the cyst expresses serous fluid and is completely collapsed at the end of the aspiration, no further biopsy is warranted. However, if the cyst fails to resolve completely, or if it appears to be complex in nature with a solid component, additional biopsy is warranted. If a lesion appears to be solid, benign versus malignant characteristics can be determined on the basis of imaging criteria. Benign fibroadenomas are well circumscribed and do not have spiculated, irregular margins typical of malignant lesions. These are generally identified with the aid of ultrasonography, and a biopsy sample can be obtained under ultrasound guidance. If a patient presents with a benign history with imaging findings supportive of a fibroadenoma and the mass is asymptomatic, then close observation with short-term interval imaging remains an option.

FIBROADENOMAS

The majority of palpable breast masses are benign, especially in younger women, and the most frequently encountered solid benign mass is a fibroadenoma. These lesions are well circumscribed with smooth edges and are mobile with rubbery consistency. Many patients have multiple fibroadenomas, either synchronous or metachronous. They can be mildly symptomatic, with patients complaining of tenderness or pain at the site, often worse at the time of menstruation. Fibroadenomas are believed to be hormonally sensitive and can increase in size or become more symptomatic at the time of menstruation or with hormonal changes associated with pregnancy or the use of oral contraception. They usually become less symptomatic with age and often calcify in postmenopausal women.

Ultrasonography is a useful diagnostic test for these lesions because they are more commonly diagnosed in younger women, and ultrasonography-guided biopsy can confirm the diagnosis. Small asymptomatic lesions can be observed and monitored, but larger symptomatic lesions usually warrant excision, especially when more than 2 cm in diameter. Furthermore, if a lesion enlarges rapidly or if any suspect pathologic process is associated with the fibroadenoma, such as increased cellularity of the lesion, excision is warranted in order to rule out a more aggressive variant of a fibroepithelial lesion known as a *phyllodes tumor.* Phyllodes tumors can be locally aggressive and recurrent, and wide local excision is required. Of course, as with any growing palpable mass, excision is also warranted to ensure that a breast cancer was not misdiagnosed. In summary, indications for resection include size greater than 2 cm, increasing size, pain associated with the lesion, increased cellularity on biopsy, or anxiety caused by the presence of the mass.

BREAST CYSTS

Breast cysts can also manifest as a palpable abnormality or a cause of breast pain. The physical examination usually reveals benign findings of a lesion with well-circumscribed borders, similar to a benign solid breast mass. Ultrasonography is a useful tool for diagnosis of a breast cyst. Cysts that are well circumscribed without septations or debris and have thin walls are referred to as *simple cysts.* An asymptomatic simple cyst with typical benign imaging features does not require intervention other than reassurance. If symptomatic, such cysts can be observed or aspirated in the physician's office under ultrasound or palpation guidance. Aspiration of serous fluid confirms the diagnosis of a simple cyst, and ultrasonography is used to document complete resolution of the cyst. If the cyst aspirate is bloody in nature, it should be sent for cytopathologic evaluation for possible malignancy. If the cyst has septations and is thought to be more complex with potentially a solid component or a thick wall, then tissue biopsy is warranted. This can be performed with ultrasonography-guided core biopsy, with a clip left in place to mark the location in case an excisional biopsy is warranted in the future.

BREAST PAIN

Breast pain, or *mastalgia,* remains a challenge to breast surgeons because the cause is not always clear and the symptom spectrum ranges from vague pain to debilitating pain. It may also be difficult to ascertain whether an associated pathologic process is contributing to the mastalgia, such as underlying bone disease, costochondritis, or fibromyalgia, all of which can contribute greatly to the sensation of mastalgia.

It is important to document a timeline of the patient's symptoms, alleviating and aggravating factors, associated symptoms, and whether it is cyclical in nature. The history should reveal whether the pain affects both breasts or whether the symptoms are unilateral. Breast pain can be hormonally driven, with escalation of symptoms during reproductive years or at the time of menses. Hormonally driven mastalgia may also be associated with fibrocystic breast disease. If cyclical in nature, mastalgia tends to be bilateral and diffuse in nature, and it often improves after the onset of menses. Noncyclical pain has no relation to the menstrual cycle, and affected patients therefore do not experience the relief from breast pain at the start of menses. The most common causes of noncyclical breast pain include cysts, fibroadenomas, and chest wall syndromes such as costochondritis.

Breast pain may resolve on its own with little intervention. Conservative measures are often helpful; they include well-fitted, appropriately-sized, supportive bras; warm compresses; and dietary modifications to reduce high fat intake and lower caffeine intake. Nonsteroidal antiinflammatory agents are very useful for persistent pain. Vitamin E, fish oil, and evening primrose oil may be helpful to women who suffer from mastalgia. Topical nonsteroidal antiinflammatory drugs (NSAIDs) are also a consideration for persistent, severe breast pain. It is important to realize that at times no further treatment is necessary other than reassurance and helping to reduce a patient's anxiety by explaining that breast pain is not a typical sign of breast cancer.

NIPPLE DISCHARGE

Nipple discharge is another common presenting complaint that can be quite worrisome to patients. Benign physiologic nipple discharge is present in many women; in many cases, it can be induced from several ducts by nipple manipulation, and it typically does not warrant any further evaluation. Nipple discharge that is spontaneous, recurrent, unilateral, and involving a single duct necessitates further diagnostic evaluation and, on occasion, surgical intervention. If pathologic discharge is present, evaluation should begin with diagnostic mammography and ultrasonography. Cytologic study and occult blood testing of nipple discharge is often insufficient for accurate diagnosis, and low diagnostic yield can produce misleading information. If a specific lesion is identified on imaging, then tissue biopsy is warranted for diagnosis. In some cases, ductography is a useful diagnostic study. The fluid-producing duct is cannulated and contrast material is injected. This is followed by mammography in an attempt to identify filling defects within the duct. The advantage of ductography is identification of lesions that are a greater distance from the nipple than would normally be excised by a resection of retroareolar tissue. If mammography and ultrasonography fail to identify suspect abnormalities, then an excisional biopsy of the duct is warranted. Cannulation of the duct with a lacrimal probe is often helpful. Another option is subareolar ductal exploration with duct ligation and excision. It is important to inform the patient that she may be unable to breastfeed after this procedure.

Nipple discharge is most commonly a result of benign intraductal lesions, specifically papillomas, duct ectasia, and fibrocystic breast disease, and it does not necessarily imply the presence of a malignancy. Of course, although it is rare, physiologic nipple discharge can develop from hyperprolactinemia, as can occur with a primary pituitary tumor, hypothyroidism, or medication. The discharge may be copious, bilateral, and milky, and it is typically expressed from multiple ducts. No breast surgical intervention is required, and affected patients should be referred to an endocrinologist for further evaluation.

In summary, a suspect nipple discharge is unilateral and spontaneous, comes from a single duct, and is bloody or clear. These discharges necessitate further evaluation because they may be the result of malignancy. However, even with these manifestations, the majority are benign.

BREAST INFECTION

Breast infections are more common in women who are premenopausal and those who are lactating. These infections are often very painful and manifest with systemic symptoms such as fever, malaise, and leukocytosis. Mastitis in a lactating woman is often caused by skin flora such as *Staphylococcus* infection. Such flora respond to oral antibiotics and conservative measures such as application of warm compresses if diagnosed promptly. Lactating women should be encouraged to continue breastfeeding and ensure that the breast is emptied with each feeding. However, many women present late with fluctuant abscesses that necessitate surgical incision and drainage. This procedure can be very painful, and drainage procedures should be performed in the operating room with the patient under sedation if possible, especially for larger abscesses. In view of the acidic environment of the abscess cavity, it is often difficult to attain adequate local anesthesia, which would significantly affect the ability to drain the cavity thoroughly.

Ultrasonography is useful for detecting the true extent of the abscess cavity and for evaluation of recurrent abscesses, inasmuch as these may be caused by undrained pockets or retained debris and may necessitate more formal débridement to prevent recurrence. It is important to submit the exudate to Gram stain and culture to help direct antibiotic therapy. Ultrasonography can also be a useful therapeutic modality if the breast infection is caught in early stages of development with a free-flowing collection of aspirate. Ultrasonography can be used to aspirate abscess cavities that have not organized into multiloculated collections, which are harder to drain completely. This conservative strategy, in combination with antibiotic therapy, may help prevent the need for operative intervention. It is important, however, to document resolution of the cavity after the aspiration and to ensure that there is no residual cavity or undrained loculations, which would predispose to recurrent infection.

Breast infections in nonlactating women are generally caused by bacteria introduced through the nipple. These infections are typically retroareolar and are managed with antibiotics and drainage if necessary, as described previously. It is of utmost importance to consider inflammatory breast cancer in the differential diagnosis. Patients with mastitis should quickly show some improvement in symptoms with the initiation of treatment. If the symptoms are not improving with antibiotics, then any underlying abnormality should be subjected to biopsy. Inflammatory breast cancer should always be suspected when the affected patient is nonlactating and postmenopausal and has no precipitating factors or systemic signs of infection.

ABNORMAL SCREENING MAMMOGRAMS

As technology continues to improve with better mammographic imaging, many suspect findings may be identified on mammography. These may include new microcalcifications, densities, architectural distortions, or developing masses. These mammographic abnormalities are typically not appreciated on clinical breast examination, and the patient has no symptoms. In these cases, an image-guided biopsy is necessary to establish the diagnosis and rule out a malignancy. The findings, such as typical ductal hyperplasia, are often benign and warrant no additional intervention. On occasion, biopsy may demonstrate a benign but indeterminate result. In these cases, additional tissue is needed to assess for a coexisting malignancy, which can occur in 10% to 15% of cases. Women with these indeterminate lesions should undergo an excisional biopsy with needle localization. An excisional biopsy is typically recommended for patients found to have atypical ductal hyperplasia, atypical lobular hyperplasia, papillomas, or sclerosing adenosis with radial scarring.

Similarly, lobular carcinoma in situ—which is considered a marker for increased risk of developing breast cancer but not an early noninvasive breast cancer, like its counterpart, ductal carcinoma in situ—should be subjected to excisional biopsy. The purpose of the excisional biopsy in all of these cases is to decrease the risk of sampling error. Affected women, although the biopsy finding is considered benign, should be offered high-risk screening with the goal of early detection of any subsequent malignancies. These women should also be offered antiestrogen therapies for risk reduction. Some women, however, refuse to undergo excisional biopsy after image-guided biopsy with the findings just described. Several studies have demonstrated that if mammotomy biopsy is performed instead of a core biopsy, then observation can be considered if more tissue is available for pathologic assessment and if patients did not experience adverse outcomes. However, the standard of care is recommendation of excisional biopsy.

SUMMARY

Patients with benign breast problems commonly present to surgeons for evaluation. The main goal is to establish the presence of a benign condition with appropriate history and physical examination, imaging, and, when necessary, biopsy. This protocol also helps ensure that the problems are not being misdiagnosed, which could result in missed early breast cancers, including inflammatory breast cancer, which masquerades as mastitis. Once the diagnosis is confirmed to be benign, then the decision regarding surgery is individualized to the patient according to the presence of symptoms amendable to surgical intervention. Patients require scheduled follow-up to ensue that no interval problems develop. Those with benign biopsy results that pose an increased risk for the development of breast cancer in the future should be appropriately screened for breast cancer. Patient education and reassurance are vital.

Screening For Breast Cancer

Michele A. Gadd, MD

OVERVIEW

Breast cancer is the most common noncutaneous cancer diagnosed in women, accounting for more than 1 in 10 new cancer diagnoses each year. Breast cancer is the second most common cause of death from cancer among women in the world. In 1989, the American Cancer Society (ACS), the National Cancer Institute (NCI), and nine other organizations joined to issue a uniform set of guidelines for breast cancer screening. The guidelines have remained largely intact over the years, with the addition of magnetic resonance imaging (MRI) to improve screening in subgroups of women at high to moderate risk. As a result of breast cancer screening, death rates in the United States have decreased by 30% since the 1990s.

Mammography remains the gold standard for breast imaging. The cost-benefit relationship associated with screening has become increasingly scrutinized as imaging technologies evolve and breast cancer treatment improves. Growing concern exists that increased utilization of alternative breast imaging technologies has resulted in an increased number of false-positive findings. These false-positive findings in turn lead to more imaging, more biopsies, and more costs, without a proven benefit towards decreasing breast cancer mortality. In 2009, the United States Preventive Task Force (USPTF) issued a modification of their 2002 screening guidelines. Their current recommendations have not been widely adapted, but this reanalysis of the benefits versus harm of screening is an important part of maintaining up-to-date recommendations as medical technology evolves. This chapter outlines standard screening practices and a brief description of cutting-edge technology used in diagnostic imaging.

SCREENING RECOMMENDATIONS

The American Cancer Society recommendations for breast cancer screening are maintained on the ACS web site (http://www.cancer.org/docroot/CRI/content/CRI_2_4_3X_Can_breast_cancer_be_found_early_5.asp; Table 1). For women at average risk, screening includes annual clinical breast examination beginning at age 40 years, counseling to raise awareness of breast symptoms, and regular annual mammography beginning at age 40 years. Breast self examination is an option starting at age 20 years and between the ages 20 and 40 years. A clinical breast examination should be done as part of a regular health examination at least once every 3 years.

Guidelines from the U.S. Preventive Services Task Force (USPSTF; http://www.ahrq.gov/clinic/uspstf/uspsbrca.htm) were revised in November 2009 to recommend screening mammograms every 2 years for women between the ages of 50 and 74 years and decisions to start regular mammograms before age 50 years on an individual basis, taking into account the benefits and harms (see Table 1). These recommendations have led to significant controversy, and most centers in the United States continue to follow the ACS guidelines. At this time, no finite age at which mammography should be discontinued exists. Mammograms for older women should be based on the individual and her overall health. As long as the individual is a candidate for treatment and her life expectancy is greater than 5 years, she should continue to be screened.

The recommendations for women whose risk is estimated to be higher than average include an increased intensity of screening depending on estimated risk level. High risk is defined as a more than 20% lifetime risk, and moderately increased risk is a 15% to 20% lifetime risk. Risk estimates can be obtained with one or more risk-prediction models. Women at high risk should have an annual mammogram, annual MRI, and breast examination every 6 months. Individuals with a strong family history should initiate screening 5 to 10 years before the youngest age at diagnosis in a relative. Individuals who are known *BRCA* mutation carriers should begin screening at age 25 years with MRI and add mammography at 30 years. Individuals with a moderate risk should discuss with their doctor the benefits of adding MRI screening to annual mammography.

SCREENING MODALITIES

Breast Self Examination

Breast self examination (BSE) was advocated in the past; however, recent updates have listed it as optional or have removed it from the screening guidelines. Clearly, some breast cancers are mammographically occult or develop between imaging sequences. In these cases, there is added value to a self examination, or at least recognition of a change, and medical attention soon after the abnormality is identified. Large randomized trials have failed to show a reduction in the breast cancer–specific or all-cause mortality from regular BSE in large populations of average risk. The current opinion is that evidence is insufficient to recommend for or against teaching or performing routine BSE. If patients are performing a routine self breast examination, a review of the examination and a discussion of findings during the clinical examination is worthwhile to improve an individual's technique and address anxiety.

Clinical Breast Examination

Clinical breast examination is a key component of breast cancer screening because approximately 10% to 20% of all breast cancers are not visible on screening mammography. Beginning at age 20 years, women should have a clinical breast examination every 2 to 3 years and then annually after age 40 years. If a suspicious or questionable finding is identified based on a clinical breast examination, often a diagnostic mammogram or ultrasound scan can assist in the evaluation. If the finding is believed to represent something other than normal breast tissue or a simple cyst, a biopsy should be performed, even if imaging is normal. Patients at high risk *(BRCA* mutation, family history, history of radiation to the chest wall, past breast cancer, lobular carcinoma in situ and atypia) should have a breast examination twice a year.

At the time of clinical examination, family history of breast cancer, the benefits of early detection, and the importance of regular mammography can be discussed. Although breast self examination has become an option in the ACS recommendations, it is useful to provide instruction on how to perform a self examination. This is also a time to inform individuals about the potential benefits, risks, and limitations of the breast examination. Individuals should be made aware that most questionable findings on a self breast examination are benign and that in some cases additional imaging or perhaps even a biopsy may be recommended to exclude an underlying breast cancer.

Screening Mammography

Mammography is the foundation of breast imaging and is used to screen asymptomatic women for breast cancer. Two-view

TABLE 1: Comparison of American Cancer Society (ACS) and U.S. Preventive Services Task Force (USPSTF) breast cancer screening recommendations

Variable	ACS guidelines	2009 USPSTF guidelines
Age to begin mammograms	40 y	50 y
Frequency of mammograms	Annually	Every 2 y
CBE	Annually	Insufficient evidence to assess additional benefits and harms of CBE beyond screening mammography in woman aged ≥40 y
SBE	Optional	Recommends against SBE

CBE, Clinical breast examination; *SBE*, self breast examination.

TABLE 2: Breast Imaging, Reporting, and Data System (BIRADS) classification of breast imaging

Category	Assessment	Recommendation
0	Incomplete	Need additional imaging or prior studies for comparison
1	Negative	Resume routine screening mammography
2	Benign	Resume routine screening mammography
3	Probably benign	Risk of malignancy, <2%; short-term interval follow-up at 6 months recommended
4	Suspicious abnormality	Intermediate risk of malignancy; biopsy recommended
5	Highly suggestive of malignancy	Chance of malignancy, >95%; appropriate action should be taken
6	Known biopsy-proven malignancy	Treatment of known malignancy

mammography has been shown in numerous studies to decrease the mortality of breast cancer as a result of earlier diagnosis. Screening mammograms provide two views of each breast: the mediolateral oblique (MLO) projection images the breast from a medial to lateral approach, and the craniocaudal (CC) projection images the breast from a superior to inferior view. Individuals generally stand for the test, and each breast is imaged separately. The breast is compressed between two firm plates, and the corresponding arm is raised or wrapped around the device. The technician requests that the individual withhold breathing for a few seconds while the image is taken. The use of two views allows physicians to localize an abnormality to a particular quadrant within the breast and increases the sensitivity of mammography. To help standardize reporting and recommendations, the American College of Radiology added a Breast Imaging, Reporting, and Data System (BIRADS) classification (Table 2). The BIRADS categories classify mammographic findings by level of suspicion. Each category is associated with guidelines for patient management to aid clinicians in their decision making about the need for a subsequent biopsy and follow-up recommendations.

Digital Mammography

A rapid influx of full-field digital mammography into screening centers has been seen over the past few years in the United States. Full-field digital mammography compared with screen film mammography offers the ability to maximize the performance of detection and display and the ability to manipulate contrast and brightness. These features have been shown to improve detection of low-contrast findings in dense breast tissue. Studies that compared digital with film-screen mammography in Europe and in the United States have produced conflicting results. The Digital Mammographic Imaging Screening Trial (DMIST) performed film-screen and digital mammography in asymptomatic women at the same screening encounter. The overall accuracy was similar, but the digital method was more accurate in premenopausal and perimenopausal women younger than 50 years with mammographically dense breasts and was less accurate in women aged 65 years or older with nondense breasts.

Another study was done by the Breast Cancer Surveillance Consortium (BCSC) among women aged 40 to 79 years in a large population-based cohort of community-based imaging facilities in the United States. Cancer detection rates were similar in women aged 50 to 79 years. Women 40 to 49 years with extremely dense breasts benefited the most from digital mammography.

Biopsies

The preferred method of biopsy is a percutaneous core needle biopsy or, in some cases, a fine-needle aspiration biopsy. The choice between these two techniques depends on the indications, location, and institutional cytologic and pathologic support within the clinic. In either case, a diagnosis of benign versus malignant disease and even markers for estrogen receptor, progesterone receptor, and *Her-2 neu* can be established on both types of samples with an adequate cell yield. In the case of a nonpalpable finding seen on imaging, a stereotactic core biopsy is preferred. Stereotactic biopsies are performed with a stereotactic device that allows for two-dimensional orientation and targets the lesion, which is then biopsied with a 3-mm core needle. The patient generally lies on her abdomen, and the breast is placed through a hole within the stereo table. If the abnormality is considered relatively vague mammographically, is not seen with ultrasound scan (or MRI), or is deemed too posterior or too close to the nipple or the individual breast is too small to adjust safely within the stereotactic unit, then a needle localized breast biopsy is recommended. In this case, a guidewire is placed into the breast while the patient is sitting in a chair with the breast in compression. A surgical biopsy is then performed with the guidewire for accurate targeting of the questionable lesion. When a breast biopsy is performed, pathologic and radiologic findings should be correlated. Discordance requires additional evaluation. For a BIRADS 5 lesion on imaging, if benign with needle biopsy, a surgical excision should be performed to exclude the possibility of breast cancer. Similarly, a clinically suspicious palpable finding that is mammographically and ultrasonographically occult and benign on needle biopsy should also be removed surgically to exclude breast cancer.

HIGH-RISK SCREENING

Several national medical organizations have developed guidelines and recommendations for screening women at high risk. The ACS published guidelines for screening with MRI as an adjunct to mammography in 2007 (Table 3). The National Comprehensive Cancer Network (NCCN) issued parallel guidelines followed by recommendations for mammography, MRI, and ultrasound scan jointly by the Society of Breast Imaging (SBI) and the American College of Radiology (ACR). In general, annual screening mammography is recommended for women of appropriately high risk beginning at 30 years, supplemental screening with breast MRI is recommended for a subset with very high risk, and screening ultrasound scan is recommended for women in whom MRI is unavailable. The results of a recent study with computer-simulated modeling concluded that annual MRI at age 25 years, alternating every 6 months with digital mammography beginning at age 30 years, may be the most effective screening strategy for mutation carriers.

Women at a substantially greater than average risk for development of breast cancer can be defined by a number of factors. Genetic abnormalities account for 5% to10% of all cases of breast cancer. *BRCA 1* or *2* mutation carriers have a 37% to 87% risk of development of breast cancer by the age of 70 years. A variety of models are available to predict risk. The most widely used is the Gail model, which is based on age, number of first-degree relatives with breast cancer, age of menarche, age of first live birth, number of previous biopsies (including presence of atypia), and race or ethnicity. The Claus model includes a more comprehensive family history. The BRCAPRO model is based on personal history and family history data, including breast and ovarian cancer and Jewish ancestry. The BOA-DICEA model incorporates family history of breast, ovarian, prostate, and pancreatic cancer, and finally the Tyrer-Cuzick model uses family history plus gynecologic history.

TABLE 3: American Cancer Society (ACS) recommendations for breast magnetic resonance imaging (MRI) screening as an adjunct to mammography

Recommend Annual MRI Screening (Based on Evidence*)
BRCA mutation
First-degree relative of *BRCA* carrier but untested
Lifetime risk ~20% to 25% or greater, as defined by BRCAPRO or other models that largely depend on family history
Recommend Annual MRI Screening (Based on Expert Consensus Opinion†)
Radiation to chest between age 10 and 30 years
Li–Fraumeni syndrome and first-degree relatives
Cowden and Bannayan-Riley-Ruvalcaba syndromes and first-degree relatives
Insufficient Evidence to Recommend for or Against MRI Screening‡
Lifetime risk 15% to 20% as defined by BRCAPRO or other models that largely depend on family history
Lobular carcinoma in situ (LCIS) or atypical lobular hyperplasia (ALH)
Atypical ductal hyperplasia (ADH)
Heterogeneously or extremely dense breast on mammography
Women with a personal history of breast cancer, including ductal carcinoma in situ (DCIS)
Recommend Against MRI Screening (Based on Expert Consensus Opinion)
Women at <15% lifetime risk

*Evidence from nonrandomized screening trials and observational studies.
†Based on evidence of lifetime risk for breast cancer.
‡Payments should not be a barrier. Screening decisions should be made on a case-by-case basis, as there may be particular factors to support MRI. More data on these groups is expected to be published soon.

OTHER IMAGING MODALITIES

Ultrasound Scan

Ultrasound scan is primarily used in diagnostic evaluation of findings on mammography, clinical examination, or MRI. Focused breast ultrasound scan characterizes palpable or screening-detected lesions and can be used to perform an image-guided needle biopsy of sonographically visible lesions. The role of whole-breast screening ultrasound scan was evaluated by the American College of Radiology Imaging Network National Breast Ultrasound Trial (ACRIN 6666). After screening of 2809 women at very high risk, an additional 4 cancers per 1000 women were detected with ultrasound scan alone. The downside of ultrasound scan is the increased numbers of false-positive findings that lead to an increased biopsy rate, the length of time that it takes to perform an ultrasound scan, and its user-dependant variability. There has been recent emphasis on screening with ultrasound scan after mammography in women at high-risk or with dense breast, or both, who may not meet the recommendations for screening MRI.

Magnetic Resonance Imaging

Breast MRI adds an additional element to the detection of cancer: tumor physiology. Most breast cancers display enhancement after administration of intravenous paramagnetic contrast, which makes them highly detectable. This feature largely results from tumor neovascularity and tumor-specific characteristics of these new blood vessels. Unfortunately, some hormonally active fibrocystic tissue and benign tumors may also enhance. Low specificity is a major limitation to screening MRI. False-positive callbacks are associated with additional mammographic imaging or ultrasound scan, biopsies, and interval repeat imaging, which adds to screening costs. Evolving technologies undoubtedly will improve this aspect of MRI.

The efficacy of MRI as a screening tool in patients at high risk has been validated in multiple studies. In 2007, the ACS recommended annual screening MRI as a supplement to screening mammography for women with high risk for breast cancer based on a known *BRCA* mutation or a lifetime risk of 20% to25% or greater with breast cancer risk models. On the basis of expert consensus opinion, the ACS also recommended annual MRI screening for those individuals who received radiation to the chest between the ages of 10 and 30 years; those with Li-Fraumeni, Cowden, or Bannayan-Riley-Ruvalcaba syndromes and their first-degree relatives. Data are still insufficient for recommendation for or against MRI screening for individuals with a lifetime risk of 15% to 20%, those with lobular carcinoma in situ (LCIS), atypical ductal or lobular hyperplasia

(ADH or ALH), and dense breast on mammography and those with a personal diagnosis of breast cancer, including ductal carcinoma in situ (DCIS).

Tomosynthesis

The key challenge to cost-effective screening is increasing sensitivity and specificity of imaging. The controversy between various screening guidelines largely arises from the additional costs incurred by follow-up diagnostic imaging and biopsies to evaluate the large number of false-positive results noted primarily in individuals with dense breasts. Tomosynthesis addresses the issue of dense breasts and overlying superimposed densities, which often hide breast cancers. Tomosynthesis involves the acquisition of multiple images of the breast recorded at difference angles while the detector is held stationary. As a result, the reader is presented with a series of images (0.05-mm slices) through the breast. Research has shown that masses are more visible in these reconstructed slices than in standard film-screen mammography. The potential benefits of tomosynthesis include improved screening sensitivity, improved lesion size detection, better characterization of vague findings, and decreased recall rates.

FUTURE

Companion digital technologies continue to be developed due to the advent of digital mammography and computer reconstruction. Stereo-digital mammography offers the potential to produce a three-dimensional image of the breast, and early studies look promising for reducing the number of false-positive results. MRI specificity may be improved with diffusion-weighted imaging or spectroscopy and also eliminate the need for intravenous contrast injection. Similarly, ultrasound scan specificity may be improved with sheer wave technology and elastography to measure the stiffness of lesions.

The Role of Stereotactic Breast Biopsy in the Management of Breast Disease

Alexandra June Gordon and Nora Hansen, MD

INTRODUCTION

With the increase in mammography in the United States, stereotactic breast biopsies have become more common. Formerly, image-detected abnormalities required mammographic localization and excision, resulting in many surgical excisions for benign pathology. In contrast to an open biopsy, stereotactic biopsy can be done with a local anesthetic through a small incision with less significant parenchymal and skin scarring, and it is more cost effective. It leaves little or no deformity as long as the incision is made in an appropriate location and orientation.

In 2005, the National Accreditation Program for Breast Centers (NAPBC) was formed as a way to accredit breast programs, with the ultimate goal of improving breast cancer management and outcomes. The NAPBC set 27 standards required for accreditation of a breast center. One of them is that 90% of cancers must be diagnosed using a minimally invasive biopsy technique. Many other organizations support this concept as well.

HISTORY

In 1908, a neurosurgeon and a physiologist at University College London Hospital developed the stereotactic method and tried it on animals. They called it the Horsley-Clarke apparatus. However, the poor quality of the images limited its use. Between 1947 and 1949, using known anatomic landmarks, Ernest A. Spiegel, Henry T. Wycisand, and Lars Leksell developed the first stereotactic devices for brain surgery in humans. For neurosurgery, however, further improvements were necessary. Russell A. Brown, a computer scientist, invented a way to target stereotactic surgery using computed tomographic (CT) scan. Because CT could capture anatomic details in the brain, this greatly improved the accuracy and usefulness of stereotactic procedures. For breast biopsies, however, imaging was not the problem. Mammograms were able to produce a clear image of breast tissue, but the biopsy tools used needed refinement. With the advent of a spring-loaded core biopsy device, and later a vacuum-assisted, rotating blade biopsy probe, stereotactic biopsy became very accurate and useful. Stereotactic breast biopsy technology was introduced in the United States in the late 1980s by Dr. Kambiz Dowlat. As a result of the accuracy of stereotactic biopsy, it has become the predominant method for biopsy of nonpalpable breast lesions (Table 1).

Although many studies have reported the accuracy of stereotactic biopsies, the core needle biopsy sample may not provide complete characterization of the histologic findings, and this can lead to an

underestimation of the presence of cancer (Table 2). This occurs most commonly in high-risk lesions such as atypical ductal hyperplasia (ADH), flat epithelial atypia (FEA), radial scars, and papillary and lobular lesions. These findings on a core biopsy require further investigation with an excisional biopsy to rule out the possibility of an associated cancer.

TABLE 1: Accuracy of stereotactic percutaneous core needle biopsy

Investigator	Year	Number of cases	Concordance with surgical biopsy
Parker	1991	102	96%
Dronkers	1992	53	91%
Elvecrog	1993	100	94%
Gisvold	1994	104	90%
Pfari	2002	214	97%
Zuiani	2007	171	98%

CERTIFICATION

There is some controversy as to who should perform stereotactic biopsies—surgeons or radiologists. Regardless of who performs the biopsy, certification should be mandatory to ensure that the physician performing the biopsy is capable and meets certain standards. Certification not only ensures that the physician is capable, but it confirms that the equipment meets certain standards as well. Certification can be achieved through several avenues, but the most common certification process is through the American Society of Breast Surgeons (ASBS). ASBS certification requirements are outlined in Table 3. Upon completion of the prerequisites and a clinical application, each applicant for certification must successfully pass a written and practical examination.

PATIENT SELECTION, INDICATIONS, AND CONTRAINDICATIONS

A complete history and physical exam are important in any patient being considered for a stereotactic breast biopsy. Patients are usually advised to stop taking aspirin or nonsteroidal antiinflammatory agents prior to the procedure, although patients who must continue anticoagulation drugs can still have a stereotactic biopsy.

TABLE 2: False negative rate of stereotactic percutaneous core needle biopsy

Investigator	Year	Method	Number of cases	Underestimation rate
Burak	2000	Stereo 11G-VAB	201	11.8%
Zuiani	2007	Stereo 11G-VAB	171	17.2%
Lourenco	2007	Stereo 11G-VAB	168	28.6%
Lourenco	2007	Stereo 9G-VAB	71	25.4%

TABLE 3: American Society of Breast Surgeons certification requirements

Stereotactic Breast Procedure Certification

Requirements
1. A clinical application
2. A written exam
3. A practical exam

Prerequisites
1. Must have attained board certification via American Board of Surgery (ABS) or American Osteopathic Board of Surgery (AOBS) or evidence of international equivalent, upon completion of training.
2. Must document an appropriate level of training and a minimum of 1 year of experience in the performance of stereotactic breast procedures.
3. Must document performance of no fewer than 12 stereotactic breast procedures per year and evaluation of a minimum of 480 mammography exams in the last 2 years.
4. All applicants must have a minimum of 4 hours of AMA PRA Category 1 CME in medical radiation physics or can attest to the review of Radiation Physics and Safety by Howard Snider, MD, which is included in application. Applicants with less than 5 years of experience must have a minimum of 15 hours of AMA PRA Category 1 CME in breast imaging, including a minimum of 7 hours in stereotactic breast procedures during the last 5 years.

OR
Applicants with 5 or more years of experience must have a minimum of 5 hours of AMA PRA Category 1 CME in breast imaging or breast intervention during the last 5 years.

TABLE 4: Breast Imaging Reporting and Data System (BI-RADS) mammography categorizing system

BI-RADS 1	Normal mammogram
BI-RADS 2	Benign finding
BI-RADS 3	Probably benign, short interval follow-up suggested
BI-RADS 4	Suspicious for malignancy
BI-RADS 5	Strongly suggestive of malignancy
BI-RADS 6	Imaging in a patient with known malignancy
BI-RADS 0	Additional imaging evaluation or comparison with previous films suggested

TABLE 5: Indications for stereotactic biopsy

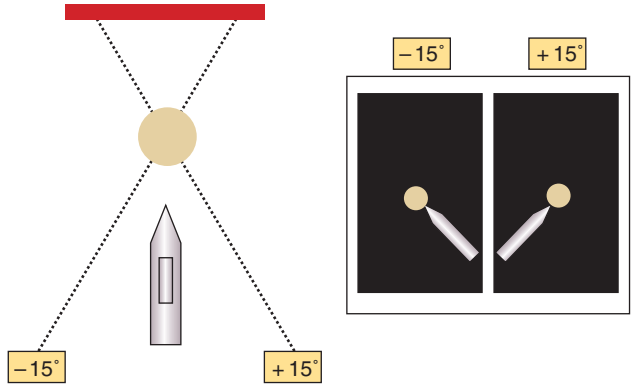
1	Lesions that are highly suggestive of malignancy, BI-RADS 5
2	Lesions that are suspicious, BI-RADS 4
3	Lesions that are BI-RADS 3 when there are other clinical reasons to perform a biopsy or in cases where a short-term follow-up would not be practical
4	Multiple suspicious lesions
5	Mammographic lesions that correspond to suspicious areas on MRI
6	A nonpalpable suspicious solid mass on mammography that is not seen on ultrasound
7	Suspicious microcalcifications that are new or at site of prior lumpectomy
8	Suspicious architectural distortion

Before the biopsy, a complete diagnostic workup must be performed. It is important to rule out pseudolesions that could lead to discordant biopsy results and require further surgical intervention for benign lesions. Additional mammographic views and ultrasound can help eliminate abnormalities caused by overlapping densities or clusters of calcifications that may appear to be suspicious. Mammograms are classified according to the American College of Radiology (ACR) Breast Imaging Reporting and Data System (BI-RADS) (Table 4).

Mammogram reports are required to categorize a mammogram according to the BI-RADS system by the Mammography Quality Standards Act and Program (MQSA). A BI-RADS 4 or 5 will likely require a stereotactic biopsy if the lesion is nonpalpable and cannot be seen on ultrasound imaging. A BI-RADS 4 lesion is one with an intermediate risk. The majority of these lesions are benign, so a stereotactic biopsy can alleviate the need for a surgical excision and can be done under a local anesthetic. For those patients with BI-RADS 5 lesions, a stereotactic biopsy can decrease the number of trips to the operating room, and the surgeon can perform a definitive operation in a single surgery. If the lesion cannot be seen on the mammogram, a stereotactic biopsy cannot be performed.

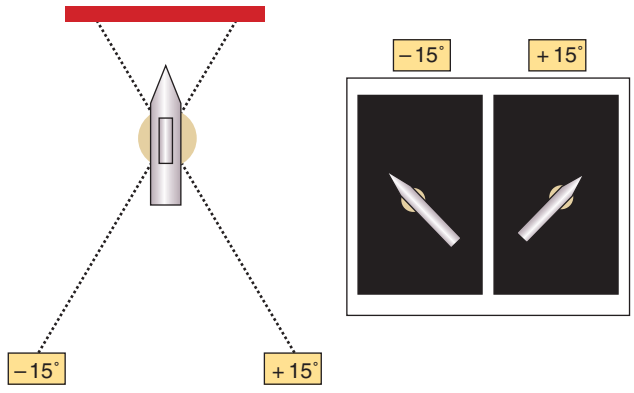
Other contraindications to a stereotactic biopsy are limited to the patient's body habitus and the patient's ability to remain in the required position during the biopsy. Obese patient may be too heavy for a stereotactic table. Upright units that are attached to the mammography unit may make biopsy possible in this group of patients. Other relative contraindications include patients with severe kyphosis, making it impossible to position the breast deep enough through the hole in the biopsy table to localize the lesion, or patients who are unable to lie prone and still for the length of the biopsy, which may be the case with patients with a chronic cough or very anxious patients. If there is not enough breast tissue to compress and the breast compresses to less than 2.2 cm, the patient is not a good candidate for this approach and a needle localization procedure may be necessary. There are also circumstances when the breast is very large and the lesion very deep so the stereotactic needle cannot reach it. If the lesion is too close to the chest wall or the skin, it may be impossible to adequately or safely perform a stereotactic biopsy. However, the vast majority of mammographic lesions are amenable to stereotactic biopsy, and this should be the biopsy mode of choice for these patients. Table 5 lists current indications for a stereotactic breast biopsy recommended by the American College of Radiologists, the American Society of Breast Surgeons, and the Radiological Society of North America.

THE FUNDAMENTALS



Four terms a surgeon must be familiar with in order to perform a stereotactic biopsy are *targeting*, *pullback*, *stroke*, and *stroke margin*. Targeting is how the surgeon interprets the stereotactic images in order to sample the appropriate area of the breast. The surgeon must interpret a pair of images that are obtained at a 15-degree angle (Figures 1 and 2).

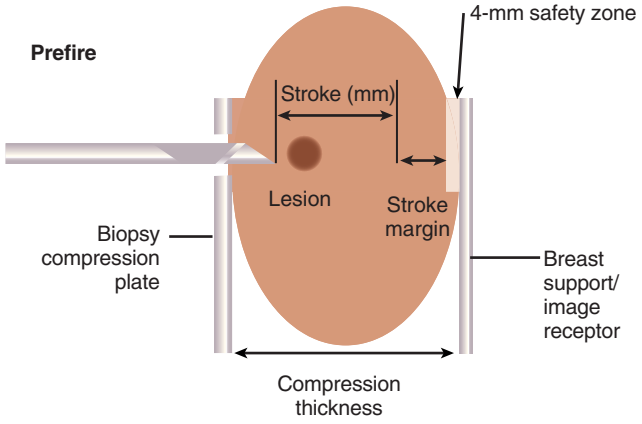
Stroke and stroke margin are related but are not identical. The stroke of a needle is the amount that it advances when fired. This can be calculated as the postfire position minus the prefire position of the tip of the needle. The stroke margin is the distance between the image receptor (i.e., the support behind the breast) and the tip of the needle after the needle has been fired. You want to have a *positive* stroke margin—that is, the stroke margin must be larger than the stroke. A negative stroke margin occurs when lesions are close to the image receptor and the stroke is larger than the stroke margin. This should be avoided because the needle can pass completely through the breast and damage the image receptor. While most machines calculate the stroke margin for you, easy-to-use stroke margin calculators are available online (Figures 3 and 4).



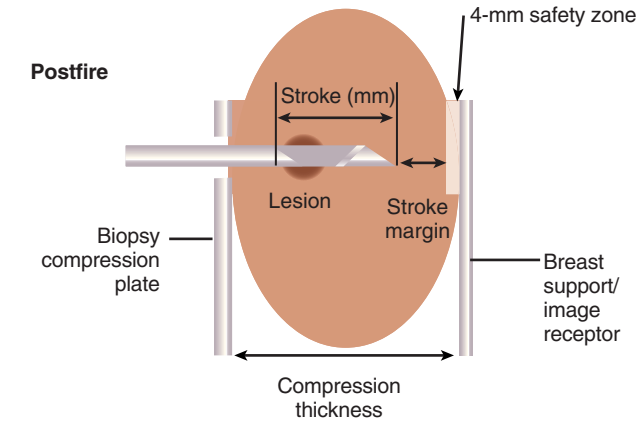
Pullback is related to the initial position of the needle relative to the area of interest. To understand this, it is important to be familiar with the features of a hollow biopsy needle. The portion of the needle that does the cutting is termed the *biopsy aperture*, and it is set back slightly from the tip of the needle. Because of this design, it is the biopsy aperture that needs to pass through the lesion and not the tip of the needle. It is imperative that the center of the biopsy aperture be in the middle of the target. In this instance the biopsy needle passes through the center of the lesion by half the length of the biopsy aperture plus the length of the tip of the needle. If the needle is placed too close to the target, when it is fired, the needle can advance past the lesion, pushing it forward and resulting in an inaccurate sample (Figures 5 and 6).

THE PROCEDURE

There are many types of stereotactic tables; the most common ones are manufactured by Hologic, Fischer, and Siemens. Stereotactic units consist mostly of tables with a circular aperture through which

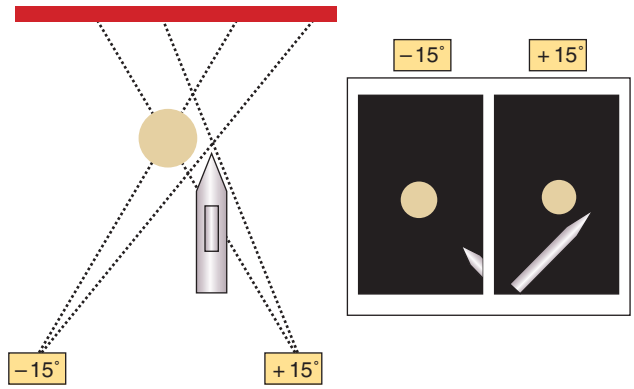


A Prefire – Proper alignment



B Postfire – Proper alignment

FIGURE 1 **A,** Prefire views of the biopsy needle properly aligned relative to the target. **B,** Postfire views. *(Based on drawings courtesy of Beth A. Boyd, RN.)*



A Stroke

B Positive stroke margin

FIGURE 3 **A,** When fired, the needle will advance a preset distance, called the *stroke*. **B,** The distance of the tip of the needle from the back plate once the needle has been fired is the *stroke margin*. It should always be a positive number to avoid damage to the image receptor. *(Based on drawings courtesy of Beth A. Boyd, RN.)*

Prefire – Needle to the right

FIGURE 2 Prefire view of the needle to the right of the target. Understanding the 15-degree offset projection will help interpret the location of a misaligned biopsy needle. *(Based on drawings courtesy of Beth A. Boyd, RN.)*

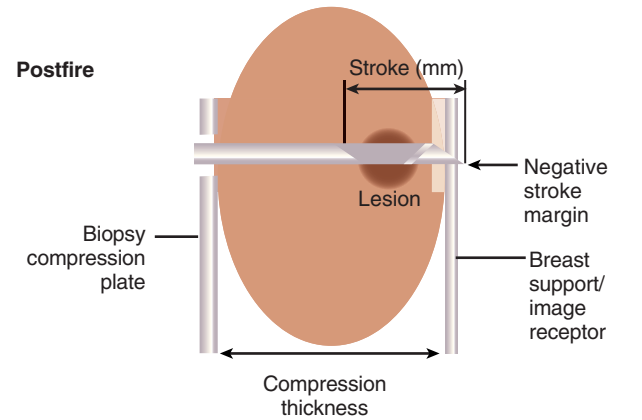


FIGURE 4 Negative stroke margin. The fully deployed needle is accurately placed but damages the image receptor. *(Based on drawings courtesy of Beth A. Boyd, RN.)*

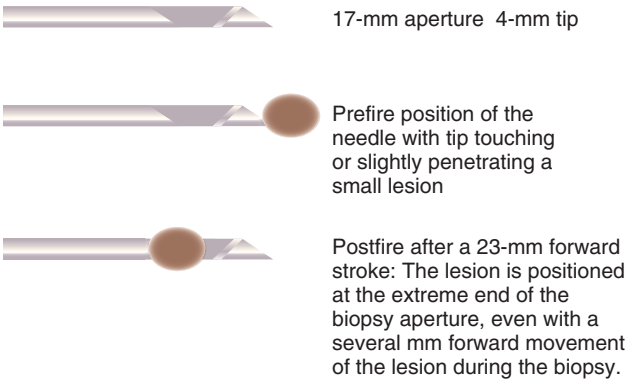

FIGURE 5 Needle without pullback. The core biopsy needle is positioned too far into the lesion; when fired, it may pass too far to adequately sample the target. *(Based on drawings courtesy of Beth A. Boyd, RN.)*

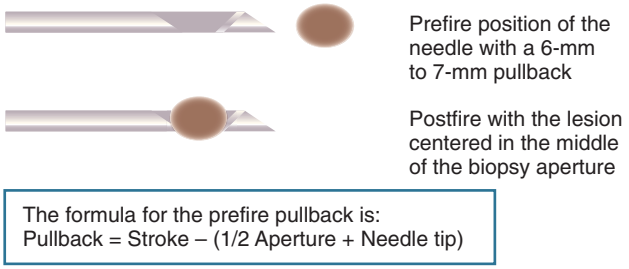

FIGURE 6 Needle with pullback. Proper position of the core biopsy needle to center the biopsy aperture within the lesion. (Note that the stereotactic machine will calculate the proper position of the biopsy device, including the required pullback.) *(Based on drawings courtesy of Beth A. Boyd, RN.)*

the breast is suspended. It is occasionally desirable to use an upright table when the patient's body habitus or other concerns prevent the patient from lying prone. Despite the type of table used, the technique is similar. The first step in a stereotactic procedure is to select the best approach for the needle insertion. This is usually based on the shortest approach to the lesion so as little breast tissue as possible is penetrated. The approach could be from the lateral, medial, cranial, or caudal direction. If more than one lesion is to be biopsied, it would be important to determine if all the lesions could be approached from the same direction so repositioning could be limited during the procedure. To keep it immobilized during the biopsy, the breast is lightly compressed between a compression plate and a support behind the breast (the image receptor). It is imperative that the lesion be identified, and based on the location of the lesion, an approach for the biopsy is chosen. At times it can be difficult to position the lesion within the field of view, and it may take several attempts to reposition the compression plate so the lesion can be seen. Landmarks on the mammogram, such as vessels or macrocalcifications, can sometimes help guide the surgeon in identifying the lesion to be biopsied. If a blood vessel is in the path of the biopsy needle, a different approach may be necessary because there is a possibility of injuring the vessels with the biopsy needle, resulting in a hematoma. The lesion is initially imaged in the center of a 5 × 5 cm cutout in a compression plate. A scout image, taken perpendicularly to the compression plate, is obtained and then used to center the target in the field of view.

After the perpendicular scout image, two more x-rays are obtained 30 degrees apart—one at +15 degrees and the other at –15 degrees. The two images are viewed on a monitor, and the physician uses a

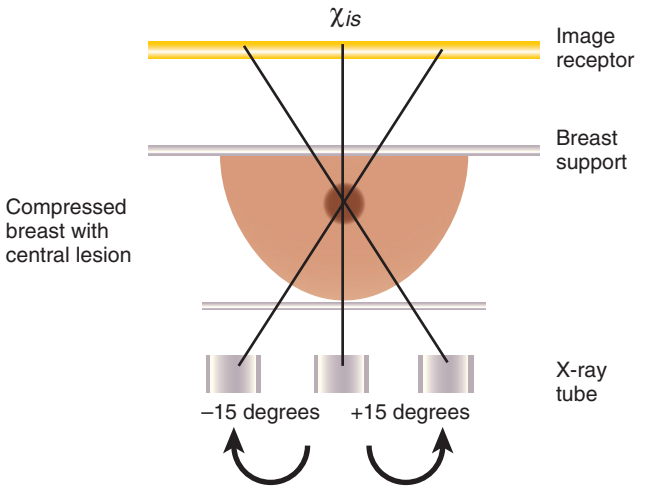

FIGURE 7 The computer calculates the position of the lesion in the breast based on the difference in the 15-degree offset views. *(Based on drawings courtesy of Beth A. Boyd, RN.)*

cursor to select the target lesion on both images. Stereotactic imaging uses the principle of parallax to locate the three-dimensional location of a target within the breast from a pair of two-dimensional images. Derived from the Greek word *parallaxis*, which means "alteration," parallax is a difference in the apparent position of an object when viewed from two locations—in our case, a right (+15 degrees) and left (–15 degrees) eye location. We can use this parallax to determine distances (Figure 7).

Two targeting systems are currently used in stereotactic equipment, and the type of system used depends on the manufacturer. The polar coordinate system is used by Siemens and defines a target by distances from a fixed point and angular distances from a reference line. The depth of the targeted lesion is determined from the back compression plate and is expressed in millimeters, while the horizontal and vertical axes are expressed in degrees. Hologic uses a Cartesian system that defines the exact position of the target in three-dimensional space in millimeters in three axes that intersect at right angles (z-depth, x-horizontal, and y-vertical), and the depth is determined by a reference point in front of the breast on the front compression plate. A z-value of zero indicates the level of a reference point on the compression plate in front of the breast or at the opening through which the biopsy is performed. The z-value corresponding to the level of the image receptor behind the breast will equal the thickness of the compressed breast, so it is important to understand that you should not attempt a biopsy of a lesion if the calculated z-value is greater than the compression of the breast. This would result in the biopsy needle traversing the breast and into the image receptor. When the center of rotation is behind the breast, a larger parallax will correspond to a *shallower* target, one closer to the compression plate. When the center of rotation is in front of the target, a larger parallax will instead be a deeper target, closer to the back support of the breast. After the computer has calculated the location in three dimensions from the initial images, an appropriate biopsy device is selected and the skin is sterilely prepared.

Several types of biopsy needles are now available for stereotactic biopsies. Guidelines from the American College of Surgeons state that stereotactic biopsy should be performed with a vacuum-assisted biopsy device to reduce sampling error and minimize the false negatives. Despite the advent of the rotating, vacuum-assisted cutting device, approximately 10% to 20% of patients thought to have atypia at the time of biopsy demonstrate ductal carcinoma in situ (DCIS) or invasive carcinoma at the time of excision. Stereotactic biopsy is typically performed with a Mammotome-type needle, an 8-gauge to 11-gauge vacuum-assisted rotating cutting device. As the probe spins,

the sample passes through the device into a hollow collection chamber. Because the device samples directionally, multiple specimens can be collected without having to remove and reinsert the device. While an 8-gauge to 11-gauge needle is typical, devices range from 18 gauge to 1.5 cm. The patient and reason for the procedure dictate the aperture of the needle used. Smaller needles would be used for a patient who required ongoing anticoagulation therapy to minimize the bleeding risk. Multiple studies suggest that false negatives are least common among biopsies with an 11-gauge needle. Larger needles would be used to remove intact tissue samples of calcifications or other mammographic densities. Prior to the biopsy, the surgeon should be familiar with the type of needle being used.

It is very important to be familiar with the biopsy device used because different devices require different amounts of breast tissue in front of and behind the lesion. Local anesthesia is administered—typically a 30-gauge needle injecting lidocaine without epinephrine into the skin, followed by a 25-gauge to 22-gauge needle for lidocaine with epinephrine deeper into the breast tissue. The addition of epinephrine helps reduce bleeding.

The biopsy device is placed in a small incision made with a scalpel, and the appropriate location of the device is verified in both the prefire and postfire views. Some biopsy devices do not require a skin nick and can be advanced directly into the breast. Specimens are obtained to sufficiently sample the target. Typically there are 10 to 15 samples taken from an 11-gauge device or 6 to 8 samples for an 8-gauge needle. Confirmation that the sample is sufficient and accurate is made by both the radiographic review of the biopsy specimens and the stereotactic views. If the biopsy was targeting calcifications and there are no calcifications in the stereo specimens, then additional biopsy samples should be obtained. It is always advisable to place a biopsy marker—a small, radiographically detectable clip—into the biopsy site if the patient requires further procedures or treatment. This marking is vital if the lesion is determined to be malignant. The most commonly used clip is stainless steel, but there are many options, including those that are deployed within the biopsy cavity rather than into the surrounding breast tissue, which may be less likely to move. Approximately 2% to 28% of traditional, stainless-steel clips are more than 1 cm away from the desired location, and the thinner the breast, the more likely there will be clip movement. Furthermore, if the clip is deployed when the breast tissue is compressed, upon release of the tissue, the clip may move a considerable amount. It is also possible that the clip may not deploy. Accurate placement is then verified with additional stereotactic views or with a two-view follow-up mammogram. If more than one lesion is biopsied, it is important to use different-shaped markers to identify each site, which is then correlated with the final pathology. If one is benign and one is malignant, the clip that marked the malignant lesion could be localized accurately for the definitive surgical procedure. The puncture site is generally closed with a Steri-strip, and dry gauze is placed either inside the patient's bra or held in place with an Ace wrap (Figures 8 to 12).

CHALLENGING CLINICAL SCENARIOS

A thin breast can be problematic for two reasons: there can be a negative stroke margin, and it may be impossible to center the lesion in the biopsy aperture, causing the sample of interest to be a small portion at the proximal end of the removed tissue. Generally a modification of the approach will resolve this issue, and the shortest approach will provide enough tissue to sample. It is also helpful to compress or bolster the breast in order to give a thin breast more volume. This can be done with anything that won't interfere with the radio waves: saline or gel bags, gauze, or Ace bandages.

A lesion that is close to the chest wall can be difficult to visualize and often necessitates a change in the patient's position. First, a chest wall lesion is most easily visualized with an medial lateral oblique (MLO) and lateral (LAT) view. It can be helpful to pull the breast downward with some force. If neither this nor repositioning helps, it is possible to put the patient's arm through the opening in the table along with the breast. In this scenario, it is important to avoid injuring axillary structures.

Lesions that are subareolar are difficult to biopsy because of the vascularity and often insufficient image quality. However, it is still possible to biopsy lesions in this location, but it may require a different approach.

Most complicated procedures occur because of the location of the lesion in the breast. It is helpful to remember that the image (especially of a faint lesion) will be better if the lesion is closer to the image receptor (breast back support) and farther from the source of the

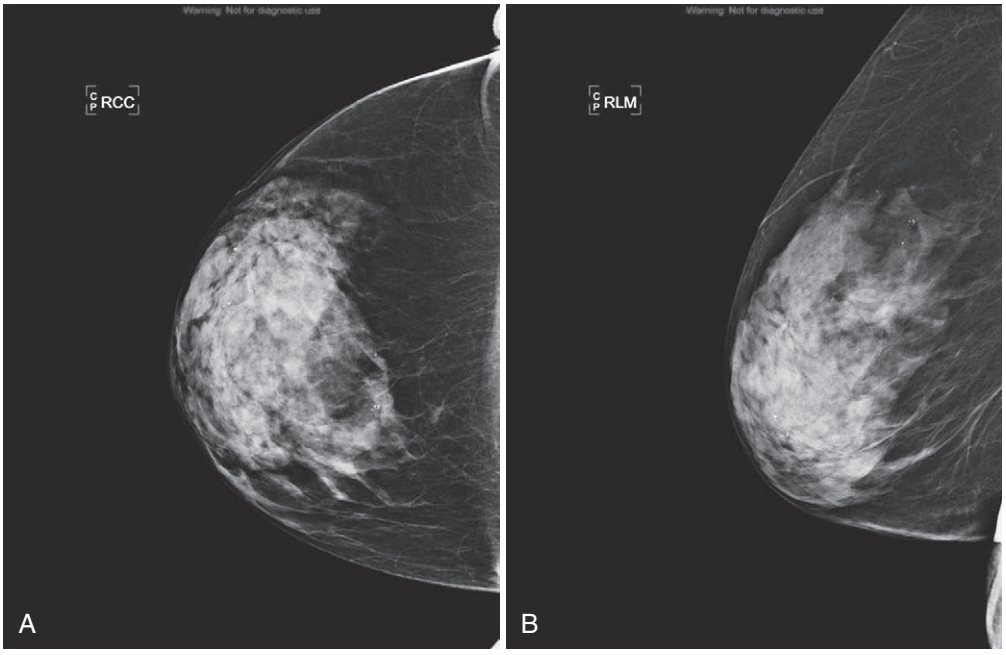

FIGURE 8 Digital mammography.

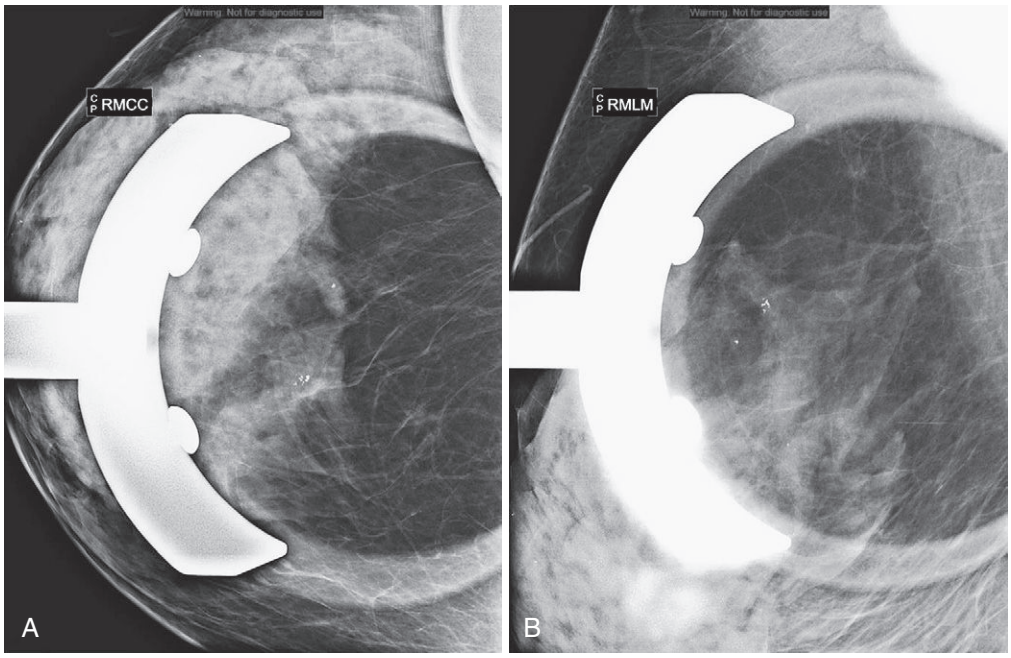

FIGURE 9 Digital mammography magnification view.

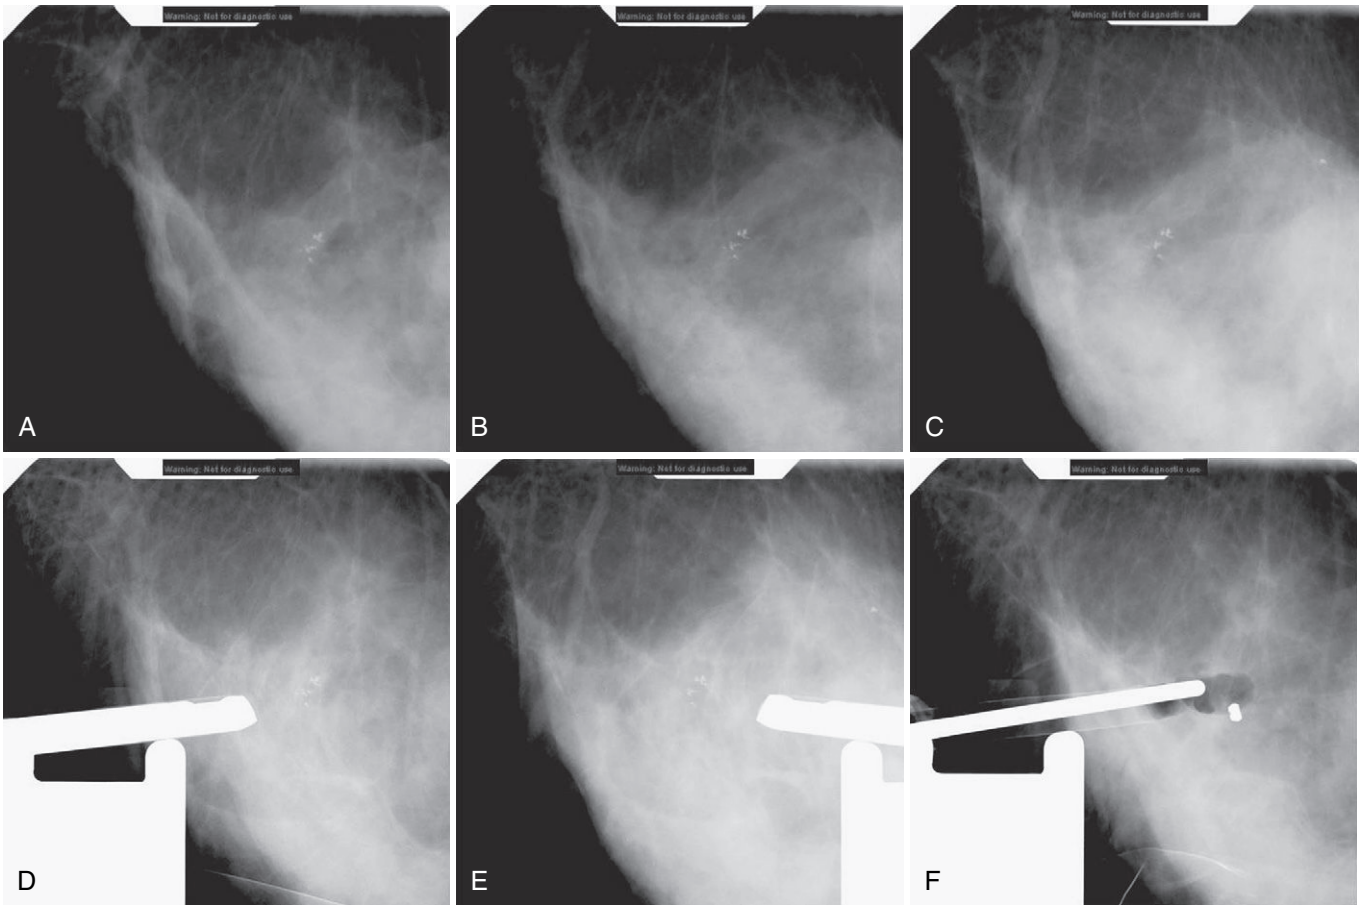

FIGURE 10 Stereotactic biopsy images.

x-ray beam. For example lesions at 6 o'clock are best approached craniocaudally.

PATHOLOGIC CORRELATION

The most important step in the biopsy procedure is to correlate the images from the procedure with the anticipated pathologic findings. If the images are not concordant with the pathology, the surgeon cannot trust the quality of the biopsy. The success of the procedure depends on accurate targeting and adequate tissue sampling. In addition to imaging before and during the procedure, the surgeon x-rays the core samples to make sure they include the area of interest. Indications that the procedure was unsuccessful would be an entirely benign tissue sample in a malignant-looking lesion. In this instance, surgical follow-up would be recommended because the targeting may have been insufficient.

Certain findings place women at a higher risk of developing breast cancer or suggest there is an adjacent malignant lesion and more surgery is required. Because the risk of coexisting malignancy is more important, the surgical excision is primarily for the purpose of ruling this out as opposed to complete excision of the atypical focus. In most instances, except those with a large radiographic area, both are accomplished. The following lesions identified on core biopsy should undergo an excisional breast biopsy to rule out the possibility of an associated malignancy. Pathologic findings that do not correspond to breast imaging findings (discordance) are outlined in Table 6.

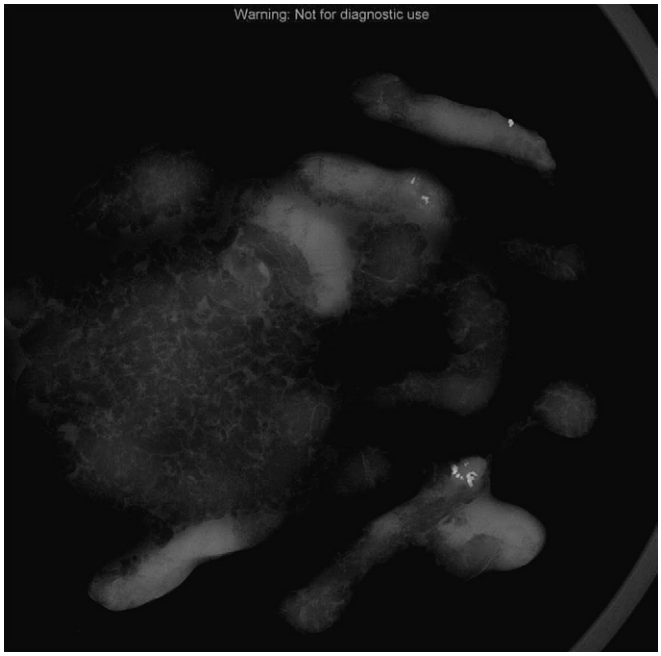

FIGURE 11 Specimen radiograph.

CONCLUSIONS AND FUTURE DIRECTIONS

Stereotactic biopsies have essentially replaced excisional breast biopsies for nonpalpable mammographic abnormalities. These biopsies can be performed by both radiologists and surgeons, but it is imperative that any physician performing these biopsies be properly trained and certified. Pathologic correlation is essential to minimize false-negative results, and if the pathologic findings are discordant with the imaging findings, further investigation of the abnormality is required. This can be achieved either through a repeat stereotactic biopsy or with an excisional breast biopsy. As technology continues to improve in the area of both imaging and device development, the stereotactic approach may become not only a diagnostic tool but also a therapeutic one. Several types of tumor ablation are being explored, including cryoablation, radiofrequency ablation, and laser ablation, which may be able to utilize the stereotactic approach and increase the indications for the stereotactic apparatus. Further investigation is needed in these areas before they can be incorporated into the management of the breast cancer patient. However, the stereotactic approach offers a direct route of access to tumors in the breast and may in the future change the way we manage the breast cancer patient.

FIGURE 12 Postbiopsy mammogram to evaluate clip placement.

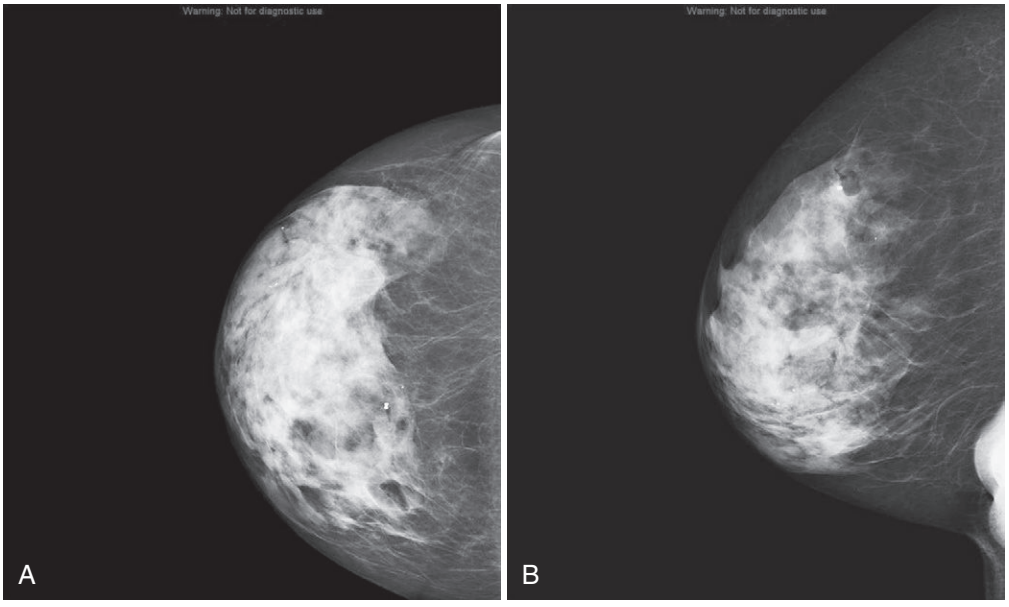

TABLE 6: Discordance

Atypical ductal hyperplasia (ADH)	Those with ADH have an upgrade rate of 15% to 20%, requiring most to be excised. Furthermore, a diagnosis of ADH carries a fourfold risk of developing cancer and thus requires close observation.
Lobular neoplasia	Note that this includes lobular carcinoma in situ (LCIS), pleomorphic LCIS, and atypical lobular hyperplasia (ALH). The distinction between these two types of lobular carcinoma is quantitative and not qualitative and thus hard to distinguish adequately on biopsy. Not all institutions excise LCIS or ALH, the decision to excise is made on an individual basis.
Radial scar	Excision is recommended unless the lesion is small and was completely removed on biopsy. If atypia is present, however, excision is always recommended.
Papillary lesions	Papillary lesions when asymptomatic are associated with DCIS about 10% to 20% of the time. When atypia is present, the upgrade rate increases and thus all lesions should be excised.
Phylloides tumor	Often impossible to diagnose a phylloides tumor on a needle biopsy. Often the core biopsy will be reported as a fibroepithelial lesion, and this should be excised to determine if this represents a phylloides tumor.

Molecular Targets in Breast Cancer

Helen Krontiras, MD, Oluwafunmi O. Awonuga, MD, and Kirby Bland, MD

The current knowledge for the complex molecular and genetic pathways involved in breast carcinogenesis has increased exponentially over the last few decades. We now know that breast cancer is a diverse and heterogeneous disease composed of an ever-enlarging number of biologic subtypes, each with differing clinical behaviors and outcomes. This chapter focuses on the clinically relevant cellular and molecular targets important for the practicing surgeon involved in the care of breast cancer.

MOLECULAR PROFILING

Contemporary advancements in molecular biology and genetics show that breast cancer has complex and diverse biologic behavior that influences its natural history and response to therapy. The introduction and widespread use of sophisticated high through-put technologies, such as gene expression arrays, coupled with effective analytic tools, has allowed for breast cancer characterization, or profiling, on a molecular level, beyond the traditional methods of anatomic stage and histologic grade.

With the use of microarrays and hierarchal cluster analysis, Perou and colleagues first described in 2000 the molecular classifications of breast cancer known as the intrinsic subtypes. These include three main subtypes of estrogen receptor (ER)–negative tumors: (1) basal-like; (2) human epidermal growth factor receptor–2 (HER2) enriched; and (3) normal-like. The two subtypes of ER-positive tumors, luminal A and luminal B, are evident, and a sixth breast cancer subtype, termed claudin-low, has also been defined. These subtypes differ significantly in prognosis and in the therapeutic targets they express. The subtypes important in the clinical setting are described subsequently (Table 1).

TABLE 1: Intrinsic subtypes of breast cancer

Type	Characteristics	Markers
Luminal A	Low grade High ER 50% of all breast cancer	ER+, PR+, HER2–, CK8+, CK18+
Luminal B	Higher grade Lower ER 10% of breast cancer	ER+, PR+/–, HER2+/–
HER2	High grade P53 mutations 5% to 10% of breast cancer	ER–, PR–, HER2+
Basal	High proliferation 30% of breast cancer	ER–, PR–, HER2–

*CK,*Cytokeratin ; *ER,* estrogen receptor; *HER2,* human epidermal growth factor receptor–2; *PR,* progesterone receptor.

Luminal Subtypes

The term *luminal* derives from the similarity in expression between these tumors and the luminal epithelium of the breast. Luminal subtypes comprise the majority of ER-positive breast cancer and are characterized by expression of ER, progesterone receptor (PR), and other genes associated with ER activation. The luminal subtypes are further divided into luminal A and luminal B subtypes.

Luminal A tumors usually have high expression of ER-related genes, low expression of the HER2 cluster of genes, and low expression of proliferation-related genes. They are typically low to moderate tumor grade. Luminal A tumors are the most common of all the subtypes (50%) and carry the best prognosis of all breast cancer subtypes. Luminal B tumors are less common (10%) and have a worse prognosis than luminal A tumors; luminal B have superior prognosis to the nonluminal subtypes basal-like and HER2-enriched. Luminal B tumors have a relatively lower (although still present) expression of ER-related genes, variable expression of the HER2 cluster, and higher expression of the proliferation cluster, including Ki67.

HER2-Enriched

The HER2-enriched subtype is characterized by high expression of the HER2 and proliferation gene clusters and low expression of the luminal cluster. This subtype is uncommon and represents only about 10% of all breast cancers. These tumors are typically negative for ER and PR and positive for HER2. Most tumors that are positive for ER and HER2 fall into the luminal B subtype. Before HER2-targeted therapy, this subtype carried a poor prognosis. However, this unfavorable outcome has been significantly improved with HER2-directed therapy.

Basal-Like

The basal-like subtype derives its name from similarity in expression to that of the basal epithelial cells. It is characterized by low expression of the luminal and HER2 gene clusters. These tumors are typically ER, PR, and HER2 negative on clinical assays that are termed triple-negative. Most triple-negative tumors (TNBC) are basal-like; however, not all TNBC are basal-like, and not all basal-like breast cancer possess triple-negative receptors. Approximately 20% of breast cancers are basal-like. The basal-like tumors have high expression of the proliferation cluster of genes and high expression of the epidermal growth factor receptor (EGFR) and the basal cluster, which includes basal epithelial cytokeratins 5, 14, and 17.

Basal-like breast cancer and triple-negative breast cancer are similar in clinical characteristics, but practically, clinical assays currently only identify TNBC; thus, triple-negative is a surrogate of the basal-like subtype in the clinical setting. Both are associated with aggressive phenotypes. In comparison with all the other subtypes of breast cancer, TNBCs present at an earlier age of onset and are seen more often in premenopausal women of African ancestry. They tend to be large, high-grade tumors with frequent lymph node positivity. They often present as interval cancers, between mammograms or on clinical examination. As a result, TNBC is characterized by poorer survival outcomes and higher relapse rates than non–triple-negative breast cancers. Distant metastases most often occur in visceral sites. Recurrences rates typically peak in the first 3 years after diagnosis and rapidly diminish thereafter, confirming the aggressive natural history of the disease. Although TNBCs often carry a poor prognosis, they tend to have an improved rate of complete pathologic response compared with luminal subtypes in studies of neoadjuvant therapy, the so-called triple-negative paradox that indicates significant heterogeneity even with the basal-like/TNBC subtype. Lehman and associates in 2011 subclassified this group into seven subtypes, each with potential specific therapeutic implications. Interestingly, most breast cancers that occur in women with the BRCA1 mutation are basal-like and triple-negative. This is being exploited in clinical trials of targeted therapy discussed later in this chapter.

Clinical Gene Expression Assays

Multiple limited-set gene expression profiling assays have been validated and are in clinical use today. First described in 2002, these gene expression profiles identify tumors with high and low risk for recurrence and provide independent prognostic information beyond the anatomic and immunohistochemical classification of breast cancer. Genetic expression profiles are commercially available and covered by most insurance carriers. These assays are typically considered in ER-positive and HER2-negative breast cancer as an *adjunct* to traditional prognostic parameters.

The 21-gene reverse-transcriptase polymerase chain reaction assay (Oncotype DX; Genomic Health, Redwood City, Calif) is performed on formalin-fixed paraffin-embedded tissue and evaluates 16 cancer-related genes (Ki67, STK15, survivin or BIRC5, CCNB1 and MYLB2, ER, PGR, BCL2, SCUBE2, HER2, GRB7, MMP11, CTSL2, GSTM1, CD68, and BAG1) and 5 reference genes. An individualized risk estimate or recurrence score (0 to 100) is provided for each tumor sample submitted: low risk, <18; intermediate risk, 18 to 30; and high risk, ≥31 (Figure 1).

Should the recurrence score indicate a low risk score, hormone therapy alone may be considered, sparing chemotherapy; if the recurrence score indicates a high-risk category, chemotherapy followed by hormonal therapy may provide a better outcome. Studies show that associations of recurrence score with survival were independent from standard clinicopathologic factors. Current National Comprehensive Cancer Network (NCCN) breast cancer clinical practice guidelines recommend considering Oncotype DX for patients with ER-positive, node-negative breast cancer to aid decision making regarding adjuvant systemic therapy. Recent studies indicate that Oncotype DX may be useful in node-positive ER-positive HER2-negative breast cancer as well.

MammaPrint (Agendia; Amsterdam, Netherlands) or the Amsterdam 70-gene profile is also validated and commercially available. This microarray assay is performed on freshly collected tissue and provides similar information regarding the potential benefit of chemotherapy in selected patients with ER-positive or ER-negative disease.

ESTROGEN RECEPTOR SIGNALING PATHWAYS

Beatson in 1896 reported regression of advanced breast cancer with removing ovaries in patients with premenopausal breast cancer after observing that rabbits that had ovaries removed stopped producing milk, indicating a relationship between the breast and the ovary. However, not all breast cancers responded to oophorectomy. It was not until the 1970s, when the estrogen receptor was discovered, that the reason became known. Jenson developed the hypothesis that some breast cancers contain the estrogen receptor and others do not. Those that did not have the receptor would not respond to endocrine manipulation. Since that time, the ER has been extensively studied, and endocrine therapy remains one of the most important modalities in breast cancer treatment for ER-positive cancers.

The ER is a ligand-dependent transcription factor and is actually composed of two receptors. The estrogen alpha receptor (ER-α) is a class I nuclear receptor located on chromosome 6q, and the estrogen receptor beta (ER-β) is located on chromosome 14q. Both ER-α and ER-β are members of the steroid receptor family of proteins, and both share common structural and functional domains, except that ER-β lacks a portion of the C-terminal domain. They bind with high

BREAST CANCER ASSAY DESCRIPTION

Oncotype DX Breast Cancer Assay uses RT-PCR to determine the expression of a panel of 21 genes in tumor tissue. The Recurrence Score® is calculated from the gene expression results. The Recurrence Score range is from 0-100.

RESULTS

Breast Cancer Recurrence Score = 12

The findings summarized in the Clinical Experience sections of this report are applicable to the patient populations defined in each section. It is unknown whether the findings apply to patients outside these criteria.

CLINICAL EXPERIENCE: PROGNOSIS FOR NODE NEGATIVE, ER-POSITIVE PATIENTS

The Clinical Validation study included female patients with Stage I or II, Node Negative, ER-Positive breast cancer treated with 5 years of tamoxifen. Those patients who had a Recurrence Score of 12 had an Average Rate of Distant Recurrence of **8% (95% CI: 5%-10%)**

The following results are from a clinical validation study of 668 patients from the NSABP B-14 study. *N Engl J Med* 2004; 351: 2817-26.

Recurrence Score vs Distant Recurrence in Node Negative, ER-Positive Breast Cancer Prognosis

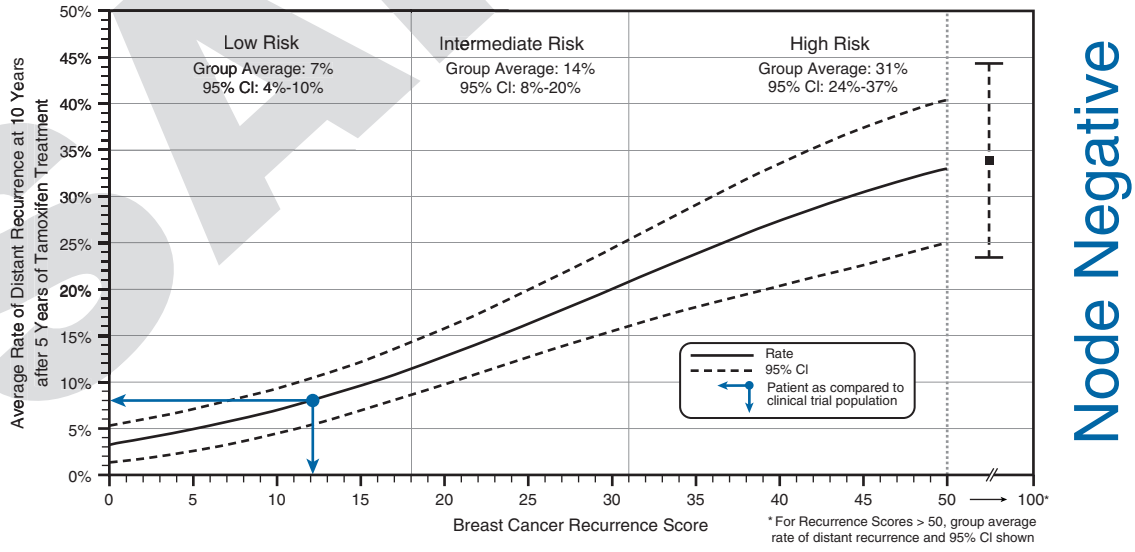

FIGURE 1 Oncotype DX Recurrence Score (RS) Report. The report provides a RS on a scale of 1 to 100. The RS result is correlated with a specific likelihood of distant recurrence at 10 years based on the average 10-year distant recurrence rate for that RS in the clinical trial population. Of note, the clinical trial population was treated with 5 years of tamoxifen. In addition, the report does provide a quantitative single gene report for estrogen receptor, progesterone receptor, and human epidermal growth factor receptor–2 scores. *(Oncotype DX and Recurrence Score are registered trademarks of Genomic Health Inc, Redwood City, Calif.)*

SAMPLE

affinity to the ligand estrogen. Estrogen binds the receptor, causes dimerization, and facilitates interaction of the receptor with promoter regions in the DNA. These regions are termed *estrogen response elements*, which function by regulating the activation or repression of gene transcription. Currently, little is known about the role of ER-β in breast cancer. Approximately 60% of tumors coexpress ER-α and ER- β. Some evidence suggests that a high ratio of ER-α to ER-β at a target site is important, and high ratios are associated with high levels of cellular proliferation and tamoxifen resistance.

The assays used for ER determination in clinical practice measure ER-α levels, the "classic ER." Approximately 70% to 80% of all invasive breast cancers and nearly all intraductal breast cancers express the ER-α protein (ER positive). Traditionally, ER positivity has been measured quantitatively with immunohistochemistry (IHC). Approximately 60% of ER-positive tumors are also progesterone receptor (PR) positive. Although patients with ER-positive tumors have a better prognosis than patients with ER-negative tumors, expression of the estrogen receptor is more useful as a predictor for response to endocrine therapy. In ER-positive/PR-positive tumors, 70% respond to endocrine therapy. In addition, 50% of ER-negative tumors express PR, perhaps indicating downstream activation of the endocrine pathways; of these, 30% respond to tamoxifen therapy.

Selective estrogen receptor modulators (SERMs) are competitive ER antagonists with partial agonist activity. Tamoxifen is the most widely used SERM for breast cancer treatment. Tamoxifen competitively inhibits the binding of estradiol to estrogen receptors in some sites and maintains agonist activity in some tissues.

Given in an adjuvant setting, tamoxifen reduces the risk of breast cancer recurrence and death in premenopausal and postmenopausal women with ER-positive disease. Specifically, the Early Breast Cancer Trialists Collaborative Group (EBCTCG) overview and meta-analysis of randomized trials of adjuvant tamoxifen found that this SERM reduced the 15-year probability of breast cancer recurrence (from 46% to 33%, a 39% reduction in the annual recurrence rate) and breast cancer mortality (from 33% to 24%, a 30% reduction in the annual mortality rate). It is given daily (20 mg). The side-effects profile is notable in some women for symptomatic hot flashes and vaginal dryness or discharge related to the antiestrogenic effect of the medication. More worrisome but rare side effects include an increased risk for the development of uterine cancer and thromboembolic events in postmenopausal women. Tamoxifen treatment may also offer beneficial side effects in postmenopausal women, including an improvement in bone density and lipid profile.

Although they do not directly interfere with the ER, aromatase inhibitors (AIs) are the mainstay of endocrine therapy in postmenopausal ER-positive breast cancer. Landmark trials have shown that AIs are superior to tamoxifen in reducing breast cancer recurrence in postmenopausal women. Specifically, 12 prospective randomized studies show that the use of an AI in this patient population reduces the risk of local recurrence and improves disease-free survival when compared with tamoxifen alone. AIs block conversion of adrenally synthesized androgens to estrogen with the aromatase enzyme, thus suppressing estrogen levels. This is the last step in steroid conversion to active hormones and does not interfere with production of corticosteroids or mineralocorticoids. Production of estrogen in the ovary is not suppressed, however, and AIs are currently indicated only for postmenopausal women with ER-positive breast cancer. Currently, three AIs are used in clinical practice: exemestane (Aromasin; Pfizer, New York, NY) anastrozole (Arimidex; Astra-Zenaca, London, England), and letrozole (Femara; Novartis, Basel, Switzerland).

AIs have been studied as initial and sequential therapy after tamoxifen and also as extended therapy. Initial use of an AI, in comparison with tamoxifen, was studied in the anastrozole, tamoxifen, alone or in combination (ATAC), trial of postmenopausal women with ER-positive breast cancer. With a median follow-up period of 120 months, there was significantly longer disease-free survival with anastrozole than with tamoxifen (hazard ratio [HR], 0.91; 95% confidence interval [CI], 0.83 to 0.99). Anastrozole was also associated with a prolonged time to recurrence (HR, 0.84; 95% CI, 0.75 to 0.93), fewer recurrences (absolute reduction of 2.7% at 5 years and 4.3% at 10 years), and fewer contralateral breast cancers (HR, 0.68; 95% CI, 0.50 to 0.91). In addition, in comparison with tamoxifen, treatment with anastrozole causes significantly fewer episodes of hot flashes, vaginal discharge, vaginal bleeding, endometrial cancer, strokes, and thromboembolic events. However, women on anastrozole in this study reported more musculoskeletal problems than those on tamoxifen, and a significantly increased number of fractures were seen in the women in the anastrozole group.

GROWTH FACTOR RECPTOR PATHWAYS AND DOWN STREAM PATHWAYS

The epidermal growth factor receptor family is made up of four receptors: HER1 (erbB1/EGFR), HER2 (erbB-2), HER3 (erbB-3) and HER4 (erbB-4). These receptors are transmembrane proteins with three cellular domains and function primarily as tyrosine kinases that activate the phosphatidylinositol 3-kinase (PI3K)/AKT and RAS/RAF/MAPK pathways.

Perhaps the best characterized of the EGFR family receptors is HER2. The HER2 gene, also known as *Her 2 neu* or c-erbB2, is located on chromosome 17q and is normally involved in regulation of cell proliferation. The HER2 gene is a protooncogene a normal gene with the potential to become an oncogene with molecular alterations, such as mutation, amplification, or overexpression of its protein product. HER2 overexpression is an early event in breast cancer development. HER2 is overexpressed or gene amplified (or both) in approximately 20% of invasive breast cancers. Patients with overexpression of HER2 often have high-grade tumors, axillary lymph node involvement, and decreased expression of estrogen and progesterone receptors. These characteristics are associated with an increased risk of recurrence and decreased survival; however, HER2 overexpression is also independently associated with poor prognosis.

Trastuzumab (Herceptin; Genentech, South San Francisco, Calif) is a recombinant humanized monoclonal antibody that targets the extracellular domain of the HER2 protein. Multiple randomized controlled trials of trastuzumab in the adjuvant setting have shown that trastuzumab given in combination with chemotherapy to patients with tumors that overexpress HER2 significantly improves disease-free and overall survival compared with chemotherapy regimens that do not contain trastuzumab. Used in the neoadjuvant setting, trastuzumab plus chemotherapy improves pathologic complete response (approximately 65% with trastuzumab and 25% without trastuzumab). Significant cardiac events occur in approximately 2% of patients who have received trastuzumab plus chemotherapy compared with 0.3% with standard chemotherapy according to a meta-analysis of almost 11,000 patients in the adjuvant setting. Data suggest that the cardiac toxicity observed with trastuzumab therapy is reversible in most cases. Those cases with tumors that possess low or negative levels of expression or amplification are not likely to have significant benefit from treatment with trastuzumab, but studies are underway examining the role of Herceptin in HER2-negative cases. Current guidelines recommend that trastuzumab be given in the adjuvant setting in conjunction with chemotherapy for invasive HER2 overexpressing tumors more than 1 cm and for HER2-positive node-positive disease. Consideration for systemic adjuvant therapy with trastuzumab is recommended for invasive HER2 overexpressing tumors between 5 and 10 mm and for HER2-positive micrometastatic nodal disease. Evaluation is ongoing to determine the optimal duration, combination, and sequencing.

Lapatinib is an oral, reversible, small-molecule dual inhibitor of both EGFR (HER1) and HER2 kinases. In 2007, lapatinib was approved for use in combination with capecitabine in trastuzumab-refractory HER2-positive metastatic breast cancer. Pertuzumab,

another monoclonal antibody, targets the extracellular domain of HER2 at a different site. This drug was approved for use in metastatic HER2-positive breast cancer in combination with docetaxel and trastuzumab in 2012.

Data from clinical trials suggest that dual blockade of the HER pathways may be superior to single therapy targeting. Trials testing different combinations of both new and approved targeted HER pathway blockers without cytotoxic chemotherapy are underway to determine whether chemotherapy and its associated additional toxicity may be avoided in this patient population. Ongoing studies of new agents and combinations will likely result in a number of new agents being approved for the metastatic, adjuvant, and neoadjuvant settings in the near future.

PI3K/AKT PATHWAY

Phosphatidylinositol 3-kinase (PI3K) is a major signaling hub downstream of HER2 and other tyrosine kinases and activates AKT, serum/glucocorticoid regulated kinase, mammalian target of rapamycin (mTOR), and several additional molecules involved in cell cycle regulation, progression, and survival. Uncontrolled activation of the PI3K/AKT/mTOR pathway occurs in more than 70% of breast cancers and appears to be involved with both endocrine and HER2-targeted therapy resistance. Combination therapy with PI3K pathway inhibitor is a promising new avenue in breast cancer treatment. In 2012, everolimus, an mTOR inhibitor, was approved for advanced hormone receptor-positive, HER-negative breast cancer in combination with exemestane after failure of treatment with letrozole or anastrozole.

ANGIOGENESIS

Angiogenesis or the growth of new blood vessels is fundamental for tumor growth and metastasis. Tumors with volumes less than a few cubic millimeters exist in a prevascular state with continued cycle of proliferation and cell death, receiving oxygen and nutrients through diffusion. Tumor angiogenesis is the proliferation of a network of blood vessels that penetrate into cancerous growths, supplying nutrients and oxygen and removing waste products.

The primary promoter of tumor angiogenesis is vascular endothelial growth factor A (VEGF-A or VEGF). VEGF is synthesized in tumor cells and is expressed in most types of human cancer. Increased expression of VEGF in tumors is usually associated with diminished prognosis. Although the VEGF family of growth factors and receptors have three known receptors, VEGF signals principally through VEGF receptor 2 (VEGFR-2) and activates a series of proteins that transmit a signal into the nucleus to initiate new endothelial cell growth, differentiation, and apoptosis. In addition, VEGF mediates vascular permeability and allows deposition of angiogenic proteins into the surrounding tissue, perpetuating angiogenesis and sustaining tumor growth. Studies by Folkman and others more than 40 years ago showed in preclinical models that inhibition of angiogenesis could inhibit cancer growth. This led to the development of agents to inhibit angiogenesis for therapeutic intention.

Bevacizumab (Avastin; Genentech/Roche) is a humanized monoclonal antibody that inhibits VEGF. It was the first angiogenesis inhibitor approved by the U.S. Food and Drug Administration (FDA). It is approved for advanced solid organ malignancies, including lung, colon, and kidney. Approval for breast cancer was withdrawn in November 2011 because of increased toxicity and a lack of survival benefit in overall survival across all breast cancer subtypes in the initial clinical trials.

Small molecule multityrosine kinase inhibitors that target, among others, the VEGF-2 receptor are currently being investigated. Studies are ongoing as to the appropriate patient subset, schedule, and partner chemotherapies; however, because of lack of specificity, successful outcomes with these targeted therapies may hinge on the work exploring response prediction.

DNA REPAIR PATHWAYS

Poly(ADP-ribose) Polymerase Inhibitors

Multiple distinct DNA repair pathways exist to maintain stability of the genome. Single-stranded DNA damage is repaired with base excision repair (BER), nucleic acid excision repair (NER), mismatch repair, or direct repair. Double-stranded breaks are repaired with homologous recombination and nonhomologous end joining.

Poly(ADP-ribose) polymerases (PARPs) are a family of enzymes involved in chromosome stability, regulation of apoptosis, cell division, and transcriptional regulation and differentiation. There are 17 enzymes in the PARP family. The best known are PARP1 and PARP2, which are important in the function of BER. PARP inhibitors interfere with DNA damage repair by inhibiting BER. DNA repair is optimal for healthy cells, but the opposite effect is desired in cancer cells that experience DNA damage from therapy such as chemotherapy and radiation.

BRCA1 and 2 genes are tumor suppressor genes that play a crucial role for maintenance of genomic stability by promoting repair of double-stranded breaks by homologous repair. Most people with the BRCA deleterious gene mutation are heterozygous for the mutation, meaning they have one normal and one mutated allele. Tumors with DNA repair defects including BRCA mutations appear to have particular sensitivity to PARP inhibition. Loss of PARP1 protein function in a BRCA1-defective or BRCA2-defective background cripples the cell's ability to repair double-strand DNA damage, leading to cell cycle arrest or cell death. Therefore, PARP inhibitors could be selectively lethal to cells deficient in BRCA1 and BRCA2. In addition to BRCA mutations, some sporadic breast cancers, including some TNBC, also exhibit similarity to BRCA1 mutant tumors, a concept referred to as BRCAness. These tumors also appear to be sensitive to PARP inhibition, and exploiting this similarity could have significant therapeutic promise for TNBC, which as of yet has no specific target. A number of PARP inhibitors are in clinical development and multiple ongoing trials to test the efficacy of this approach.

Breast Cancer: Surgical Management

Megan K. Baker, MD

INTRODUCTION

Breast cancer surgical management continues to evolve in response to evidence-based clinical research and burgeoning basic science investigations. The surgeon's role, however, remains constant. It is our role to ensure a proper diagnosis, timely treatment planning, and patient care follow through. With reliance on a multidisciplinary model, surgeons are best able to provide patients with state-of-the-art care and thereby improve the patient's chance for successful outcome.

DIAGNOSIS AND WORKUP

In addition to the technical aspects of diagnosis and imaging, the importance of a thorough history and physical examination cannot be overstated. Elements of the history and examination should strongly influence decisions on genetics referral, staging evaluation, and care planning. The gold standard for the diagnosis of breast cancer is image-guided or palpation-guided core biopsy. The routine use of fine needle aspiration (FNA) and excisional biopsy as diagnostic tools is no longer recommended. In an era in which the histology and biologic features of a breast cancer so strictly dictate treatment, FNA of a breast mass is an unnecessary and typically incomplete evaluation. At the same time, excisional biopsy subjects the patient to a needless level of intervention that may compromise aesthetic outcome or result in a delay or abdication of neoadjuvant chemotherapy options. Similarly, routine or indiscriminate use of radiologic staging studies is discouraged because this has not been shown to change outcome. Thorough bilateral breast imaging remains essential and commonly consists of diagnostic digital mammography. It is often augmented with ultrasound scan (US) or magnetic resonance imaging (MRI) where appropriate. The routine use of preoperative MRI has not been shown to improve outcome in terms of overall survival, disease-free survival, or margin reexcision rates in randomized studies. At the author's center, MRI has been useful in situations with discordance between physical examination and routine imaging, in cancers with lobular histology, in patients with predisposing genetic conditions, and in cases with unexpected involved margins or planned neoadjuvant chemotherapy.

TREATMENT

Noninvasive and Invasive Breast Cancer

As established by the National Surgery Breast and Bowel Project (NSABP) B06 and NSABP B17, breast-conserving therapy (BCT) may be used in the surgical management of the breast for most noninvasive and invasive breast cancers. Partial mastectomy, most commonly complemented with radiation therapy, may be conducted via excisional, wire-guided, hematoma, or ultrasound scan–guided techniques. The principles are the same: localization of the lesion, surgical excision of the cancer with adequate margins, and maintenance of the breast aesthetic. Contraindications to breast-conserving surgery include multicentric disease, locally advanced breast cancer, inflammatory breast cancer, unfavorable breast-to-tumor ratio, and any contraindication to radiation therapy.

Breast Incision and Procedure Selection

Incision style and placement depends both on the location of the tumor and on the strategy for radiation therapy. Historically, incisions have been placed directly overtop the tumor, and only the most superficial skin layers have been closed, leaving a wound seroma to resolve spontaneously. In the setting of partial breast irradiation therapy, this seroma cavity is instrumental. When present in the context of whole breast irradiation, this seroma can lead to an unfavorable cosmetic result. For some patients who plan to undergo partial breast irradiation therapy with an after-loading catheter technique, the shape of the partial mastectomy cavity and the distance from cavity-to-skin or cavity-to-rib surface are relevant. These considerations may be mitigated by the type of after-loading balloon catheter chosen or avoided with three-dimensional (3D) conformal radiation. Careful coordination with radiation oncology is essential to ensure the safest treatment plan and to optimize patient eligibility, safety, and cosmesis. In the author's practice, after-loading balloon catheters are used. These catheters are placed with US guidance at the time of the patient's postoperative visit after final pathology results and adequacy of resection are reviewed. For minimization of discomfort at the time of catheter removal, a short track, 2 to 3 cm, between the catheter skin entry and the cavity is favored.

Depending on the amount of tissue excised, location of the tumor, and degree of ptosis, oncoplastic surgical techniques may be useful and favorable. These techniques often reduce, if not eliminate, the seroma cavity. Parallelogram technique is well suited to upper outer quadrant wounds, and crescent or batwing mastopexy excision planning can offer an improved aesthetic outcome for more centrally located lesions (Figure 1). The principles of ensuring glandular coverage of the pectoralis muscle and removal of any redundant skin envelope can mitigate many potential concave results that often become exaggerated after radiation therapy.

Localization

Localization of the lesion can be completed with standard palpation when the lesion is easily noted on examination. In the nonpalpable setting, US guidance, hematoma guidance, wire localization, or more recently, radioactive nucleotide seed implant may be used. At the author's institution, US guidance for nonpalpable solid mass localization and stereotactic wire-guided localization of calcifications are often used. More recently, the availability of biopsy clip markers with coating visible on ultrasound scan has reduced the need for stereotactic wire placement in many centers.

Surgical Margins

The definition of an *adequate margin* remains controversial. The most historical clinical trial data commonly required no tumor on ink, but many institutions, like the author's, rely on a more conservative 2-mm margin. Recent studies have looked at margin-to-tumor ratio as a method to predict adequacy of resection. Ultimately, the heterogeneity of much of the level I data renders any conclusion difficult. Nonetheless, most agree that clear margins are necessary and surgeons should strive to minimize need for reexcision. Multiple strategies exist to reduce the need for reexcision of margins and

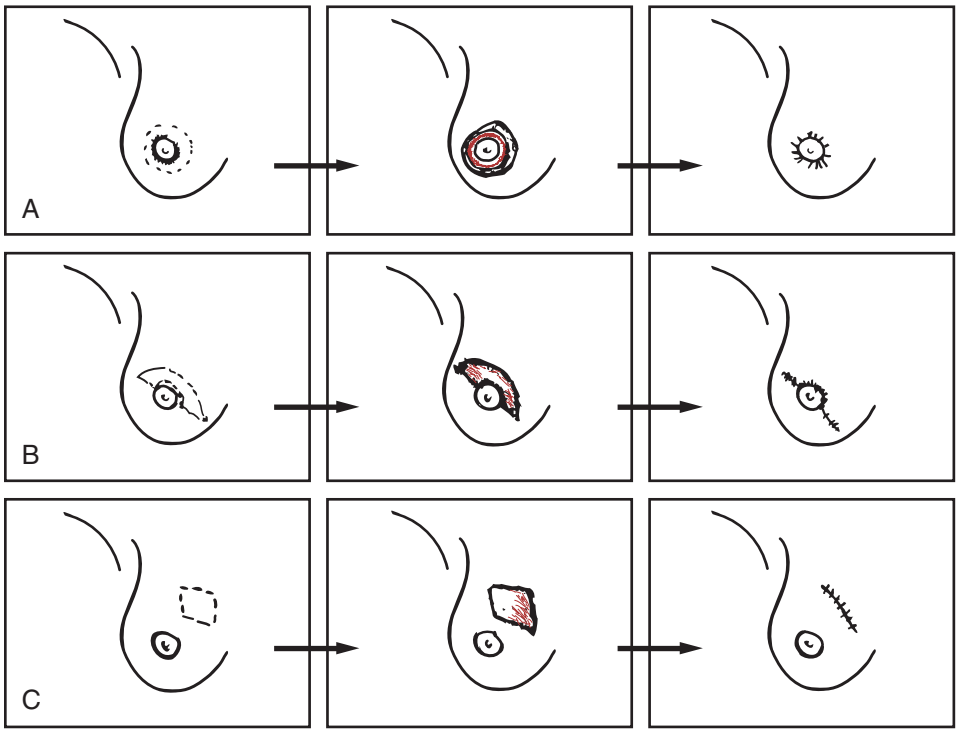

FIGURE 1 **A,** Parallelogram technique. **B,** Batwing mastopexy technique. **C,** Oncoplastic incision planning. *(A and B from Anderson BO, Masetti R, Silverstein MJ: Oncoplastic approaches to partial mastectomy: an overview of volume-displacement techniques,* Lancet Oncol *6(3):145–157, 2005. C Hussein O, El-Khodary T: "Diamond" mammoplasty as a part of conservative management of breast cancer: description of a new technique,* Int J Surg Case Rep *3(6):203–206, 2012.)*

include routine cavity reexcision or, as in the author's practice, selective reexcision based on intraoperative specimen radiograph imaging. Alternatively, intraoperative US assessment of the excised specimen may be instrumental. Attention to margins can significantly reduce reexcision rates without compromising breast contour.

All surgical lumpectomy specimens should be carefully oriented in a two-point orientation system and handled carefully so as not to distort margin integrity. The wounds are generally closed in two layers with absorbable suture. In the setting of oncoplastic closures, deeper pexing sutures may be necessary and, on occasion, a drain if a large tissue rearrangement was undertaken.

Staging the Axilla

The surgical management of the axilla has undergone recent and dramatic change. In the late 20th and early part of the 21st century, stage I and II breast cancers typically underwent axillary staging via sentinel lymph node (SLN) biopsy. In the event that any SLN was found to have tumor, completion lymph node dissection was then undertaken, classically involving level I and II axillary lymph nodes. With the publication of American College of Surgeons Oncology Group (ACOSOG) Z0011 trial results, the further management of the axilla in the setting of a positive SLN has changed considerably. For those patients who meet inclusion criteria and for whom whole breast irradiation and standard of care adjuvant therapy are planned, further axillary lymph node dissection can be avoided. This strategy has been shown to have equivalent overall and disease-free survival rates but 30% less morbidity when compared with the dictum of complete node dissection (Table 1).

The use of SLN biopsy for in situ disease is less well defined. SLN biopsy is commonly used in the setting of an in situ diagnosis for any patient with suspicion for microinvasive disease and for those undergoing mastectomy. SLN biopsy is selectively offered to patients with high-grade ductal carcinoma in situ. The latter is a reflection of the 15% to 20% increased risk for upstaging to invasive carcinoma after complete excision of an area diagnosed as ductal carcinoma in situ (DCIS) on core biopsy.

TABLE 1: Patient selection criteria for avoidance of axillary lymph node dissection

Avoidance of axillary lymph node dissection patient selection guidelines (ACOSOG Z0011)
Tumor size <5 cm (T1 or T2)
Fewer than three positive SLN
No evidence of extracapsular tumor extension in SLN
Planned whole breast radiation therapy
Planned standard of care adjuvant therapy

ACOSOG, American College of Surgeons Oncology Group; *SLN,* sentinel lymph node.

In an era of ever increasing use of preoperative axillary ultrasound scan staging, patients who are found to have abnormal pathologic lymph node characteristics may undergo FNA or core biopsy. In the event that that regional axillary metastasis is identified, the SLN biopsy may be avoided. The use of preoperative axillary US has become more challenging given the results of the ACOSOG Z0011 trial and has not yet been reconciled in the literature.

Lastly, the timing of SLN biopsy in the setting of neoadjuvant chemotherapy is debated. Proponents of staging the axilla before neoadjuvant therapy stress the advantage of most accurately predicting benefit from postmastectomy radiation therapy. Many centers commonly perform the SLN biopsy after neoadjuvant chemotherapy, embracing the decreased need for complete node dissection in the commonly downstaged axilla. To date, no definitive consensus exists, so planning in concert with the multidisciplinary team is imperative.

Sentinel Lymph Node Technique

In the absence of clinically positive or US biopsy positive axillary lymph nodes, the SLN is identified and removed to stage the axilla.

It may be effectively identified with vital blue dye, with radionucleotide tracer, or, as at the author's center, with the combination of both. When dye technique is used, 5 mL are typically injected in the subareolar parenchyma of the ipsilateral breast, followed by 5 minutes of massage. A small incision is made at the base of the axillary hair line and dissection is taken deep to the clavipectoral fascia, and careful attention is paid to the identification of a blue lymphatic or focus of tracer uptake. Once the SLN is identified and removed, the bed to ex vivo tracer counts ratio are 10% or less, and no other blue nodes or clinically worrisome nodes are palpated, the SLN may be sent to pathology. The author's practice is to send SLN for frozen hematoxylin and eosin (H&E) staining should patients desire partial breast irradiation therapy or concomitant mastectomy. With respect to the former, accelerated partial breast radiation is not offered in the setting of a positive SLN; and as such, surgeons may choose to close the partial mastectomy cavity in such a way to obliterate the seroma cavity. If the SLN is negative, the skin is simply closed, with the seroma cavity left intact to facilitate future placement of an afterloading balloon.

Axillary Lymph Node Dissection Technique

In situations in which axillary lymph node dissection is required, level I and II dissections are classically performed. The boundaries of level I are as follows: anterior, clavipectoral fascia; posterior, subscapularis muscle; inferior, axillary tail; superior, axillary vein; medial, lateral edge of pectoral major muscle; and lateral, anterior border of the latissimus dorsi muscle. Level II lymph nodes are located just deep to pectoralis minor muscle. During the dissection, care should be taken to avoid skeletonizing the axillary vein, which can increase lymphedema risk. At the same time, careful identification of the long thoracic and thoracodorsal nerves is paramount to avoid future muscle weakness. When feasible, attention to the preservation of the intercostal nerves minimizes postoperative paresthesias. The wound is closed primarily, and a drain, typically a 15F closed suction drain, is placed and maintained on closed suction until daily output drops below 20 mL.

Mastectomy Technique

For those patients who are not candidates for BST or who prefer mastectomy, several options are available depending on the decision for or against reconstruction and what type. In any of these scenarios, the necessary extent of glandular excision is similar for traditional total mastectomy, skin-sparing mastectomy, and nipple-sparing mastectomy (NSM; barring removal of the nipple areolar complex [NAC]). Unlike the historic subcutaneous mastectomy, the axillary tail is removed and the gland is excised to its superior extent at the clavicle, medially to the lateral edge of the sternum, laterally to the latissimus muscle, inferiorly at the inframammary fold, and posteriorly deep to the pectoralis fascia. Preservation of the inframammary fold depends on whether or not the patient is undergoing reconstruction. The author's practice is to remove the inframammary fold if a patient is not undergoing reconstruction to better facilitate ease of prosthesis fitting in the future.

The thickness of the skin flap varies between patients. The skin flap should represent not only the skin but its supporting subcutaneous adipose tissue, which varies depending on body habitus. The tenet of dissection in the relatively avascular plane between the superficial breast fascia and the subcutaneous dermal fat remains true today. At the author's center, adequate exposure is achieved with Adair clamps and blunt rake retractors. This method of retraction is efficient but also minimally harmful to the skin flap. The mastectomy wounds are closed primarily, and two 15F round JP drains are placed. The drains are maintained on closed bulb suction until their daily output is less than 20 mL.

Reconstruction

In the author's practice, barring comorbid conditions that represent contraindications to reconstruction, all patients undergoing mastectomy are offered consultation with plastic and reconstruction surgery. In the event that patients choose reconstruction, their options typically include implant reconstruction or autologous tissue options. In most cases, utilization of donor muscle and its resultant muscle weakness can be avoided in favor of perforator flap techniques, such as deep inferior epigastric perforator (DIEP) or gluteal arterial perforator (GAP) flaps. If necessary, either approach can be preceded with tissue expander placement. Further, for optimal cosmesis for those women undergoing reconstruction, they may be safely offered skin-sparing mastectomy or at times nipple-sparing mastectomy where the inframammary fold and the majority or entirety of the skin envelope are preserved.

Nipple-Sparing or Total Skin-Sparing Mastectomy Technique

Emerging data support the use of NSM or total skin-sparing mastectomy (TSSM) techniques. The author's practice most commonly uses an inframammary incision, oriented and centered laterally at 7:30 and 4:30 on the patient's right or left side, respectively, just above the inframammary fold (Figure 2). Unlike a radial incision, these are slightly longer, averaging 8 to 9 cm, but rarely visible with the patient in the upright position. Either strategy allows for excellent exposure and access to internal mammary vessels for autologous reconstruction. Attention should be paid to avoid incisions that involve the nipple areolar complex, as this has been associated with an increased risk of nipple necrosis.

Exclusion criteria for NSM include extensive DCIS, large tumor of more than 4 cm, less than 2 cm proximity to NAC, inflammatory breast cancer, or locally advanced disease. Several operative techniques are quite helpful during this procedure: use of a lighted retractor, early dissection at the pectoralis fascia, and countertraction of the skin envelope by an operative assistant. The author typically instills local anesthetic liberally behind the NAC to facilitate easier dissection, which is sharply undertaken in this location. The tissue immediately behind the nipple is sent for intraoperative frozen section. In the event that atypia or malignancy is identified, the NAC is resected. Given the rare rate of nipple recurrence and the natural history of breast cancer most commonly developing in the terminal duct units, the author does not find it necessary to core out the

FIGURE 2 Nipple-sparing mastectomy incision.

nipple. A SLN biopsy is commonly performed through a separate small axillary incision. For those patients who desire immediate autologous reconstruction, the SLN is often performed in advance of the mastectomy to elucidate those patients who will need postmastectomy radiotherapy and therefore identify those patients who should have a temporizing tissue expander placed.

ADJUVANT THERAPY

Both local and systemic adjuvant therapy should be considered at the same time as surgical planning in the context of a multidisciplinary care model. Biologic factors such as hormone receptor status, *Her 2 neu* status, and gene signature assay results often dictate need for systemic therapies and impact surgical decision making. Likewise, the incorporation of partial breast irradiation therapy into the treatment paradigm mandates cooperative surgical treatment planning with the radiation oncology colleagues. The standard duration of radiation therapy varies depending on type of radiation technique: 5 days for accelerated partial breast and 6 weeks of whole breast external beam. Additional consideration may be given to the use of a boost, accelerated whole breast technique, or avoidance of radiation therapy all together. The author's center's practice is to avoid radiation therapy for those women over 70 years of age who have undergone breast-conserving surgery for small tumors (<2 cm), who have node-negative hormone-receptor positive disease, and who are able to undergo endocrine therapy.

PROPHYLACTIC SURGERY

A significant increase in the utilization of prophylactic mastectomy has occurred in parallel with an improved understanding of high-risk breast cancer genetic syndromes (i.e., BRCA, p53, PTEN) and improved reconstruction techniques. Immediate breast reconstruction is often performed in this setting. The author strongly encourages a complete diagnostic workup and examination and detailed consultations before surgery with a genetics counselor to delineate a patient's risk for cancer, a medical oncologist to explore chemoprophylaxis options, a plastic surgeon, and at times a psychologist to review issues of body image, risk, and family planning. Prophylactic mastectomy has been shown to be effective in reducing the risk of subsequent breast cancer in this high-risk setting by more than 95%.

Even more recently, the use of contralateral prophylactic mastectomy (CPM) has dramatically increased. No large study has shown an overall survival benefit with this approach, and several have noted improved disease-free survival and improved patient satisfaction. The author strives to prioritize the therapeutic principles of the ipsilateral breast at all times and attempts to reduce risk that prophylactic intervention might compromise therapeutic intent. For example, the author's preference is for a patient who desires both mastectomy and CPM and who will be receiving systemic chemotherapy to do so in the neoadjuvant setting. This decreases the risk that an unintended complication on the prophylactic side might delay systemic therapy.

SUMMARY

The surgeon is central to the multidisciplinary treatment of breast cancer. A surgeon must work collaboratively with the breast cancer team to optimize the patient's options and outcome.

Ablative Therapies in Benign and Malignant Breast Disease

John Cox, MD, Paul Toomey, MD, Evan Tummel, MD, Robert Gabordi, MD, and Charles Cox, MD

OVERVIEW

As the management of breast cancer evolves toward improved cosmetic results and minimally invasive surgery, the possibility of removing the primary tumor through ablative techniques is being investigated. Ablative techniques have been based on two methods: heat through radiofrequency ablation (RFA) or cold cryoablation through the use of liquid nitrogen. Material science improvements and software modeling have led to commercial development of these two technologies, which allow discrete control of the size and shape of the tissue destruction. One aspect that remains unpredictable is the adequacy of margins in the pathologic destruction of cancer. This uncertainty has led to the investigation of the efficacy of the cryoablation technique for the cancers that are discrete lesions with clearly defined margins. Most ductal breast cancers are a mixture of ductal carcinoma in situ (DCIS) and invasive ductal carcinoma (IDC). Early-stage, low-grade discrete tumors exhibiting minimal DCIS show promise for ablative techniques.

The current cryoablation study of the American College of Surgeons Oncology Group (ACOSOG), the Z1072 trial, is being conducted to evaluate the feasibility of applying this technology to the treatment of primary breast tumors. Before the application of an ablative technique, it is critical to identify the tumor's histologic features, percentage of DCIS, genomic tumor markers, and hormone receptor status for estrogen, progesterone, and *HER-2/neu.*

Radiographic concordance with ultrasonography and magnetic resonance imaging (MRI) are essential in defining the tumor size, margins, and adequacy of tumor destruction both before and after ablative procedures. An understanding of the imaging modalities typically applied to breast cancer will also help in the evolution of ablative techniques. Precise imaging techniques to visualize the extent of the breast cancer also remain elusive. Combined pathologic and radiologic understanding of breast cancer may allow ablative techniques to safely and effectively destroy the primary breast tumor while also eliminating the need for surgical resection of the breast tumor.

CRYOABLATION

Controlled tissue destruction by freezing was first described by James Arnott in 1845 when he used a mixture of salt and ice to alleviate pain and bleeding, as well as to decrease tumor size. At the Great Exhibition of 1851 in London, Arnott displayed his cryotherapy apparatus for its use on readily accessible cancers such as breast, cervical, and skin tumors. There has been resurgence in the utilization of cryotherapy since 2000 in the treatment of benign fibroadenomas, and investigation of its use for cancer therapy continues.

Cryoablation for patients with a biopsy-proven fibroadenoma was approved by the U.S. Food and Drug Administration in 2001. The Fibroadenoma Cryoablation Treatment (FACT) registry reported on 444 patients with fibroadenomas who were treated with cryoablation. Overall patient satisfaction was 88% to 91%. One year after cryoablation, 35% of patients reported palpable masses, and 29% had residual masses visualized by ultrasonography. Palpability after cryoablation correlated with the size of the initial fibroadenomas. Only 25% of patients exhibited a palpable mass for fibroadenomas measuring less than 2 cm in diameter, whereas 59% of patients with masses greater than 2 cm demonstrated a residual palpable mass at 1 year.

The use of cryoablation for the treatment of breast cancer remains investigational. In the current studies, prerequisites for cryoablation treatment of IDC include a discretely imaged mass less than 2 cm at largest dimension and a minimal component of DCIS on core biopsy. The insidious nature of the margins for DCIS necessitates careful pathologic review to qualify the patient for ablative techniques alone. The technical limit of the freezing mechanism achieves a maximum "ice ball" diameter of 4 cm, which allows up to a 1-cm margin for a 2-cm tumor.

Complete ablation has been achieved for early-stage IDC. In the largest series, needle localization excision was compared with ultrasonography-guided cryoablation for patients with biopsy-proven IDC. The maximum tumor size was 1.7 cm and the goal ice ball created an 8-mm margin around the mass. The degree of DCIS on preoperative core biopsy was not limited in this study. After cryoablation with a single freeze cycle, the negative margin rates were significantly lower than those for needle localization for IDC (11% vs 20%, respectively). However, margins positive for DCIS were found more frequently in patients who underwent cryoablation (30% vs 18%). Achieving a minimum 6-mm freeze margin beyond the tumor has been shown to reduce positive margins to 6%.

More recently, a cohort of 29 patients with a maximum tumor diameter of 1.5 cm underwent cryoablation with two freeze cycles and an interposing thaw cycle to create a 6-mm margin. Two freezing cycles were performed during the same procedure, with an interposing thaw cycle to increase cellular destruction within the ice ball. All patients had microscopically negative margins for invasive cancer on pathology review. Five patients (17%) displayed margins positive for DCIS.

Ongoing Cryoablation Trials

The ACOSOG's Z1072 study is a phase II trial for treatment of IDC with cryoablation technology and was scheduled for completion in March 2013. In this study, the utility of MRI was also evaluated to detect residual IDC or DCIS after cryoablation. Another phase II trial involving cryoablation after neoadjuvant therapy for IDC is scheduled for completion in 2014.

Cryoablation Technique and Mechanism

The current U.S. Food and Drug Administration–approved Visica system for cryoablation of breast fibroadenomas allows technical limits of tissue destruction in a 4-cm diameter (Figure 1). Another system is the IceCure in its third generation. It is a liquid nitrogen system that offers fast procedure times (3 to 12 minutes) and two probe sizes (freeze zone 2.5 cm or 4.0 cm) for tailored tissue treatment. Other systems are also under development. Ultrasound guidance is utilized to place the cryoprobe tip in the center of the desired target. A continuous stream of liquid nitrogen flows throughout the probe and creates a spherical freezing zone measuring 4 cm in diameter (Figure 2). The initial freeze cycle is followed by a period of passive thawing before the final freeze cycle. Cytotoxic temperatures are achieved during the freezing process. The freezing target temperatures are −160°C to −190°C[15]. The passive thaw between the first and second freeze is continued until the probe is warmed to approximately −1°C. Peritumoral injection with saline may be utilized to increase the distance away from adjacent epidermis or the chest wall so as to protect them from cold injury (Figure 3).

Cells closest to the cryoablation probe die immediately as a result of intracellular ice formation. Farther away from the probe, the extracellular ice formation results in direct mechanical destruction and osmotic damage from dehydration. Ischemia is also induced as a result of blood vessel damage, platelet activation, and thrombosis. Moreover, mitochondrial damage ensues in cells not completely destroyed and subsequently compels cells to undergo programmed cell death. Repeated freeze-thaw cycles increase the efficacy of these mechanisms, inasmuch as the thawing allows for an influx of

FIGURE 1 Visica II machine is liquid nitrogen based. *(Courtesy Sanarus Technologies LLC, Pleasanton, Calif.)*

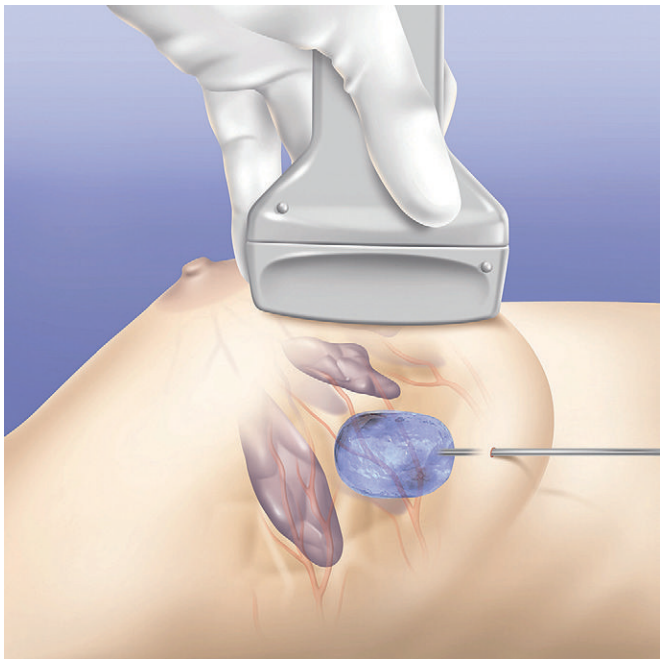

FIGURE 2 Ultrasonography is used to monitor the developing cryogenic zone created by the cryoprobe. *(From Kaufman C, Littrup P, Freman-Gibb L, et al: Office-based cryoablation of breast fibroadenomas: 12 month follow-up,* J Am Coll Surg *198[6]:914–923, 2004.)*

extracellular fluid into the cells; as a consequence, the cells swell, which causes them to burst (Figure 4).

The technique itself requires insertion of the probe precisely into the lesion and automatically freezing the lesion to attain the correct ice ball size to engulf the lesion with adequate freezing of margins. The freezing process takes 10 to 30 minutes, depending on the size. Technologic advancements have increased the ease and speed of cryoablation especially on smaller lesions. Commercial offerings from Sanarus Technologies and IceCure Medical have enabled this procedure to reach production levels.

Cryoablation Benefits

One of the major benefits of cryoablation is its convenience of use in the clinical setting under ultrasound guidance. Local anesthesia is usually sufficient because the cryogenic process further anesthetizes the breast tissue. Furthermore, the financial burden associated with operating room costs and risks of general anesthesia can be avoided. Cosmesis is maximized and the rate of infection is minimized with ablative technology, in contrast to surgical excision.

Oncologically, perhaps the most exciting potential benefit occurs with the subsequent biologic immune response and tumor necrosis after cryoablation. Tumor proteins and tumor-associated antigens are preserved, which potentially initiates an antitumor immune response to develop through T-cell stimulation. This immune response is directed against tumor cells and has even been shown to attack distant disease, which leads to regression after cryoablation. As cellular destruction occurs, inflammatory cytokines, heat shock proteins, DNA, and RNA are released from the tumor cells. These substances, partially destroyed proteins, along with other proteins, attract granulocytes, macrophages, and natural killer cells, which in turn provide additional immune responses that stimulate release of cytokines and chemokines. This proinflammatory environment attracts dendritic cells, a type of antigen-presenting cell (APC), which capture, process, and present tumor antigens to tumor-specific T cells. Once these APCs reach the tumor bed and are activated, they undergo a change in phenotype with upregulation of cell surface markers and eventually travel to nearby lymphatic vessels to present tumor antigens to tumor-specific T cells. The activated T cells are then able to destroy major histocompatibility complex class II+ tumors and provide help to a variety of antitumor effector cells, including $CD8^+$ cytotoxic T cells, B cells, and macrophages.

There is anecdotal evidence of the regression of metastatic disease in patients after cryoablation of the primary tumor. Unfortunately, these antimetastatic effects have not been consistently replicated. The immune system also has several mechanisms in place that seem to inhibit the mentioned antitumor immunity. Some of these mechanisms include regulatory T cells, suppressive or tolerogenic APCs, and an unfavorable tumor environment. It has been suggested that in order to capitalize on the tumor-fighting immune response after cryotherapy, clinicians must first find a way to counteract the inhibitory influence of metastatic cancer on antitumor immunity. This is a topic of intense laboratory research. One method involves injecting activated dendritic cells loading with specific tumor antigens simultaneously with cryoablation in order to enhance antigen presentation for the generation or augmentation of antitumor immunity. In addition, clinical trials for renal and prostate cancer have shown some success with vaccines consisting of irradiated tumor cells transduced with granulocyte-macrophage colony–stimulating factor (GM-CSF). Other immune modulators act to disrupt the inhibitory influences on antitumor immunity (e.g., decreasing the number or function of regulatory T cells, which act to block the function of antitumor T cells).

Cryoablation clearly has the potential to stimulate the immune system through a variety of pathways by either enhancing antitumor immunity or suppressing the inhibitory influences on the antitumor immune system. A better understanding of innate immunity after cryoablation may lead to antitumor vaccines. Further research on adjuvant cellular immunotherapy and improved comprehension as to why such a complex immune response exists after cryoablation may lead to promising therapies in the fight against cancer. In addition, current investigation of cryoablative therapy for antitumor immune modulation involves preoperative injection of intratumoral immunomodulatory ipilimumab (human monoclonal anti–CTLA-24 antibody) for early-stage, resectable IDC, with results expected in 2013.

Two other techniques being investigated for breast cancer treatment include laser and microwave ablation. In laser ablation, heat is generated for tissue destruction. The laser device is also placed under

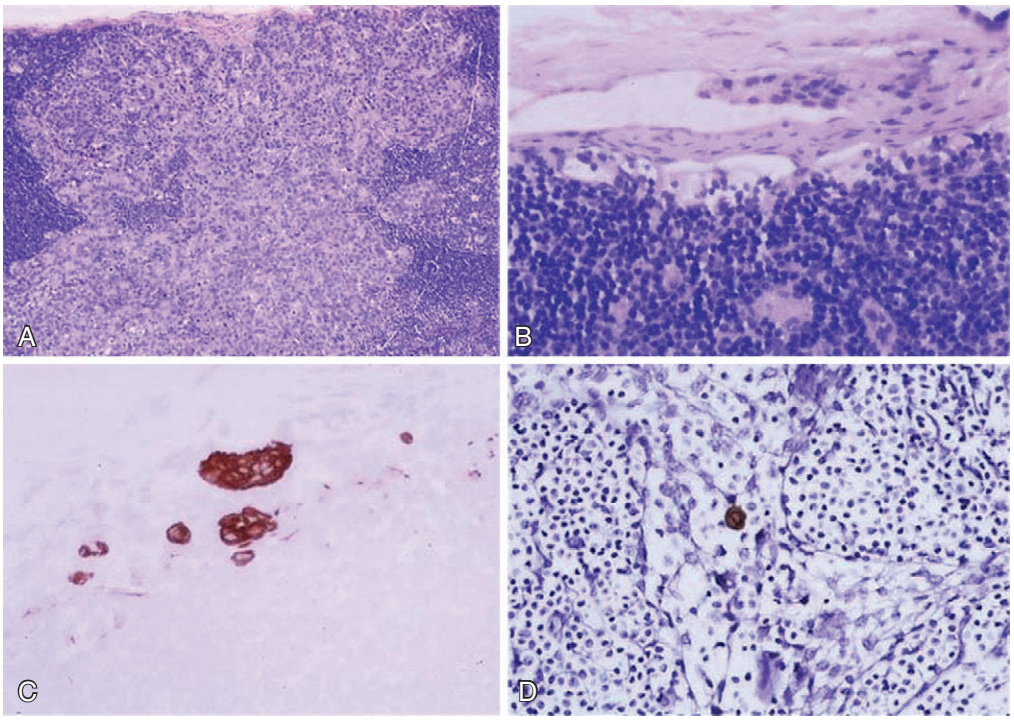

FIGURE 4 Photographs of mucinous invasive carcinoma after cryoablation, demonstrating histologic tumor destruction. *(Courtesy of Dr. Fred Odere, Raleigh Community Hospital, Raleigh, North Carolina. image guidance with stereotactic mammography or MRI. The high water content of breast cancer tissue enables focused microwaves to achieve specific tissue ablation.

RADIOFREQUENCY ABLATION

RFA is a technique in which thermal energy is applied to a specific location in order to cause focal tissue destruction. The tissue damage is achieved through the generation of intense heat by an alternating electric current running through one or more uninsulated electrode tips in the frequency range of radio waves (460 to 500 kHz). This current creates penetrating electromagnetic waves that agitate charged ions in adjacent tissue, creating an intense frictional heat, which in turn induces the desired effect: cellular protein denaturation and coagulation necrosis. As the temperature within the tissues become elevated beyond 45°C to 50°C, the tumor cells begin to die, and a localized region of necrosis around the electrode is created.

The technical means by which RFA is delivered to breast lesions is relatively straightforward. Local anesthesia and occasionally light sedation are used for patient comfort in preparation for the procedure. Some authorities have proposed either sterile saline or 5% dextrose solution to be locally infused peritumorally when there is less than 1 cm of margin from tumor edge to skin or from tumor edge to chest wall/pectoralis muscle. This infusion, whether superficial or deep to the tumor, is resistant to heating by RFA because of its high impedance; thus skin burns and chronic chest pain from inadvertent radial damage are minimized. A grounding pad is placed on the patient's skin as a reference electrode, which completes the electrical circuit and prevents electrical shock. The RFA probe with the uninsulated electrode is introduced into the tumor under ultrasound guidance. There are limits to the size of the ablation field that can be generated by a single electrode, and thus the use of secondary electrodes that deploy out of the distal end of the primary electrode has been the treatment standard (Figure 5). Initially the temperature of the tissue rises as the power through the electrode is gradually increased. The thermal zone of injury is monitored by ultrasonography and is delineated by a hyperechoic region, and at times the

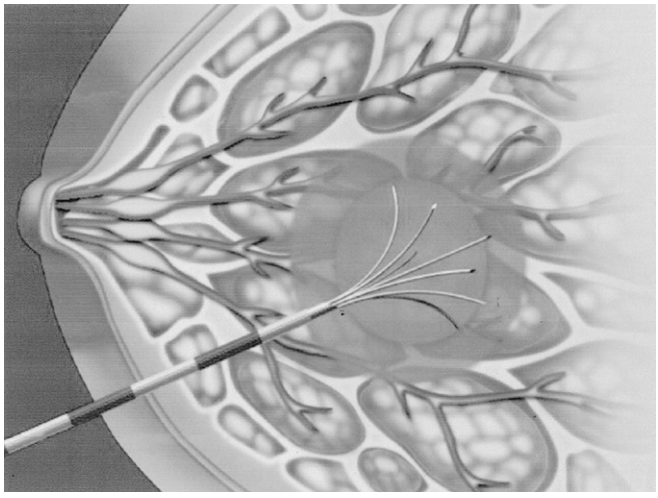

FIGURE 5 Representation of radiofrequency ablation, showing star array probe with breast and surrounding frozen ablation zone. *(Courtesy of RITA Medical Systems. From Simmons R: Ablative techniques in the treatment of benign and malignant breast disease,* J Am Coll Surg *197[2]:334–338, 2003. Copyright by the American College of Surgeons.)*

Doppler function is used as adjunct for hypervascular tumors. The RFA device continuously monitors impedance and power throughput during the treatment cycle, and once the involved region of tissue nears complete ablation, the impedance begins to rise, and the power delivered drops accordingly (Figure 6).

Breast cancer treatment by means of RFA has been studied only since 2000; researchers have attempted to duplicate its success in treating other tumors. The initial results of Jeffrey and colleagues (Jeffery SS, et al., 1999) in their pilot study were inspiring and paved the way for additional studies. Izzo and associates (Izzo F, et al., 2001) used ultrasonography-guided RFA for stages T1 and T2 breast cancers, followed by immediate resection, on 26 patients. They

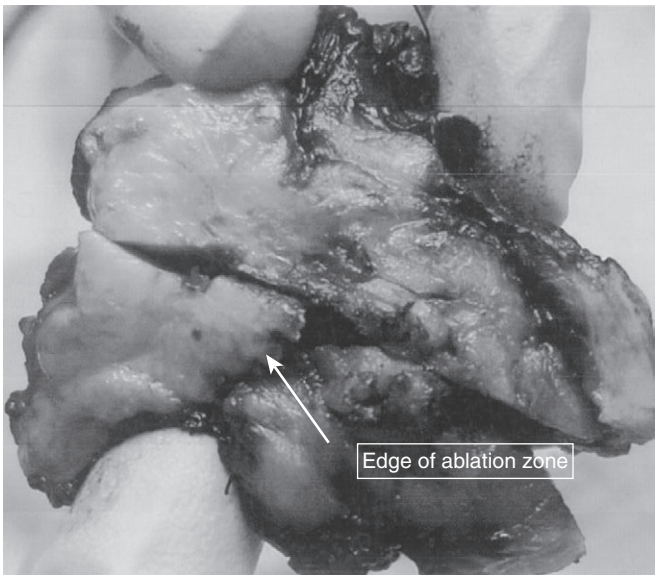

FIGURE 6 Excised breast cancer after radiofrequency ablation. *Arrow* marks outer red rim of ablation. *(From Simmons RM: Image-guided ablation of breast tumors. In Bland KI, Copeland EM, editors:* The breast: comprehensive management of benign and malignant disorders, *ed 3, Amsterdam, 2003, Elsevier.)*

demonstrated complete coagulation necrosis in 25 (96%) of 26 patients. One patient had remaining tumor cells adjacent to the needle penetration site, and one patient was found to have full-thickness burn of the skin overlying the tumor. Burak and colleagues (Burak WE, et al., 2003) demonstrated that RFA can be safely performed in the outpatient setting under ultrasound guidance and with local anesthesia, with accurate tumor ablation and good patient tolerance. Their series of 10 patients, all with stage T1 tumors, underwent RFA with delayed excision (1 to 3 weeks later). One patient had residual tumor, which was seen on post-RFA MRI and confirmed histologically.

Some of the later studies had difficulties in reproducing the results of their predecessors. Up through 2007, most of the large published series have shown that more than 85% of patients had complete ablation of the index lesion. However, in 2008, Medina-Franco and associates reported a mere 76% rate of complete target lesion ablation as reviewed by histopathology in their 25-patient study. This may have resulted in part because the tumors treated were larger, with a mean size of 20.8 mm (range, 9 to 38 mm). Garbay and colleagues (Garbay JK, et al., 2008) aborted their phase II clinical trial of RFA in recurrent breast cancer because of poor efficacy. They were able to show only 60% complete ablation rate in their first 10 patients, with a mean tumor size of 14 mm (range, 10 to 22 mm). Significant complications in almost 30% of study patients was reported by Imoto and associates (Imoto S, et al., 2009). Thirty patients were enrolled for the RFA study involving clinical stage I breast cancers. Of the 30, 9 had complications: 2 with skin burns and 7 with pectoralis major burns.

In 2012, Wilson and colleagues were able to reduce margin reexcision rates to less than 5% with a combination of local excision (lumpectomy) with immediate intraoperative RFA to the cavity site. The margins that were ablated were 1 cm circumferentially under ultrasound guidance. Only 3 of 73 patients in the study needed reexcision of margins after initial resection with immediate RFA treatment.

Currently it is believed that RFA is one of the most promising noninvasive techniques that have been proposed for treatment of breast cancer. It has already been demonstrated to have significant efficacy in treating liver, lung, and renal cancers, and results in pancreas, bone, brain, and prostate carcinomas have been encouraging as well. RFA is currently approved for the treatment of several cancers, including unresectable liver cancer and metastatic bone cancer, and has been under investigation for its utility in malignant breast disease.

In the majority of the initial studies of RFA in patients with breast cancer, investigators used intraoperative ablation immediately before surgical excision. RFA in these patients was delivered in the operating room with patients under a general anesthetic. Because of the risks of general anesthesia alone, some authorities question the benefits of RFA over lumpectomy. Moreover, with immediate resection, the true zone of necrosis could be underestimated. In the testing of pathologic margins for tumor viability, investigators utilized differing markers for immunohistochemical staining, and such testing has been inconsistent across studies. Of most importance, rates of short-term and long-term survival with RFA as a substitute for surgical resection cannot be accurately extrapolated from studies in which immediate or subsequent resection was undertaken.

Clearly RFA is a promising noninvasive technique for management of primary breast cancer; however, its use is still in its infancy at this point. Although the results are encouraging, some limitations in study design constrict clinical applicability. It appears as though stringent patient selection and a standardized method of delivery will be necessary to maximize patient safety and to obtain a consistent therapeutic effect. Additional studies are necessary before this treatment modality becomes mainstream.

Lymphatic Mapping and Sentinel Lymphadenectomy

Melissa S. Camp, MD, MPH, and
Barbara L. Smith, MD, PhD

INTRODUCTION

Patients diagnosed with invasive breast cancer typically require evaluation of the axillary lymph nodes. This information is important for staging purposes and has prognostic and treatment implications. Before the advent of sentinel lymph node biopsy (SLNB), axillary staging consisted of a level I and II axillary lymph node dissection (ALND). Although complete axillary node information is obtained from a full ALND, it comes at the risk of complications, including lymphedema, paresthesias, and arm dysfunction.

In the 1990s, SLNB was shown to reliably predict axillary nodal status in breast cancer. In the breast, the lymphatic anatomy consists of lymphatic channels that converge as they leave the breast, delivering fluid and cells to a specific node or small group of nodes referred to as the sentinel nodes. These are the first lymph nodes to receive drainage from the breast. Sentinel lymph node (SLN) mapping takes advantage of this anatomic arrangement, as radioactive or blue dye particles injected into the breast travel through the lymphatic channels and accumulate in the sentinel nodes first. Identification of the sentinel nodes is important because they are the most likely nodes to contain metastatic tumor if metastasis to the lymph nodes has occurred. If the sentinel nodes do not contain evidence of metastatic tumor, there is a very low risk of clinically significant axillary lymph node involvement.

Multiple studies have shown that SLN mapping for SLNB is successful approximately 95% of the time and is accurate in prediction of the presence of positive axillary nodes, with a false-negative rate of approximately 10%. No difference has been shown in axillary recurrence or survival for patients with a negative SLNB as compared with a negative ALND. Moreover, SLNB has been shown to have a significantly lower risk of lymphedema and the other complications associated with ALND. Therefore, if the SLNB results are negative, a full ALND can be omitted. If the SLNB results are positive, a full ALND may or may not be indicated.

INDICATIONS AND CONTRAINDICATIONS FOR SENTINEL LYMPH NODE BIOPSY

Patients eligible for SLNB include patients with clinically node-negative diagnosis of T1 to T3 invasive breast cancer who are undergoing lumpectomy or mastectomy. Certain patients with ductal carcinoma in situ (DCIS) may have an indication for SLNB, including those with suspicion of microinvasion and those with extensive DCIS requiring mastectomy. Patients with palpable DCIS or large areas of high-grade DCIS may also be considered for SLNB.

Patients with inflammatory breast cancer, T4 breast cancer, and biopsy-proven positive nodes are generally not eligible for SLNB. If patients are found to have clinically positive axillary nodes on physical examination, they should undergo an axillary ultrasound and biopsy (either fine-needle aspiration [FNA] or core biopsy) of any suspicious-appearing nodes to confirm axillary metastases. A level I and II ALND is indicated if clinically positive lymph nodes are found to contain metastatic disease on biopsy.

As imaging modalities improve, more patients with clinically negative nodes will have evidence of suspicious-appearing nodes on ultrasound or magnetic resonance imaging (MRI). For patients with suspicious nodes based on imaging criteria and a FNA result positive for malignancy, many recommend proceeding with a full ALND. Some, however, consider these patients with clinically negative but imaging and FNA positive nodes eligible for SLNB and tangent radiation if they meet the eligibility criteria for the American College of Surgeons Oncology Group (ACOSOG) Z0011 trial.

TECHNICAL ASPECTS

Mapping of the SLN can be achieved with either blue dye (isosulfan blue or methylene blue) or radioisotope (technetium-99 m sulfur colloid). The blue dye or radioisotope can be injected in a subareolar, subdermal, or peritumoral location. The blue dye is typically injected in the operating room after the induction of anesthesia and is followed by 5 minutes of breast massage, whereas the radioisotope can be injected up to 24 hours before surgery. Although each technique can be used individually with good success, use of blue dye and

radioisotope in combination increases the success of mapping and identifying the SLN.

If radioisotope is used for SLN mapping, a lymphoscintigram can be obtained to show whether mapping has been successful and to show the location of the sentinel lymph nodes. Lymphoscintigrams do not need to be ordered routinely, however, because a handheld gamma probe can be used in the operating room before the start of the procedure to determine whether mapping was successful. If a strong signal is not detected with the gamma probe, blue dye can be injected at the start of the procedure to aid with localization of the sentinel lymph node.

If a lymphoscintigram is obtained, nonaxillary sentinel lymph nodes (such as internal mammary nodes) can be identified up to 10% of the time. In general, the probability that a nonaxillary sentinel node would be the only positive node or that the status of a nonaxillary sentinel node would alter decisions about adjuvant therapy is small (~6%). Resection of nonaxillary sentinel nodes is typically not recommended, given the increased morbidity associated with internal mammary SLNB and the fact that clinical management algorithms are based on the status of the axillary sentinel nodes.

Isosulfan blue has been associated with a 1% to 3% incidence rate of allergic and anaphylactic reactions. No anaphylactic reactions have been reported with methylene blue, but skin necrosis has been reported with injection of methylene blue in an intradermal location. Methylene blue dye is contraindicated for use in pregnant women (U.S. Food and Drug Administration [FDA] pregnancy category X: studies have shown evidence of fetal abnormalities or fetal risk, contraindicated for use in pregnant women), and isosulfan blue is a FDA pregnancy category C agent (no adequate studies in pregnant women, but can be used if potential benefit to mother justifies potential risk to fetus). Technetium-99 m sulfur colloid can be used for mapping in pregnancy because the total radiation exposure to the fetus is low, particularly with adequate hydration to facilitate excretion via the urine.

The operative technique for performing a SLNB involves a 2-cm to 3-cm incision in the axillary skin over the point of maximal gamma probe signal. If blue dye but not radioactive dye is used, the incision is made at or just above the lower aspect of the hairline in the axilla. Dissection is carried down through the subcutaneous fat and clavipectoral fascia to enter the axillary fat pad. If radioisotope is used, a gamma probe is used to identify "hot" nodes. Any nodes with counts of more than 10% of the hottest node are considered to be hot. If blue dye is used, blue lymphatic channels can be followed and blue nodes identified with visual inspection. All hot or blue nodes should be removed, as should any other nodes that appear suspicious via palpation. Palpable suspicious nodes, for example, may be nodes that are completely replaced with tumor and that no longer have the ability to take up blue dye or radioisotope. If the SLN fails to map with either radioisotope or blue dye, a level I and II ALND is recommended. Failure to map most commonly occurs in the setting of previous breast or axillary surgery that may have altered the lymphatic drainage.

The sentinel nodes that are removed are sent to pathology for evaluation and can be evaluated with an intraoperative frozen section or permanent section. Sentinel lymph nodes removed during mastectomy should be sent for evaluation with intraoperative frozen section. If SLN are positive on frozen section, a level I and II ALND can then be performed at the time of mastectomy. On the basis of the recently published results of the ACOSOG Z0011 trial (discussed in greater detail subsequently), it is now recommended that sentinel lymph nodes removed during breast-conserving surgery be sent for permanent section only. Exceptions to this recommendation include patients in whom intraoperative palpation of the axillary lymph nodes is suggestive of gross extranodal extension or three or more positive nodes and patients who have received neoadjuvant therapy. These patients do not meet Z0011 eligibility criteria, and a second procedure can be avoided if a positive frozen section is followed by an immediate completion ALND. An intraoperative frozen section is also appropriate if patients undergoing breast conserving surgery do not receive systemic therapy and radiation therapy as per Z0011 guidelines.

SPECIAL CONSIDERATIONS

Neoadjuvant Chemotherapy

For patients undergoing neoadjuvant chemotherapy, discussion continues as to whether SLNB should be performed before or after completion of neoadjuvant treatment. If SLNB is performed before neoadjuvant chemotherapy and evidence is found of nodal disease, then ALND is generally performed regardless of the response to treatment. SLNB performed after neoadjuvant chemotherapy, on the other hand, allows for a single operative procedure, and ALND can be avoided if neoadjuvant chemotherapy has eradicated whatever nodal disease may have been present.

One concern with SLNB performed after neoadjuvant chemotherapy is whether it is as accurate as SLNB performed before therapy. Neoadjuvant chemotherapy has been suggested to potentially alter the lymphatic drainage pathway, interfering with the ability of the radioisotope or blue dye to accurately map the location of the sentinel nodes. Moreover, the effects of chemotherapy may not be uniformly distributed across all nodes, raising the question of whether there may still be residual disease in nonsentinel lymph nodes even if the sentinel node has had a complete response and is negative.

Several studies have addressed the issue of whether SLNB is accurate after neoadjuvant chemotherapy. Within the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-27 trial, the success rate for SLN mapping after neoadjuvant chemotherapy was 95.6% and the false-negative rate was 10.7%, very similar to the rates obtained with SLNB performed before chemotherapy. Another study by Hunt and colleagues showed that after neoadjuvant therapy the SLN was identified 97.4% of the time, compared with 98.7% in the group who had SLNB before chemotherapy. The false-negative rate was 5.9% in the neoadjuvant group, compared with 4.1% in the group who had SLNB before chemotherapy. Moreover, they showed that SLNB after neoadjuvant chemotherapy resulted in fewer positive SLNB and therefore decreased the rates of ALND. Other studies have had similar findings, confirming that SLNB is feasible and accurate after neoadjuvant chemotherapy.

More recently, studies have addressed the question of whether SLNB is accurate after neoadjuvant chemotherapy in patients who initially present with clinically positive axillary nodes. Small studies to date have concluded that SLNB is accurate in predicting the status of the axilla in these patients and can correctly identify patients who have been downstaged to node negative status and therefore can avoid an ALND. The ACOSOG Z1071 trial is currently accruing patients to determine the reliability of SLNB after neoadjuvant chemotherapy in patients with biopsy proven axillary nodal disease at presentation.

Another important consideration with SLNB and neoadjuvant chemotherapy is the impact on decisions about postmastectomy radiation therapy (PMRT). Historically, decisions about the need for PMRT and inclusion of additional radiation fields (such as axillary or supraclavicular fields) have been made based on axillary staging performed before systemic therapy. With neoadjuvant therapy and the potential for downstaging or complete pathologic response, debate exists about how to interpret posttreatment axillary nodal status when making decisions regarding the need for PMRT or additional radiation fields. Some radiation oncologists prefer SLNB before neoadjuvant therapy to help guide radiation decisions. The need for PMRT can also impact reconstruction options, so advance knowledge of a positive SLN can allow for appropriate planning in terms of delayed rather than immediate reconstruction or choices regarding use of autologous tissue versus tissue expanders or implants.

Implications of Micrometastatic Disease and Isolated Tumor Cells Detected with Sentinel Lymph Node Biopsy

Positive SLN detected with SLNB is classified into one of three categories: isolated tumor cells (ITC; N0[i+]), which are 0.2 mm or less in size; micrometastases (N1mic), which are more than 0.2 mm but not more than 2.0 mm in size; and macrometastases, which are more than 2.0 mm in size. Micrometastases and macrometastases are typically seen on routine hematoxylin and eosin (H&E) staining, but ITC often cannot be identified without the use of immunohistochemistry (IHC). The Z0010 trial found that 10.5% of SLN that were negative with H&E had evidence of occult metastasis with IHC, but no difference was found in overall survival between patients with IHC-positive and IHC-negative SLN. The NSABP B-32 trial found that 15.9% of SLN that were negative with H&E were positive with IHC for occult metastasis. Patients with IHC-positive nodes were found to have a small but statistically significant 1.2% decrease in overall survival at 5 years compared with those with IHC-negative nodes. This difference was deemed clinically insignificant, however, and the trial concluded that IHC analysis of negative SLN is not warranted. On the basis of subgroup analysis, the NSABP B-32 trial also showed that the risk associated with ITC was lower than the risk associated with micrometastases for all outcomes evaluated.

Although the presence of macrometastases in SLNB has traditionally led to a completion ALND, the need for ALND when micrometastases are found on SLNB is debated. One study with patients in the Surveillance Epidemiology and End Results (SEER) database diagnosed from 1998 to 2004 found that the proportion of patients with micrometastases who underwent SLNB alone increased from 21% to 37.8%. There was no statistically significant difference in overall survival for patients with micrometastases who underwent SLNB alone compared with SLNB followed by completion ALND. This study concluded that there was a trend towards foregoing completion ALND in patients with micrometastases on SLNB even before the publication of the ACOSOG Z0011 trial.

ALTERNATIVES TO AXILLARY LYMPH NODE DISSECTION FOR POSITIVE SENTINEL LYMPH NODES

ACOSOG Z0011 Trial

The ACOSOG Z0011 trial, published in 2010, has resulted in a paradigm shift in the management of the axilla for patients undergoing breast-conserving therapy. The trial was designed to evaluate the need for completion ALND in patients with low-volume metastatic disease on SLNB and randomized 446 patients to SLNB alone and 445 patients to SLNB plus ALND. The primary outcome was overall survival, and secondary outcomes included disease-free survival and locoregional recurrence.

Eligibility criteria included patients with T1 or T2 clinically node-negative breast cancer who were treated with lumpectomy and SLNB, had one or two positive SLN detected with H&E staining (on frozen section, touch prep or permanent section), received whole breast radiation but no specific axillary radiation, and received systemic therapy as determined by the treating physician. Although the trial closed in 2004 because of slow accrual (planned accrual of 1900 patients) and a low event rate, at a median follow-up of 6.3 years, there were no statistically significant differences in overall survival, disease-free survival, or locoregional recurrence between the SLNB alone and SLNB plus ALND groups.

The ACOSOG Z0011 study concluded that completion ALND provided no benefit in locoregional control or survival, despite the removal of additional positive lymph nodes. Of the patients in the SLNB plus ALND group, 27.4% were found to have additional positive nodes beyond the SLN, so it can be assumed that a similar proportion of patients in the SLNB alone group had additional positive nodes that were not removed. The rate of axillary recurrence in the two groups, however, was similar (0.9% in the SLNB alone group vs 0.5% in the SLNB plus ALND group). This suggests that adjuvant radiation and systemic therapy have a significant impact on any remaining positive nodes and contribute to effective local control without ALND.

One clinical implication of the Z0011 trial is that the use of intraoperative frozen section for SLNB is no longer indicated for patients undergoing lumpectomy and SLNB who meet Z0011 eligibility criteria. Patients who are found on permanent section to have one or two positive SLN are able to forego ALND, and those found to have three or more positive SLN are recommended to undergo delayed completion ALND. The Z0011 trial is not applicable, however, to patients receiving neoadjuvant chemotherapy, patients suspected to have extranodal extension or three or more positive nodes based on intraoperative assessment, or patients undergoing mastectomy. For these situations, the use of intraoperative frozen section for SLN is still warranted, and completion ALND is indicated if SLN are found to be positive.

IBCSG-23-01 Trial

The International Breast Cancer Study Group, IBCSG-23-01 trial was designed to address whether differences in survival exist between patients with micrometastases who undergo SLNB only versus those who undergo completion ALND. Preliminary results suggest that there is no difference in 5-year disease-free survival between the two groups. In addition, the rate of axillary relapse at 5 years was about 1% in patients with micrometastases who underwent SLNB only.

AMAROS Trial

The After Mapping of the Axilla: Radiotherapy or Surgery? (AMAROS) trial enrolled 4767 patients undergoing lumpectomy and SLNB and randomized those with positive SLN to either ALND or axillary radiotherapy. This trial is ongoing and the results are not yet available.

COMPLICATIONS

Complications associated with SLNB include paresthesias from disruption of sensory nerves, seroma, lymphedema, hematoma, and wound infections. All of these complications occur much less frequently after SLNB than after ALND. In the Z0011 trial, for example, adverse effects were reported in 25% of patients who underwent SLNB alone compared with 70% of patients who underwent SLNB plus ALND. With respect to specific complications, patients in the SLNB plus ALND group had more wound infections (8% vs 3%), seroma (14% vs 6%), paresthesias (39% vs 9% at 1 year), and subjective lymphedema (19% vs 6% at 1 year) compared with patients in the SLNB alone group. Other studies have also shown that the risk of complications with SLNB is about half that of ALND.

FUTURE DIRECTIONS

With publication of the data from Z0011 and the anticipation of results from trials such as AMAROS and IBCSG-23-01, debate about management of the axilla in the setting of a positive SLN continues. Can the results of Z0011, for example, be extrapolated to other clinical scenarios? If a patient is clinically node negative but has a node suspicious on ultrasound and positive on FNA, can they be

considered for SLNB and not automatically undergo a full ALND if all other Z0011 eligibility criteria are met? Other clinical situations that are being debated include whether patients undergoing mastectomy with positive SLN need a completion ALND if they will be receiving PMRT, whether all patients with positive SLN after neoadjuvant chemotherapy need a completion ALND, and whether patients with more than two positive SLN can forego a completion ALND. Future studies in these areas will hopefully provide answers to these questions.

CONCLUSION

Currently, SLNB is the standard of care for axillary staging in patients with T1 to T3 invasive breast cancer and for patients with DCIS undergoing mastectomy. SLNB has been shown to reliably and accurately predict nodal status with significantly decreased morbidity compared with ALND. Completion ALND for positive SLN is still indicated in certain clinical situations, but radiation and systemic therapy contribute to local control, allowing omission of axillary dissection in selected patients with a positive SLN.

The Management of the Axilla in Breast Cancer

Jennifer H. Lin, MD, and
Armando E. Giuliano, MD, FACS, FRCSEd

OVERVIEW

Axillary nodal status remains one of the most important factors predictive of long-term survival in patients with breast cancer. Axillary nodal metastases are associated with a poorer prognosis and often prompt more aggressive systemic and local treatment. Although the standard for staging and treatment has been levels I and II axillary dissection for invasive breast cancer, the surgical management of the axilla has evolved. Aggressive dissection of the axilla is no longer necessary for most patients with early breast cancer.

Nineteenth century theories of breast cancer championed by William Halsted maintained that breast cancer metastasized sequentially from the primary tumor to regional lymphatics, then to distant metastatic sites. He proposed that the radical mastectomy, with removal of the pectoralis major and minor muscles, complete axillary node dissection, and supraclavicular node dissection, would lead to higher cure rates. Bernard Fisher disputed this theory in the 1970s, proposing instead that breast cancer was a systemic disease at the time of diagnosis. Fisher's National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 prospective randomized clinical trial proved that extensive local treatment aimed at the removal of axillary node metastases did not, in fact, lead to improved survival. This pivotal study, with 25 years of follow-up, compared radical mastectomy with simple mastectomy with nodal and chest wall radiation, and with simple mastectomy alone, and showed no difference in overall survival between the three treatment arms.

Axillary lymph node dissection (ALND), once consistently used for staging and treatment of breast cancer, is no longer routinely indicated. This procedure has significant morbidities, including lymphedema, pain, neuropathy, cosmetic deformity, and decreased range of motion. Sentinel lymph node biopsy (SLNB), with its decreased morbidity, has replaced axillary dissection as a highly accurate axillary staging procedure in patients with clinically node-negative early-stage breast cancer.

CLINICALLY NODE-NEGATIVE INVASIVE BREAST CANCER

Sentinel node biopsy has been validated in numerous clinical studies and has replaced axillary dissection for clinically node-negative breast cancer. This technique is based on the hypothesis that the first node draining the primary tumor reflects the status of the remaining lymph nodes in that basin. This procedure is highly predictive (96%) of the tumor status of the remaining axillary nodes in which a sentinel node is identified, with an acceptably low false-negative rate (0 to 11%). This was determined from a comparison of results of patients randomized to SLNB or ALND and from studies that compared sentinel node status with completion ALND status in the same patient.

Management of Patients With Pathologically Negative Sentinel Nodes

Patients with tumor-free sentinel nodes are adequately treated with SLNB only, and no further axillary treatment is needed. Axillary recurrence rates are less than 1%, with greatly decreased morbidity compared with ALND.

This has been validated in a number of prospective randomized trials. The NSABP trial B-32 was the largest multicenter randomized control trial designed to examine whether SLNB was equivalent to ALND in breast cancer with tumor-free sentinel lymph nodes. This trial showed that overall survival, disease-free survival, and regional control were all equivalent in patients who had SLNB plus ALND or SLNB alone. Other trials from Europe have shown the same results.

Management of Patients With Sentinel Node Micrometastases

Sentinel node biopsy has allowed for more intensive examination of the draining lymph nodes. Complete histologic analysis of these nodes has involved serial sectioning with three to five sections per node examined. Tumor deposits in lymph nodes may be detected with routine hematoxylin and eosin (H&E); immunohistochemical (IHC) methods, which stain breast epithelial cytokeratins and facilitate identification of small tumor deposits; or even polymerase chain reaction (PCR). These staging procedures have led to the detection of micrometastases (>0.2 mm to 2.0 mm, or more than 200 cells; N1mi) and isolated tumor cells (ITCs; defined as small clusters of cells ≤0.2 mm, single tumor cells, or nonconfluent or nearly confluent clusters of cells not exceeding 200 cells in a single histologic cross section; N0[i+]; American Joint Committee on Cancer [AJCC] Breast Cancer Staging, ed 7). Although the most recent guidelines from the American Society of Clinical Oncology (ASCO) Consensus Statement in 2005 recommend completion axillary dissection when either micrometastatic disease or isolated tumor cells in lymph nodes is found regardless of the method of detection, recent studies show this to be unnecessary, especially for patients treated with breast-conserving surgery and whole-breast irradiation.

A cohort analysis of the NSABP B-32 randomized trial examined whether patients with occult sentinel lymph node micrometastases and ITCs had worse survival compared with patients without micrometastases or ITCs, assessed with both H&E and IHC analysis. Although this study showed a small statistically significant but clinically insignificant decrease in 5-year overall survival rate of 1.2% in patients with occult sentinel lymph node metastases, this difference was concluded to be insufficient to cause alterations in adjuvant systemic treatment or justify the use of routine IHC.

Similarly, the American College of Surgeons Oncology Group (ACOSOG) Z0010 trial, one of the largest multicenter prospective trials to examine the significance of occult sentinel node metastases, showed that IHC-detected occult sentinel node metastases were not associated with survival differences in women undergoing breast-conserving surgery, sentinel node biopsy, and whole-breast irradiation for treatment of T1 or T2 clinically node-negative breast cancer. Long-term follow-up study may eventually reveal small differences in outcome, but these too are likely to be of no clinical significance. Most patients in the ACOSOG Z0010 trial and NSABP B-32 trial received adjuvant systemic therapy, which demonstrates practice patterns independent of IHC findings because IHC results were blinded to clinicians in both studies.

The findings of these two trials are confirmed by the 2011 preliminary results of the randomized International Breast Cancer Study Group (IBCSG) Trial 23-01 that compared axillary dissection versus no axillary dissection in patients with sentinel node micrometastases and have important implications for current clinical practice in the management of micrometastases and ITCs. Patients with micrometastases or ITCs should not have additional axillary node dissection or systemic therapy solely on the basis of the findings of sentinel lymph node (SLN) micrometastases or ITCs.

Management of Patients With Sentinel Node Macrometastases

The management of patients with lymph node macrometastases, defined as tumor deposits of more than 2.0 mm, has also undergone recent radical changes. Although the 2005 ASCO guidelines recommend routine axillary dissection for patients with a positive SLN, recent data from the ACOSOG Z0011 trial show this to be unnecessary for many patients.

In the ACOSOG Z0011 trial, patients with early breast cancer and H&E-detected sentinel node metastases were randomized to SLNB alone versus ALND. The patients who were enrolled had clinical T1 or T2 invasive breast cancer, no palpable lymphadenopathy, and one or two sentinel nodes with macrometastases and underwent breast-conservation surgery (BCS) and received whole-breast irradiation. This multicenter randomized trial showed no difference in local control, disease-free survival, or overall survival for patients with H&E-detected sentinel node macrometastases who were randomized to SLNB alone versus SLNB plus ALND. The results of this trial indicate that axillary node dissection is not necessary after SLNB in women undergoing BCS and whole-breast irradiation, with one or two tumor-involved SLNs, a T1 or T2 tumor, and no significant extranodal extension. No axillary specific radiation was given, and 96% of the patients received adjuvant systemic therapy (chemotherapy or hormonal therapy or both). These findings have resulted in a change of the 2012 National Comprehensive Cancer Network (NCCN) guidelines, which no longer recommend mandatory completion ALND for macrometastases, micrometastases, or ITCs in patients who meet *all* of the following criteria: T1 or T2 tumor, one or two positive sentinel lymph nodes, breast-conserving surgery, whole-breast irradiation planned, and no neoadjuvant chemotherapy. These results are not applicable for patients treated with mastectomy, partial breast irradiation, prone radiation, neoadjuvant chemotherapy, or T3 cancers. These women undergoing mastectomy who are found to have sentinel node macrometastases still should undergo completion axillary node dissection.

CLINICALLY NODE-POSITIVE INVASIVE BREAST CANCER

In patients with grossly palpable nodes, the standard remains axillary node dissection with the removal of level I and II axillary nodes. In patients with suspicious palpable axillary nodes, however, clinical examination is often unreliable and can be falsely positive in up to 40% of patients. In these circumstances, axillary ultrasound scan with needle biopsy is a reliable technique. Alternatively, patients with clinically suspicious axillary nodes can undergo sentinel node biopsy with removal and evaluation of the palpable nodes.

Traditional level I and II axillary dissection requires that at least 10 lymph nodes be evaluated for accurate staging of the axilla. Axillary dissection should not include level III nodes unless gross disease is apparent.

Other Indications for Axillary Node Dissection

Axillary node dissection should be performed in patients when many clinically suspicious nodes are present in the axilla after all sentinel nodes have been removed. In addition, a complete axillary node dissection should be done if no sentinel node is identified or if the SLNB is technically unsatisfactory. Although the indications for completion axillary dissection in patients with tumor-involved

sentinel nodes have been altered by recent data from the ACOSOG Z0010 and Z0011 trials, those undergoing mastectomy with tumor-involved sentinel nodes still need completion axillary dissection. Axillary dissection remains indicated in women undergoing BCS and whole-breast irradiation found to have more than two tumor-involved sentinel nodes or gross extranodal extension.

In patients with inflammatory breast cancer, sentinel node biopsy should not be performed because the subdermal lymphatics can be partially obstructed with tumor emboli, leading to an unacceptably high false-negative rate. Thus, in patients with inflammatory breast cancer, an axillary node dissection should be performed.

Axillary dissection, and even SLNB, may be omitted in patients who have particularly favorable tumors, patients for whom the selection of adjuvant systemic therapy is unlikely to be affected, the elderly, and those with serious comorbid conditions, with the understanding that they may be at increased risk for ipsilateral lymph node recurrence.

AXILLARY MANAGEMENT FOR DUCTAL CARCINOMA IN SITU

Sentinel node biopsy in patients with ductal carcinoma in situ (DCIS) is generally not indicated because of the low risk of axillary node metastases; however, it can be performed in selected clinical situations. Although up to 15% of patients with DCIS are found to have involved sentinel nodes, usually ITCs or occasionally micrometastases, this finding is of no clinical significance. In retrospective and prospective studies, these sentinel node ITCs and micrometastases are not associated with increased local or distant recurrence in patients with pure DCIS or even microinvasion. Because these rates of sentinel node involvement in DCIS are not consistent with the pathogenesis of DCIS, these small deposits are thought to represent tumor debris, perhaps from biopsies, rather than viable metastatic tumor cells in the nodes.

SLNB in patients with DCIS may be performed selectively in certain clinical circumstances. Because DCIS is now frequently diagnosed with core needle biopsy, invasive carcinoma is subsequently found on definitive excision in up to 15% to 20% of patients. Mastectomy precludes sentinel node biopsy if an invasive tumor is subsequently found, so SLNB is recommended for patients with DCIS undergoing mastectomy. This avoids the need for axillary dissection if an invasive cancer is identified and no sentinel node biopsy was performed. Selective use of SLNB is recommended in patients with large (>4 cm), palpable, or high-grade DCIS diagnosed with core-needle biopsy who are having BCS to avoid a second operation if invasive cancer is subsequently found.

AXILLARY MANAGEMENT IN PREGNANT PATIENTS

Radiolabeled colloids for sentinel node biopsy for pregnant patients are safe based on the rapid clearance and uptake of the colloid. The dose of radiation received by the fetus with standard technetium 99m (Tc-99m) sulfur colloid has been shown to be minimal and falls well below National Council on Radiation Protection and Measurements threshold guidelines for pregnant patients. Limited studies document the safety of SLNB during pregnancy with low-dose lymphoscintigraphy (10 MBq) with Tc-99m and recommend the use of injection on the same day as the operation to reduce the dose of radiation. Some centers advocate the use of Tc-99m sulfur colloid with hydration and placement of a bladder catheter to avoid accumulation of excreted isotope in the pelvis.

Blue dye should not be used for sentinel node biopsy in pregnant patients because it is currently classified as a category C drug and limited data exist on its teratogenic effects and its low risk of anaphylactic maternal reaction.

AXILLARY MANAGEMENT IN THE ELDERLY

For elderly patients with clinically negative nodes, careful consideration must be given before surgical staging of the axilla. SLNB should be considered only if the nodal status will alter treatment decisions. SLNB can be omitted in elderly or frail patients with estrogen receptor-positive, clinically node-negative tumors in which chemotherapy is not an option and endocrine therapy will be used regardless of nodal status. In elderly patients, axillary recurrences after BCS and endocrine therapy are low (1% at 5 years), even with the omission of radiation and axillary surgery.

Age greater than 70 years was found to be associated with increased SLNB difficulty and failure rates. SLNB should be performed in elderly patients based on their health and need for information of axillary nodal status. SLNB should be performed in healthy elderly patients with clinically node-negative breast cancer in whom chemotherapy is under consideration. Axillary dissection should be performed in elderly patients with clinically positive nodes.

AXILLARY MANAGEMENT IN MALE BREAST CANCER

Because the delayed diagnosis of breast cancer in men often leads to the presentation with more advanced tumors, the most common surgical procedure in these patients is a modified radical mastectomy, followed by radiation therapy for large tumors, nodal metastases, or skin involvement. The feasibility and accuracy of SLNB in male patients with breast cancer, however, has been supported by numerous small institutional studies. The SLNB procedure has been shown to be reliable in male patients with breast cancer, sparing many patients unnecessary axillary node dissections.

POSITIVE AXILLARY NODES WITH AN OCCULT PRIMARY TUMOR

Up to 1.0% of breast cancer patients may present with only enlarged axillary nodes and an occult primary tumor not present on physical examination, breast ultrasound scan, or mammography. A core or fine-needle biopsy of the suspicious axillary node should be obtained and appropriate immunohistochemistry performed (i.e., estrogen receptor [ER]/progesterone receptor [PR] and human epidermal growth factor receptor–2 [HER2]) to help identify a breast origin. Other tumor types, such as lymphoma, ovarian cancer, melanoma, and occasionally lung, thyroid, or neuroendocrine tumors, should be ruled out with an expanded panel of immunohistochemical markers. If axillary node histology is consistent with a breast origin, breast magnetic resonance imaging (MRI) is indicated for identification of the primary tumor in 50% of such patients. A staging workup should be performed to rule out distant metastases.

In patients with histopathologic evidence of breast cancer in axillary nodes, but no primary breast lesion identified after additional imaging, complete axillary node dissection should be performed. Subsequent treatment of the breast with whole-breast irradiation without mastectomy has shown low rates of local failure. Alternatively, mastectomy may be performed. In patients with bulky or fixed axillary nodes, neoadjuvant systemic therapy followed by axillary dissection may be considered.

AXILLARY MANAGEMENT AFTER NEOADJUVANT CHEMOTHERAPY

Neoadjuvant chemotherapy is often considered in women with large clinical stage IIA, IIB, and T3N1M0 tumors who wish to undergo

BCS. The appropriate timing of SLNB in women treated with neoadjuvant chemotherapy remains under debate; initial early data showed mixed results of feasibility and accuracy of SLNB in this setting.

Proponents of SLNB after neoadjuvant chemotherapy cite the benefits of a single operative staging procedure. Furthermore, because neoadjuvant chemotherapy may eradicate nodal disease in up to 40% of patients, many patients can theoretically be spared from a complete ALND.

However, concerns exist that SLNB after neoadjuvant chemotherapy may decrease the accuracy of identification of SLN and increase the false-negative rate. Chemotherapy may cause fibrosis and obstruction of tumor-involved lymphatic channels, which may lead to inaccurate mapping. Furthermore, the response to chemotherapy may not occur uniformly in lymph nodes, leaving residual disease in nonsentinel lymph nodes and limiting the accuracy of SLNB in this setting. The false-negative rate of sentinel node biopsy in the preneoadjuvant or postneoadjuvant chemotherapy setting is low; however, a pathologic complete response after chemotherapy may occur in lymph node metastases previously undetected with clinical examination. The information gained from prechemotherapy axillary staging may have implications on further clinical treatment decisions, such as the need for completion axillary dissection, postmastectomy radiation, and axillary nodal irradiation.

Patients with a negative sentinel node after neoadjuvant chemotherapy are often recommended to undergo axillary irradiation because the true axillary status was unknown. A negative sentinel node found before neoadjuvant chemotherapy spares the patient axillary irradiation.

The largest series to examine the feasibility of SLNB after neoadjuvant chemotherapy was completed as part of the NSABP B-27 trial. These patients underwent SLNB with radioactive colloid, blue dye, or both and had an identification rate of 84.8%. The study suggested that the use of SLNB after neoadjuvant chemotherapy could be most applicable to patients who had a complete clinical response after therapy. Nevertheless, no convincing evidence shows that patients with previously tumor-involved axillary nodes, which subsequently become negative after neoadjuvant chemotherapy, can be spared axillary dissection.

A recent prospective study, ACOSOG Z1071, showed higher than expected false-negative rates with SLNB after neoadjuvant chemotherapy. This study, however, does not answer the important question of the outcome of the untreated axilla after conversion from positive to negative with neoadjuvant therapy and the impact on survival.

In patients with clinically negative axillary nodes anticipated to undergo neoadjuvant chemotherapy, sentinel node biopsy may be performed for accurate staging of the axilla before initiation of systemic treatment. For those with clinically suspicious axillary nodes, needle biopsy of the nodes before treatment is recommended, along with SLNB before neoadjuvant chemotherapy if the needle biopsy results are negative.

If the prechemotherapy SLNB is histologically negative, axillary dissection may be omitted. If the prechemotherapy needle biopsy or SLNB is histologically positive, then a completion axillary dissection should be performed at the time of definitive surgical therapy. A clip may be placed at the time of needle biopsy to ensure the removal of the affected node at the time of axillary dissection. Alternatively, if prechemotherapy nodes are initially positive and then convert to negative on SLNB after chemotherapy, axillary-specific irradiation can be considered as an alternative to completion axillary nodal dissection.

MANAGEMENT AFTER PRIOR AXILLARY SURGERY

SLNB after prior axillary surgery is less successful because of the disruption of the lymphatic drainage pattern. Multiple studies, however, have shown that reoperative SLNB is feasible after previous axillary surgery. In patients who have had previous complete axillary dissection, the success of reoperative SLNB is between 29% and 38%. Because nonaxillary lymphatic drainage can occur in up to 30% of patients being considered for reoperation after a prior complete axillary dissection, preoperative lymphoscintigraphy is necessary to identify aberrant nonaxillary drainage patterns.

MANAGEMENT OF AXILLARY TUMOR RECURRENCE

Patients with isolated axillary recurrence have 5-year survival rates of approximately 60% to 80%. In patients with involved supraclavicular nodes, internal mammary nodes, or multiple sites of nodal disease, the prognosis is worse. Nodal recurrences may present up to 10 years after initial treatment but are usually seen in the first 2 to 3 years.

Axillary node recurrences often present as an asymptomatic mass in the axilla. This can indicate regional recurrence of the prior cancer, in-breast tumor recurrence occurring in the axillary tail, or a new breast primary. A tissue diagnosis with needle biopsy confirms the presence of recurrence. Should a regional recurrence be found, a search for a new breast primary, and a full metastatic workup, is indicated. A completion axillary node dissection is indicated, usually with regional radiation and additional systemic therapy.

AXILLARY RADIATION AFTER AXILLARY DISSECTION

After ALND, axillary and supraclavicular nodal irradiation is used in select patients who are at high risk for local recurrence. Patients with multiple tumor-involved axillary nodes (usually four or more) or significant extranodal tumor deposits usually require axillary-specific radiation with an additional radiation field that includes the supraclavicular nodes. Occasionally, a fourth field is added posteriorly to bring up the dose in the posterior axilla (known as the posterior axillary boost [PAB] field). A total dose of 45 to 50 Gy is given, over 1.8 to 2.0 Gy fractions daily. This dose is typically what is necessary to eradicate microscopic disease. Higher doses are sometimes needed with gross disease remaining or with extensive extranodal spread.

The morbidity after ALND increases significantly with the additional axillary radiation therapy, with reported lymphedema rates up to 30%. Brachial plexus injury may be seen after axillary irradiation. These morbidities are significantly reduced with modern techniques, such as intensity-modulated radiotherapy (IMRT) and image-guided radiotherapy (IGRT).

ALTERNATIVES TO AXILLARY SURGERY

Alternative nonsurgical methods of axillary treatment are being investigated in patients with clinically negative lymph nodes to avoid the morbidities of ALND. These alternatives include radiation, systemic therapy, and observation only.

Axillary irradiation has been shown to be effective in several studies. In standard tangential whole-breast irradiation, approximately 80% of level I and of level II axillary lymph nodes are treated to 95% of the prescribed dose. Similarly, systemic therapy contributes to local control. This has been shown in the ACOSOG Z0011 trial, which effectively compared the efficacy of tangential whole-breast irradiation and adjuvant systemic therapy with ALND with whole-breast irradiation and adjuvant systemic therapy for patients with positive sentinel nodes. Randomized control trials have shown the

efficacy of axillary radiation therapy. Studies of ALND versus axillary radiation therapy show axillary failure rates of 1% to 3%, with no impact on survival rates. Axillary observation, with no treatment specific to the axilla for patients at low risk, show low failure rates and no difference in 5-year survival rate (96%) compared with ALND.

Several trials investigating axillary irradiation are still in progress. The European Organization for Research and Treatment of Cancer (EORTC) 10981 AMAROS (After Mapping of the Axilla: Radiotherapy or Surgery) trial is a phase III study to compare completion ALND with axillary irradiation in patients with positive sentinel nodes. This study aims to prove equivalence of axillary surgery and axillary radiation therapy for locoregional control in the setting of a tumor-involved sentinel node. A new EORTC trial, the POWER trial (Positive Sentinel Node: Wait & See, Excision, or Radiotherapy), aims to identify axillary recurrence rates in patients with sentinel node micrometastases if no further axillary therapy is offered.

In frail patients with node-negative breast cancer and estrogen receptor-positive tumors, endocrine therapy only without axillary surgery or axillary radiation may be applicable. Axillary radiation therapy without surgical staging may also be considered in patients with clinically node-negative disease whose nodal status will not alter adjuvant treatment plans.

TECHNICAL ASPECTS OF AXILLARY LYMPH NODE DISSECTION

The ALND is best performed when the patient is positioned supine, with the ipsilateral upper extremity prepped and wrapped free to allow for elevation and adduction. This maneuver provides better exposure to the upper levels of the axilla by decreasing tension on the pectoral muscles. The incision is placed transversely in the mid axilla, posterior to the pectoralis major margin. The dissection begins with the exposure of the lateral border of the pectoralis minor with dividing the interpectoral tissues. Division of the clavipectoral fascia medially along this border and transversely in line with the coracobrachialis muscle releases the specimen and exposes the axillary vein. Effort should be made to preserve median pectoral nerve whenever possible. The inferior branches of the axillary vein are divided, releasing the specimen cranially. Care should be taken to remove only axillary tissue inferior to the axillary vein to avoid brachial plexus injury. Blunt dissection of the remaining attachments of the specimen along the serratus and subscapularis muscles releases it inferior and posteriorly. Preservation of the upper intercostal nerves is often possible, but sensation may be altered after mobilization and retraction of these branches. The long thoracic and thoracodorsal nerves are carefully identified and preserved. A marking stitch for orientation is often placed at the apex of the specimen. A drain is often left in place and removed after surgery.

Inflammatory Breast Carcinoma

Rosemarie Hardin, MD, and Julie R. Lange, MD, ScM

INTRODUCTION

Inflammatory breast cancer (IBC) is a rare and aggressive form of breast cancer that warrants special consideration. It accounts for less than 5% of invasive breast cancers in the United States, but accounts for a disproportionate number of breast cancer deaths. It has unique diagnostic criteria, and the history and physical exam are central in determining whether a patient has inflammatory breast cancer. This subtype of breast cancer is mainly diagnosed on clinical suspicion and physical exam and then confirmed with diagnostic biopsy and breast imaging. The rapid progression of symptoms differentiates IBC from neglected, locally advanced invasive breast cancer with skin involvement. IBC demonstrates aggressive behavior from the outset and requires multimodality treatment, including systemic chemotherapy, surgery, radiation therapy, and hormonal therapy and trastuzumab when appropriate. Long-term survival rates remain well under 50%.

CLINICAL PRESENTATION

Compared to other types of breast cancer, IBC tends to be diagnosed at younger ages, with a median age of 57 years, compared to a median age of 62 years for other types of breast cancer, according to the National Cancer Institute statistics. It is also more common among African American women and tends to occur at somewhat younger ages in this population, with a median age of 54 years.

The clinical presentation of IBC is unique and is the key to its proper diagnosis. IBC has rapid onset, typically from several weeks up to 6 months. The usual clinical presentation of IBC is with erythema, swelling, and warmth involving at least one third of the breast, giving an "inflamed" look to the breast. The swelling and edema of the breast can in some cases be quite noticeable, with an increase in the size of the breast over a short time; patients may report a growing sense of heaviness in the breast. The skin of the breast often displays the classic thickening referred to as *peau d'orange*. These skin changes result from blockage of the cutaneous lymphatics. A skin biopsy often demonstrates adenocarcinoma invading the dermal lymphatics. However, there is no direct correlation between the presence, number,

or size of the emboli and the degree of erythema present. Although nipple involvement is not a defining clinical feature of IBC, there may be nipple changes evident, such as retraction or swelling, and certainly the skin changes affecting the breast can also affect the nipple-areolar complex. The skin changes are often the most notable feature of IBC and can rapidly progress in some cases from a vague pinkish discoloration to deep or bright red in a matter of days and can involve the breast diffusely. There may or may not be a distinct tumor mass on exam. The striking erythema of IBC can be mistaken for breast infection. While mastitis or cellulitis can occur in women of any age, it is more common around the time of lactation. Clinical concern should be raised regarding the possibility of IBC among nonlactating women presenting with erythema and swelling of the breast.

Most women diagnosed with IBC have regional nodal involvement at the time of diagnosis; therefore, it is common to find palpable or matted axillary lymph nodes. It is estimated that the frequency of involvement of axillary and supraclavicular lymph nodes in IBC ranges from 60% to 85%.

IBC is a distinctly separate clinicopathologic entity from locally advanced breast cancer (LABC). While the presentation of LABC can include skin thickening, erythema, peau d'orange, and axillary adenopathy, these changes in LABC are generally found after a long clinical history of a slowly enlarging (and neglected) breast mass. IBC, however, is characterized by a very short clinical history, with rapid development of skin changes usually prior to (or without) the development of a distinct mass. The clinical history is the key to distinguishing these two entities.

DIAGNOSIS AND STAGING

Evaluation of the woman with suspected inflammatory breast cancer includes history and physical exam, diagnostic breast imaging, biopsy, liver function tests, and systemic staging studies. The main goals of diagnostic breast imaging are to identify a possible primary breast tumor, evaluate the regional nodes, and enable image-guided biopsy for pathologic confirmation of IBC. Image-guided needle biopsy also allows for evaluation of estrogen receptor, progesterone receptor, and *Her 2 neu* status. The goals of systemic staging are to properly evaluate regional disease and determine whether distant metastatic disease is present.

Initial breast imaging includes diagnostic mammogram and breast ultrasound as needed. The most common mammographic findings in a patient with IBC include skin thickening, diffusely increased density unilaterally, discrete mass, axillary adenopathy, architectural distortion, and suspicious calcifications. If a lesion is identified in the breast parenchyma or a suspicious regional lymph node is identified, then an image-guided core biopsy can be performed to confirm the diagnosis and provide information regarding histologic grade, estrogen and progesterone receptor status, and *Her 2 neu* status. Breast ultrasound can also be useful in detecting signs of the disease and in particular can be helpful for evaluation of tumor burden in the regional lymph nodes. Ultrasound guidance is frequently used for needle biopsy to establish the status of abnormal-looking axillary nodes. Magnetic resonance imaging (MRI) has found increasing use in the diagnosis and evaluation of breast cancer in general. MRI is not necessary for all cases of IBC, but it can be used selectively when helpful, such as for women with dense breast parenchyma that might limit the sensitivity of mammograms.

Skin punch biopsy is sometimes done as part of the initial evaluation. Punch biopsy of the skin may reveal dermal lymphatic invasion of the papillary and reticular dermis, resulting from lymphovascular tumor emboli. If a skin punch biopsy is chosen, it is recommended that at least two biopsies between 2 and 8 mm in diameter be performed in a representative area of the breast with skin changes. While dermal lymphatic invasion is considered to be strongly supportive of a diagnosis of IBC, it is neither necessary nor sufficient. A negative skin biopsy does not rule out IBC if clinical suspicion is strong.

Essential findings to establish a diagnosis of IBC include a history of rapid development of breast erythema with skin edema with duration of symptoms less than 6 months (and usually less than 3 months); diffuse changes, usually including at least a third of the skin of the breast; and pathologic confirmation of invasive mammary carcinoma.

At diagnosis approximately one fourth of patients with IBC will have distant metastases. Systemic radiologic staging is an essential part of the initial evaluation of patients diagnosed with IBC. Minimally, this can include liver enzymes; computed tomographic (CT) scan of chest, abdomen, and pelvis; and bone scan. The proper role of positron emission tomography-computed tomographic (PET-CT) scan for staging of breast cancer is evolving. It is most helpful in situations where conventional staging studies are equivocal and when the result of PET-CT would alter treatment decisions. There is some suggestion that PET-CT may have a role in the early assessment of response to systemic therapy. At present the use of PET-CT must be decided on an individual basis.

In the seventh edition AJCC TNM staging system, IBC is the only primary tumor classified as T4d. Patients with N0, N1, or N2 disease without evidence of distant disease are designated as stage IIIB. Those with evidence of metastases to supraclavicular, infraclavicular, or internal mammary nodes but without distant disease are stage IIIC. Patients with distant disease have stage IV disease. About 20% to 35% of patients with IBC have identified distant disease at the time of presentation.

TREATMENT

IBC requires a multimodality approach involving systemic therapy as the first treatment, given the aggressive nature of this disease, followed by locoregional therapies with surgery and radiotherapy, as well as the addition of systemic hormonal therapy when indicated.

Neoadjuvant Chemotherapy

Given the presentation of IBC and its propensity for rapid progression and distant metastasis, the cornerstone of therapy remains the prompt institution of systemic therapy with anthracycline-based neoadjuvant chemotherapy. The benefit of taxanes is also recognized for this population, as it is for other breast cancer patients. Trastuzumab should be included for patients whose tumor is positive for *Her 2 neu* overexpression. Neoadjuvant chemotherapy allows systemic treatment as expeditiously as possible and often results in decreased disease burden in the breast, improving operability and completeness of resection. Furthermore, the clinical response to neoadjuvant chemotherapy can be a good indicator of prognosis. Response to neoadjuvant chemotherapy should be carefully monitored with a combination of physical examination and radiologic imaging. Patients responding to chemotherapy (with a decrease in locoregional tumor burden) will proceed on to surgery as the next step. Patients who do not respond to neoadjuvant chemotherapy should be considered for alternate additional chemotherapies and/or preoperative radiation therapy. Those responding to these secondary treatments can then proceed on to surgery. Patients with stage IV disease can be restaged after initial chemotherapy; surgery is considered on an individual basis, depending on the estimation of systemic disease control versus the need for expectant palliation of the primary site.

Surgery

Surgery plays an important role in the multimodal approach to the treatment of IBC and is done for the purpose of locoregional control following response to neoadjuvant chemotherapy. Patients who fail

to respond to neoadjuvant chemotherapy should be considered for radiotherapy to improve local control; if improvement is seen, they can then be considered for surgical intervention. Appropriate surgery for patients with IBC is a modified radical mastectomy—that is, total mastectomy along with levels I and II axillary dissection. Sentinel node biopsy has been shown to be an unreliable method of assessing the regional lymph nodes in patients with IBC, and it is recommended that patients have an axillary dissection of levels I and II even if the initial clinical evaluation of the axillary nodes was negative. Lumpectomy is not used for patients with IBC, even in the case of complete response to neoadjuvant therapy, given the diffuse nature of this disease within the breast. Similarly, skin-sparing mastectomy is not used in patients with IBC, given the likelihood of diffuse skin involvement at diagnosis. If reconstruction is desired, it is considered in a delayed fashion, once the patient has completed all chemotherapy and radiation therapy, and demonstrated lack of systemic progression on follow-up staging studies.

Decision making regarding surgery for patients who fail to respond to neoadjuvant therapies and for those with stage IV IBC remains difficult. These patients require careful restaging after initial systemic therapy, multidisciplinary discussion, and sound judgment about the potential benefit of surgery for expectant palliation. Even in the face of chemotherapy-resistant local disease or established distant disease, there may be a role for surgery as a palliative measure for select patients.

Radiation Therapy

Following modified radical mastectomy, patients with IBC are recommended to receive radiation to the chest wall, axilla, and supraclavicular fossa, with consideration of radiation to the internal mammary nodes if there is concern about involvement of that basin. The primary purpose of such radiation is for locoregional control because its effect on survival in this population is unclear. Radiation is also used as a local control treatment in patients who do not respond well to neoadjuvant therapy and may make subsequent surgery more complete.

Targeted Therapy With Trastuzumab

A higher incidence of *Her 2 neu* overexpression has been documented in IBC. *Her 2 neu* is overexpressed or amplified in approximately 36% to 60% of patients with IBC. Trastuzumab should be given in combination with systemic chemotherapy regimens for *Her 2 neu* positive IBC and continuing beyond the end of chemotherapy to extend to a year of trastuzumab. The largest series of patients with *Her 2 neu* positive IBC treated with neoadjuvant trastuzumab were part of the NOAH (neoadjuvant trastuzumab) trial. A significantly higher pathologic complete response was noted in women who received neoadjuvant chemotherapy in combination with trastuzumab (54%) than in women who did not receive trastuzumab (19.3%).

Hormonal Therapy

The result of hormone receptor status on the original core biopsy can drive decision making for adjuvant hormonal therapies, which are generally started once the locoregional therapies have been completed. Most IBC are estrogen- and progesterone-receptor negative. This may contribute to the difficulty in obtaining durable control of this aggressive disease. In the subset of patients with receptor positive tumors, hormonal therapy with either an aromatase inhibitor or tamoxifen for 5 years is an important part of the overall therapeutic plan.

PROGNOSIS AND FOLLOW-UP

As with other types of breast cancer, prognosis is dependent on lymph node status and stage; the presence of distant metastatic disease is strongly associated with poorer outcome. Women with stage III IBC have a better prognosis than those with stage IV IBC. Women with stage III disease have a 40% 5-year survival compared to 11% in women with stage IV; both of these are significantly worse than survival in other types of breast cancer.

The response to neoadjuvant chemotherapy is an important indicator of prognosis. In a study conducted at MD Anderson Cancer Center, patients who achieved a pathologic complete response had a far better 5-year survival than those with residual disease. Similarly, patients with a pathologic complete response in the axillary lymph nodes had a better overall survival and disease-free survival than those with residual nodal disease.

Given the infrequency of this disease and the advanced stage at presentation of most patients, IBC remains a challenging clinical problem. Many patients with IBC may benefit from evaluation and treatment at an established breast program with clinical trials available. More research to better define the molecular and genetic characteristics of IBC is needed, with the hope that a more complete understanding of the disease will lead to improved treatments.

Ductal and Lobular Carcinoma in Situ of the Breast

Thomas N. Wang, MD, PhD, and Marshall M. Urist, MD

Ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS) of the breast are noninvasive cancers with dissimilar implications. Whereas DCIS is a precursor lesion to invasive ductal carcinoma, LCIS is considered a marker of increased risk for breast cancer development. Malignant cell proliferation in both entities is confined to the basement membrane. Because the risk of systemic metastases is virtually nonexistent, the prognosis for DCIS and LCIS is excellent. The goal of treatment of in situ breast carcinoma is to prevent the development of invasive disease. The challenge in management is determining which patients are at risk for subsequent invasive breast cancer (IBC) and providing the appropriate therapy that minimizes recurrence without causing unnecessary morbidity. Personalization of treatment necessitates careful patient evaluation and multidisciplinary planning.

DUCTAL CARCINOMA IN SITU

DCIS is a clonal proliferation of malignant epithelial cells confined within the basement membrane of the mammary ducts. It represents a spectrum of pathologic lesions with variable malignant potential predetermined by histologic architecture, presence of necrosis, and nuclear grade. Two major histologic subtypes of DCIS exist: comedo (presence of central necrosis, many mitotic figures, and large pleomorphic nuclei) and noncomedo (absence of central necrosis and mitotic figures, presence of specific papillary, micropapillary, or cribriform architecture) carcinoma. Nuclear grade is classified as low, intermediate, or high grade as determined by nuclear morphology and mitotic index. High-grade DCIS is commonly associated with necrosis and has the most aggressive biologic characteristics with the highest local recurrence rates. Regardless of nuclear grade or histologic subtype, the long-term prognosis of DCIS is excellent, with survival rates at 10 years exceeding 95%. Therefore, the challenge in the treatment of DCIS is to balance the risk for local recurrence with unnecessary surgical morbidity.

DCIS incidence rates have increased 7.2-fold from 1980 to 2007. In 2008, the incidence of DCIS was approximately 67,000 new cases in the United States, making it the fastest growing subtype of breast cancer. The growing incidence is a result of the increasing use of screening mammography. DCIS currently accounts for over 20% of all mammographically detected breast cancers. DCIS usually presents as microcalcifications detected by screening mammography with confirmation of the diagnosis by histologic examination of biopsy specimens. IBC develops at or near the same site in the ipsilateral breast as the index DCIS lesion in the majority of women in whom DCIS goes untreated. Therefore, management of DCIS aims to rule out concurrent IBC (present in 10% to 25% of cases of DCIS) and prevent the future development of IBC. The optimal treatment of DCIS is complete surgical excision by either breast-conserving surgery (BCS) and adjuvant radiation therapy or mastectomy. Areas of controversy include adequate margin size of excision, the role of sentinel lymph node biopsy to assess for regional metastasis, the need for adjuvant radiation therapy after lumpectomy, and the need for systemic therapy with hormonal agents.

Diagnosis

The majority (90%-95%) of cases of DCIS present as suspiciously grouped, pleomorphic, or fine linear microcalcifications on mammograms. In rare cases, patients with DCIS have a palpable mass, a mammographically detected mass, Paget's disease of the nipple, or suspicious nipple discharge. Indeterminate calcifications are further evaluated with magnification views of the breast. Breast cancer that is diagnosed by detecting incidental calcifications on mammography is pure DCIS in 65% of cases, DCIS with a focus of invasion in 32% of cases, and IBC in 4% of cases. The presence of invasive foci is more often associated with large areas of calcifications (>10 mm) and linear versus granular calcifications. All mammographically detected lesions are confirmed by pathologic evaluation of breast tissue obtained through biopsy. Stereotactic core needle biopsy has replaced needle-localized excisional biopsy as the optimal diagnostic tool as it permits the acquisition of tissue for accurate strategic planning without an additional operation that may be potentially deforming. However, breast biopsy with needle localization is still necessary in cases where lesions are not amenable to stereotactic core needle biopsy (too superficial, adjacent to the chest wall, too close to breast implants, or not enough breast tissue necessary for compression).

The role of breast magnetic resonance imaging (MRI) in the diagnosis of DCIS is evolving. Currently, mammography remains the standard of care for the detection and diagnosis of noninvasive breast cancer. Because MRI often misses small, mammographically visible foci, it is not an adequate replacement for mammography as a tool for diagnosing DCIS.

Treatment

Similar to IBC, management of noninvasive breast cancer has evolved with the application of multimodality therapy and less aggressive surgery. In the past, DCIS was often treated with simple mastectomy or even modified radical mastectomy. However, when overwhelming evidence demonstrated that BCS and adjuvant radiation therapy for IBC achieved survival rates similar to those of total mastectomy, investigators questioned whether mastectomy for DCIS was overtreatment and unnecessary. Unlike IBC, no randomized trial is currently being conducted that compares total mastectomy with BCS as treatment for DCIS. Retrospective studies have shown that total mastectomy for DCIS is superior to BCS in terms of disease-free survival. Silverstein and colleagues compared local recurrence among 227 patients with DCIS. They reported a disease-free survival rate of 98% in patients undergoing mastectomy versus 81% in those receiving BCS ($P = 0.0004$). Recently, Tunon-de-Lara and colleagues reported similar results in a review of 676 patients with DCIS. They reported a local recurrence rate of 2.6% for the mastectomy group, 7.5% for the lumpectomy plus radiation therapy group, and 14.5% for the lumpectomy only group. Involved surgical margins and young patient age were predictive of local recurrence after BCS. Nevertheless, there was no significant difference in survival in any subgroup comparison, regardless of treatment. Thus, the standard therapy for DCIS is BCS followed by radiation therapy or mastectomy alone.

Surgical Therapy

In choosing the optimal management of DCIS, physicians and patients need to take into consideration the patient's risk of local recurrence associated with BCS. Although the long-term prognosis of DCIS is excellent with low mortality rates regardless of treatment,

the psychologic impact of a local recurrence, especially an invasive recurrence, is devastating for any patient. Therefore, the aim of BCS for DCIS is complete excision with clear margins and a cosmetically acceptable result. Mastectomy should be considered for multicentric DCIS, large lesions, centrally located disease, inadequate margins after repeated attempts at breast conservation, in patients who prefer to have a mastectomy, or if adjuvant radiation therapy is contraindicated. Certainly, deciding between BCS and mastectomy involves extensive discussion among the patient, surgeon, radiologist, medical oncologist, and radiation oncologist. A multidisciplinary approach allows for the personalization of care. Finally, all patients requiring total mastectomy for DCIS should be offered the option of immediate breast reconstruction, which is associated with a psychologic benefit and a similar oncologic outcome. In the United States, approximately one third of patients with DCIS undergo mastectomy.

The size of the negative margin remains controversial because there are no prospectively acquired definitive data defining an adequate margin. Silverstein and colleagues retrospectively evaluated margin status in 469 patients with DCIS, 256 of whom were treated with BCS alone and 213 treated with BCS and adjuvant radiation therapy. They acquired precise data on margin size by analyzing samples with three-dimensional reconstruction. The authors observed that with a margin width of 10 mm or more, the incidence of local recurrence was only 2.3%, and there was no added benefit from adjuvant radiation therapy. Patients with margin widths between 1 and 10 mm benefited from adjuvant radiation therapy to an acceptable risk of recurrence. However, patients treated with a margin width of less than 1 mm had a suboptimal outcome with or without adjuvant radiation therapy. Although adjuvant radiation therapy significantly decreased the incidence of local recurrence from 58% to 30% in this group, such a recurrence rate is unacceptably high, suggesting that adjuvant radiation therapy is not adequate treatment. More recently, Neuschartz and colleagues also showed that a margin width of less than 1 mm was associated with an increased rate of local recurrence despite adjuvant radiation therapy. Margin widths greater than 1 mm were associated with a 5-year recurrence rate of 10.9% for BCS alone and 4.6% for BCS plus adjuvant radiation therapy. Therefore, we recommend at least a 2- to 3-mm margin of excision for DCIS if adjuvant radiation will be administered. Further excision, or possibly mastectomy, may be indicated in patients with an excision margin of less than 2 mm.

Traditionally, axillary dissection and sentinel lymph node biopsy have had no role in the management of DCIS. The risk for nodal metastases in patients with DCIS is less than 3%. The low rate of nodal metastases, the high survival rate of patients with DCIS, and the significant morbidity rate of patients with an axillary lymph node dissection makes axillary nodal dissection unnecessary. However, the evaluation of axillary nodes by sentinel lymph node biopsy may be considered in certain situations, such as the presence of large DCIS lesions (>4 cm), palpable breast lesions, high-grade disease, microinvasive disease, or suspicious-appearing axillary lymph nodes on physical examination or by ultrasound examination. These particular features may increase the chances of finding an invasive cancer in the lumpectomy specimen to as much as 20%. Sentinel node biopsy performed at the same time as the lumpectomy may save the patient an additional operation. In addition, all patients undergoing a mastectomy for DCIS should undergo a concomitant sentinel node biopsy because a sentinel node biopsy would not be possible after a mastectomy.

Radiation Therapy

Three prospective randomized controlled trials have investigated the role of adjuvant radiation therapy in patients with DCIS after lumpectomy (Table 1). The National Surgical Adjuvant Breast and Bowel Project (NSABP) study B-17 enrolled 818 patients with DCIS between 1985 and 1990. The patients were randomized to undergo either lumpectomy alone or lumpectomy followed by breast irradiation to a total dose of 50 Gy. Through 12 years of follow-up, the investigators observed a 58% lower incidence of ipsilateral breast tumor recurrences associated with the use of adjuvant radiation therapy. Local recurrence rates were 17% in patients who did not receive radiation and 8% in patients who did. All subsets benefited from radiation therapy, regardless of the clinical or mammographic tumor characteristics. These data led to the recommendation that all patients with DCIS treated with BCS receive adjuvant radiation therapy. There was no difference in the distant disease-free or overall survival. Two other randomized controlled trials, the European Organization for Research and Treatment of Cancer (EORTC) study and the United Kingdom and Australia and New Zealand (UK/ANZ) study, demonstrated similar findings, as summarized in Table 1. Together, these three prospective trials show that adding radiation to lumpectomy of DCIS statistically decreases a patient's risk for developing recurrent breast cancer.

TABLE 1: Clinical trials evaluating radiation therapy in patients with DCIS after breast-conserving surgery

Trial	Follow-up (years)	Breast recurrence rate	
		No radiation	Radiation
NSABP B-17	12	17%	8%
EORTC	4	16%	9%
UK/ANZ	5	14%	6%

Although adjuvant radiation therapy significantly decreases local recurrence in BCS, it does not provide a clear survival advantage for patients with DCIS. In addition, radiation therapy is time consuming and condemns the patient to potential morbidities. Therefore, many clinicians are interested in identifying a subset of patients that can be treated with BCS alone. Silverstein and colleagues evaluated the effect of pathologic features (tumor size, margin width, nuclear grade, and the presence or absence of necrosis) on local recurrence. Patient age was later included to improve the accuracy of predicting local failure. By assigning a numeric score to each parameter, this group devised the University of Southern California/Van Nuys Prognostic Index (USC/VNPI; Table 2). In a retrospective review of a prospective database, which included 12-year surveillance of 706 women who had BCS for pure DCIS, they found that USC/VNPI scores of 4, 5, and 6 had an average recurrence rate of 2%, of which 0% was invasive. USC/VNPI scores of 7, 8, and 9 had an average recurrence rate of 22%, of which 46% were invasive. USC/VNPI scores of 10, 11, and 12 had an average recurrence rate of 52%, of which 43% were invasive. Based on these findings, Silverstein and colleagues recommended lumpectomy alone for scores of 4, 5, and 6; lumpectomy and radiation for 7, 8, and 9; and mastectomy for 10, 11, and 12.

Wong and colleagues from the Dana-Farber Cancer Institute conducted a single-arm prospective study of the use of wide excision alone for patients with favorable DCIS, defined as non–high-grade DCIS without necrosis, diameter less than or equal to 2.5 cm, and excision margins greater than or equal to 1 cm. They accrued patients from May 1995 to July 2002. These patients were treated with surgery alone and no radiation. The trial was terminated early when the number of local recurrences met the predetermined stopping boundary. Only 158 patients had been enrolled (the initial target had been

TABLE 2: The USC/Van nuys prognostic index scoring system for DCIS

	SCORE		
	1	2	3
Size	< 15 mm	16-40 mm	> 40 mm
Margin	> 10 mm	1-9 mm	< 1 mm

Age	> 60	40-60	< 40

DCIS, Ductal carcinoma in situ; *USC,* University of Southern California.

200 patients). The rate of ipsilateral local recurrence was 2.4% per patient-year, corresponding to a 5-year recurrence rate of 12%. Thirty-one percent of these recurrences were IBC. Despite the use of margins greater than or equal to 1 cm, the local recurrence rate was substantial in patients with small, low- to intermediate-grade DCIS lesions treated with excision alone. These findings contradict Silverstein's evaluation and question the validity of the USC/VNPI.

Criticisms of the Dana-Farber study include the fact that this was a single-arm study that was not compared with studies of treatment with adjuvant radiation therapy. In addition, the number of patients enrolled in the study was small, and the follow-up time was relatively short due to its required early termination. Undoubtedly, the USC/VNPI is a simple and reliable scoring system that has been confirmed by other groups to accurately identify a subset of patients who are at risk of local recurrence and benefit from radiation therapy or mastectomy. However, only prospective randomized trials can precisely predict the risk of local recurrence of conservatively treated DCIS. Except in a controlled trial adopting uniform criteria for margin evaluation, USC/VNPI should not be used to determine which patients can be treated with local excision alone. To date, no subset of patients from prospective randomized clinical trials has been identified that does not benefit from radiation therapy when undergoing BCS for DCIS.

Hormonal Therapy

Similar to the success of tamoxifen in the treatment of early IBC, the NSABP B-24 trial demonstrated a benefit from tamoxifen for women with DCIS after treatment with BCS and adjuvant radiation therapy. Conducted from 1991 to 1995, investigators randomized 1804 patients with DCIS treated with excision and radiation to receive either tamoxifen or placebo for 5 years. Tamoxifen and radiation were administered concurrently. In that trial, surgical margins were allowed to have tumor involvement. At 7 years of follow-up, the women treated with tamoxifen had a 27% reduction in the annual incidence rate of all breast cancer–related events and a 48% reduction in IBC. The cumulative incidence of all IBC events in the tamoxifen group was 4.1% (2.1% ipsilateral, 1.8% contralateral) versus 7.2% (4.2% ipsilateral, 2.3% contralateral) in the placebo-treated group. Additionally, a retrospective analysis of estrogen receptor (ER) expression in the NSABP B-24 trial demonstrated that increased levels of ER expression predict for a better tamoxifen benefit with respect to improved risk reduction for the development of breast cancer following BCS. Therefore, tamoxifen treatment should be considered as a strategy to reduce the risk of breast cancer recurrence in women with DCIS treated with BCS, especially in those women with ER-positive DCIS.

Recently, retrospective evaluation of the NSABP B-24 database corroborates the belief that adjuvant tamoxifen reduced subsequent ipsilateral breast cancer only in patients with ER-positive DCIS. Allred and colleagues from the Washington University School of Medicine retrospectively reviewed the hormone receptor status of patients enrolled in the NSABP B-24 clinical trial. The investigators evaluated the receptor status in 732 patients with DCIS and known receptor status by immunohistochemistry. They found a significant discrepancy between the ER results from an experienced central laboratory, which used a comprehensively validated assay for ER, and other institutional laboratories. Assuming that the central laboratory results were correct, the authors demonstrated that the false negative rate from institutional laboratories was 30% to 40%, which may be responsible for the benefit observed in ER-negative patient cases observed in the NSABP B-24 database. We advocate adjuvant tamoxifen therapy for the treatment of patients with ER-positive DCIS unless medically contraindicated.

Surveillance

Surveillance of patients previously treated with DCIS includes physical examination every 6 months for 5 years and then annually. A diagnostic mammogram should be performed yearly. Evaluation of both breasts is paramount, and special attention should be paid to the ipsilateral breast following BCS. Most recurrences occur in close proximity to the site of prior disease. Often, mastectomy is necessary in patients who have a DCIS recurrence initially treated with BCS and adjuvant radiation therapy. Local recurrences following a mastectomy for DCIS should be treated with a negative margin resection followed by chest wall radiation, if possible. Finally, patients with local recurrences that present as IBC should receive the appropriate systemic therapy after the indicated surgical treatment. Figure 1 outlines our management algorithm of patients with DCIS.

LOBULAR CARCINOMA IN SITU

Foote and Stewart first coined the term *lobular carcinoma in situ* in 1941 to emphasize the similarity between cells of LCIS and cells of invasive lobular carcinoma. In addition, they noted that the foci of neoplastic cells in LCIS were contained within the basement membrane similar to those in DCIS. They believed that LCIS was a premalignant lesion to invasive lobular carcinoma and recommended mastectomy as the primary treatment. Later, the term *atypical lobular hyperplasia* (ALH) was introduced to describe morphologically similar but less well developed lesions. Over the past 60 years, it has become clear that LCIS and ALH are not precursor lesions for invasive carcinoma in the same way that DCIS is a precursor lesion to invasive cancer. The diagnosis of LCIS represents a marker for increased risk for subsequent carcinoma. Radical surgery has fallen out of favor, but recommendations for treatment are not uniform and vary from close surveillance with mammography to surveillance alone to bilateral mastectomy in some cases. Recently, new data suggesting that LCIS may be an obligate precursor lesion for IBC may have significant implications for the future management of patients with LCIS.

Pathophysiology

The histologic features of LCIS and ALH are well established. LCIS is divided into two specific subtypes: classic and pleomorphic. Classic LCIS consists of a monomorphic population of small, round, polygonal or cuboidal cells with a thin rim of clear cytoplasm and a high nuclear-to-cytoplasmic ratio. The cells are loosely cohesive and regularly spaced, and they fill and distend the acini. The nucleus is characterized by small nucleoli and few mitotic figures. Pagetoid spread, in which the neoplastic cells extend along adjacent ducts, is

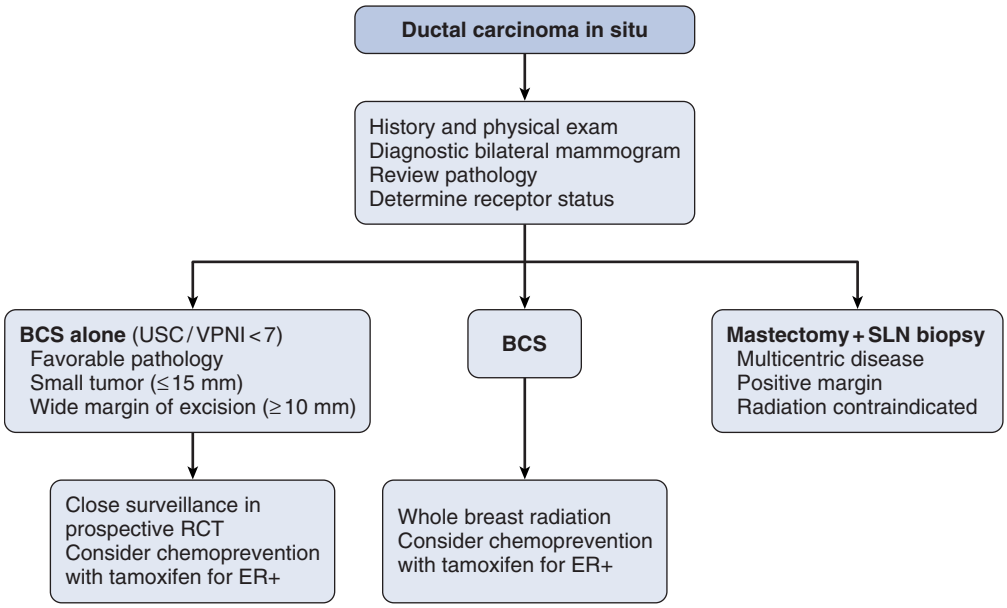

FIGURE 1 Management algorithm for ductal carcinoma in situ (DCIS). *BCS*, Breast-conserving surgery; *ER*, estrogen receptor; *RCT,* randomized controlled trial; *SLN,* sentinel lymph node; *USC/VNPI*, University of Southern California/Van Nuys Prognostic Index.

frequently seen. Pleomorphic LCIS exhibits cells with distinctly larger nuclei and prominent nucleoli with frequent mitotic figures. Central necrosis and calcification within lobules are common. For a diagnosis of LCIS, more than half of the acini in an involved lobular unit must be filled and distended by the LCIS cells, leaving no central lumina. A lesion is regarded as ALH when the characteristic cells fill less than half of the acini with no or only mild distension of the lobule and the lumina are visible.

Natural History

Women with LCIS are usually in their fifth decade of life with a mean age of diagnosis between 44 and 46 years of age, 10 years younger than women with DCIS. Only 10% of women with LCIS are postmenopausal. The risk of developing IBC in patients with LCIS is 7 to 18 times higher than that of the general population. The SEER data between 1973 and 1998 revealed that the minimum cumulative risk of developing IBC after LCIS was 7.1% at 10 years, with a lifetime risk of 30% to 40%. It was a common belief that this increased risk was equal for both breasts. However, studies that are more recent demonstrate that carcinoma is 3 times more likely to develop in the ipsilateral breast compared to the contralateral breast. Furthermore, the SEER data between 1988 and 2002 revealed that women with LCIS are also 5.3-fold more likely to develop invasive lobular carcinoma and 0.8-fold less likely to develop invasive ductal carcinoma. These new data suggest that LCIS may behave as both a precursor lesion to invasive lobular cancer and a risk indicator for IBC.

Diagnosis

The diagnosis of LCIS is often an incidental finding after a breast biopsy is performed for another reason. There are no specific clinical abnormalities that would alert a physician to LCIS on breast examination or patient symptomatology, and rarely is LCIS visible on mammography or other imaging modalities. Therefore, the true incidence of LCIS in the general population is unknown. The incidence of LCIS in otherwise benign breast biopsies is between 0.5% and 3.8%. Similar to DCIS rates, LCIS rates have also increased since the 1980s as a result of the increasing numbers of screening mammograms and biopsies being performed, in some series as much as a threefold increase. Characteristically, LCIS is multifocal and bilateral in many cases. Over 50% of patients contain multiple foci in the same breast, and 30% will have LCIS in the contralateral breast. It is this multifocality in a clinically undetectable lesion that makes management of this disease a significant challenge.

Treatment

As previously mentioned, new epidemiologic data support the premise that LCIS may be a precursor lesion to invasive lobular carcinoma as well as a risk indicator for IBC. In addition, recent studies comparing the molecular signatures of LCIS and coexisting invasive lobular carcinoma also support the hypothesis that LCIS may act as a precursor. Therefore, advocates for the precursor role of LCIS suggest that a more definitive treatment strategy with BCS and adjuvant radiation may be necessary for patients with LCIS. Recently, Ciocca and colleagues challenged this premise and hypothesized that if LCIS were a precursor, its presence in the lumpectomy specimen, particularly at the margin, would increase local recurrence after BCS. They evaluated 2894 patients treated with BCS at the Fox Chase Cancer Center for DCIS, stage I or stage II breast cancer, of which 290 patients also exhibited findings of LCIS, with 84 LCIS present at the margin of excision. Five- and 10-year local recurrence rates were not statistically different among patients with LCIS at the margin, LCIS within the lumpectomy specimen but not at the margin, or no LCIS. The presence of LCIS at the lumpectomy margin did not have an impact on local recurrence, unlike the increase in local recurrence rates found in patients with positive or close lumpectomy margins for DCIS. These findings do not support LCIS as a precursor to the development of IBC. In addition, their results also confirm that reexcision of a positive margin for LCIS is not necessary. Until further studies can definitively clarify the precursor function of LCIS, we maintain that LCIS should still be managed as a risk indicator for the development of IBC.

Specimen Evaluation

Stereotactic core needle biopsy has become the most common method for breast tissue sampling after a suspicious mammogram. Controversy exists as to the need for surgical excision after the finding of LCIS or ALH on a core needle biopsy specimen. Elsheikh and colleagues prospectively studied 33 cases of core biopsies that underwent follow-up surgical excision. Surgical excision of the tissue

surrounding a core biopsy of LCIS revealed IBC in 4 of 13 cases (31%). Five of the 20 cases (25%) of ALH revealed carcinoma, including 4 DCIS and 1 invasive lobular carcinoma. Underestimation of cancer when a core biopsy showed LCIS or ALH was found in 28% of prospectively examined patients, including 20% of those with ALH and 38% of those with LCIS. The authors recommended surgical excision in all patients with core needle biopsy specimens exhibiting findings of LCIS or ALH to rule out malignancy. We believe that the best strategy for the management of LCIS or ALH found on core needle biopsy is a multidisciplinary team approach to determine whether there is discordance between the radiologically identified abnormality and the pathologic findings. If LCIS is identified in a core specimen with other high-grade lesions or the imaged abnormality has not been adequately explained by the pathology found (radiologic-pathologic discordance), then further surgical excision is necessary. If LCIS is a true incidental finding with no suspicious findings or discordance, further excision is not necessary.

Management of surgical excision specimens exhibiting LCIS is also an area of some controversy. If LCIS only is seen in an excisional biopsy, no further excision is required. Finally, a finding of LCIS at the margin of an excisional biopsy in association with an IBC also does not warrant further excision if the IBC has been completely excised.

Treatment Options

Counseling regarding LCIS necessitates informing patients of their increased risk for IBC and the need for close follow-up. The risk of IBC is 0.5% to 1.0% per year. Because the risk is low, observation is the preferred treatment option for patients diagnosed with LCIS. In addition, patients should understand that the biology of the potential IBC tends to be favorable and deaths from an early detected IBC unlikely. Prophylactic bilateral mastectomy should be considered in special circumstances, such as in women with a *BRCA1* or *BRCA2* mutation or a strong family history. Nevertheless, the decision to pursue prophylactic mastectomy for risk reduction should be made only after careful evaluation and multidisciplinary counseling. Women treated with bilateral mastectomy are appropriate candidates for breast reconstruction.

Two studies, the NSABP P-1 Breast Cancer Prevention Trial and the NSPBP P-2 Study of Tamoxifen and Raloxifene (STAR), examined chemoprevention of invasive and noninvasive breast cancer for patients with LCIS. The NSABP P-1 trial evaluated the use of tamoxifen for the prevention of breast cancer in 13,388 women at high risk. High risk was determined by the Gail model risk assessment based on the patient's age, age at menarche, age at first live birth, family history of breast cancer, and number of breast biopsies, including diagnosis of atypical hyperplasia and/or diagnosis of LCIS. Of the participants, 8.4% had a diagnosis of LCIS. The study found that tamoxifen decreased the risk for developing IBC by 49% in all enrolled women at high risk. Subset analysis of patients with LCIS had an even greater risk reduction of 56%. The STAR trial enrolled 19,747 high-risk women also determined by the Gail model. All of the women studied were postmenopausal, of which 9% had a diagnosis of LCIS. They were randomized to receive daily doses of tamoxifen or raloxifene. The two drugs were equally effective for the prevention of IBC in the postmenopausal women with a history of LCIS. Women taking raloxifene had a lower risk of thromboembolic events and fewer uterine cancers as compared with women taking tamoxifen. However, unlike tamoxifen, which reduced the incidence of DCIS and LCIS by half, raloxifene had no effect in the prevention of noninvasive breast cancer occurrences.

The present National Comprehensive Cancer Network guidelines (2009) recommend observation as the primary treatment for women with LCIS. The use of tamoxifen in premenopausal women or tamoxifen or raloxifene in postmenopausal women should be considered as a risk-reduction strategy in women with LCIS. Risk-reduction or prophylactic bilateral mastectomy may be considered as an option for women with a history of LCIS, especially in women with a *BRCA1* or *BRCA2* mutation or a strong family history of breast cancer, only after careful evaluation and counseling. Surveillance of patients with LCIS should include interval breast examinations by a physician every 6 to 12 months and periodic self-breast examinations. All patients being followed by close observation should undergo annual diagnostic mammography (Figure 2). Finally, all patients with LCIS should be offered the option of participation in clinical research protocols evaluating screening or risk assessment.

Advances in Neoadjuvant and Adjuvant Therapy for Breast Cancer

Nicole Kounalakis, MD, and
Christina Finlayson, MD

OVERVIEW

Systemic therapy for breast cancer is evolving rapidly. The medical treatment of cancer includes chemotherapy, endocrine therapy, and therapy with targeted biologic agents. In the past, a patient's stage, based on tumor size and nodal involvement, would determine the recommendations for medical therapy, whereas now the biologic features of the tumor direct the treatment plan. As a result of advances in the understanding of these biologic features, individualized systemic therapy is effective, less toxic, and directed at the tumor profile. Systemic treatment may influence the surgical and radiation options; thus surgeons should be involved with these medical decisions in both the neoadjuvant and adjuvant settings. In view of the many treatment options available, a multidisciplinary approach, starting at the time of diagnosis, can provide a tailored plan that results in the best outcome for patients. The adjuvant and neoadjuvant therapy for operable stages I, II, and III breast cancer are described in this chapter.

NEOADJUVANT SYSTEMIC THERAPY

Neoadjuvant systemic therapy has many proven benefits. Its effectiveness offers valuable prognostic information, and the rates of disease-free and overall survival are equivalent to those for adjuvant therapy. Clinicians can alter therapy if the tumor does not respond and can also distinguish a subset of patients who have an improved outcome: pathologic complete response (pCR). In addition, neoadjuvant therapy has the potential to improve surgical outcomes. For women in whom at presentation mastectomy appears to be the best option, it increases the possibility for breast-conserving surgery by approximately 16%. For women who are potential candidates for breast conservation at presentation, it limits the area of resection, and cosmesis is better. Neoadjuvant systemic therapy can be delivered either as chemotherapy, with or without biologic therapy, or as hormonal therapy.

Neoadjuvant Chemotherapy

The safety and efficacy of neoadjuvant chemotherapy have been demonstrated in several randomized controlled trials. Patients who are candidates for adjuvant therapy can also be considered for neoadjuvant therapy. Neoadjuvant chemotherapy does not increase the surgical complication rate, worsen survival by delaying surgical treatment, or decrease the accuracy of findings in the sentinel lymph node biopsy (Table 1).

There is no difference in overall survival or disease-free survival benefit between neoadjuvant and adjuvant therapy. Benefits for the patient include improved prognostic information and increased opportunities for breast conservation. Patients with a pCR after neoadjuvant therapy have an improved prognosis, and patients with no response have a considerably worse prognosis. The most immediate benefit from the neoadjuvant approach occurs in patients who are candidates for mastectomy at presentation but whose treatment can potentially be converted to breast conservation if the tumor has a favorable response to treatment; the best results occur with tumors more likely to achieve a pCR. Patients more likely to have a pCR tend to be younger (<40 years of age), have a high-grade tumor with a Ki67 protein level greater than 20%, and have tumor receptors that do not have estrogen receptor (ER), progesterone receptor (PR), or *Her 2 neu* (triple negative) or are ER-negative and PR-negative and *Her 2 neu*-positive (Table 2).

For breast cancers that are either ER+ or ER– but also *Her 2 neu*–negative, standard neoadjuvant chemotherapy is a doxorubicin (Adriamycin)–based regimen for 3 to 4 months before surgery. If the patient is *Her 2 neu*–positive, trastuzumab (Herceptin) is administered with a taxane (e.g., docetaxel) and carboplatin; doxorubicin is usually omitted because of the potential for increased cardiac toxicity. The patient should be monitored during therapy with a clinical examination after each cycle. If the tumor is not clinically responding after two to three cycles, chemotherapy should be stopped, and the patient should proceed to surgery.

Neoadjuvant Endocrine Therapy

Historically, the use of neoadjuvant endocrine therapy was limited to patients whose conditions were not suitable for chemotherapy. However, several trials demonstrated similar overall response rates in postmenopausal ER/PR-positive patients treated with neoadjuvant endocrine therapy or chemotherapy. Certain tumor characteristics are predictive of a poor response to neoadjuvant chemotherapy but could be considered for neoadjuvant endocrine therapy: low-grade tumors with high ER/PR positivity, low Ki67 protein proliferative index, and certain histologic features such as lobular, tubular, and low-grade mucinous tumors (see Table 2).

For postmenopausal patients who are candidates for neoadjuvant endocrine therapy, aromatase inhibitors are recommended over tamoxifen. Several trials have shown increased rates of response, which lead to a higher rate of breast-conserving therapy with aromatase inhibitors. The P024 trial was the first to compare neoadjuvant use of letrozole with tamoxifen in postmenopausal women with locally advanced ER/PR-positive disease. The overall response rates were 55% for letrozole and 36% for tamoxifen ($P < 0.001$). Significantly more letrozole-treated patients underwent breast-conserving surgery (45% vs 35%, respectively; $P = 0.022$). Based on the American College of Surgeons Oncology Group's (ACOSOG's) Z1031 trial, no particular aromatase inhibitor is preferred in the neoadjuvant setting; exemestane, letrozole and anastrozole all had equivalent outcomes.

The duration of neoadjuvant endocrine therapy must be at least 4 months to produce an optimal response; this time period varies among patients. In those who desire a lumpectomy and are showing a good clinical response, neoadjuvant endocrine therapy can safely be extended to a maximum duration of 8 months with carefully monitoring.

At this time, premenopausal women are not considered candidates for neoadjuvant endocrine therapy outside of a clinical trial. Future research will reveal whether such patients could also benefit from this treatment approach.

Surgery After Neoadjuvant Therapy

Before the initiation of systemic therapy, the tumor must be adequately marked with clips, and biopsy samples must be taken from any lesions of concern. Tumor response should be assessed with

TABLE 1: Considerations in the timing of sentinel lymph node biopsy

Timing of sentinel lymph node biopsy	Advantages	Disadvantages
Before neoadjuvant chemotherapy	More data on false-negative rate More data to support choice of chemotherapy on basis of nodal staging Assists in preoperative decisions: need for postmastectomy radiation	ALND may be unnecessary Additional surgical procedure
After neoadjuvant chemotherapy	False-negative rate: 10% in clinically node-negative patients Reduces the need for ALND by 30% in clinically node-negative patients at presentation For clinically node-positive patients at presentation, according to findings of ACOSOG Z1071 study, the axilla can be restaged with a sentinel lymph node biopsy after chemotherapy; in 40% of patients, disease converts to node negative, and ALND may be avoided	Not as much data on false-negative rates No long-term data on rates of axillary recurrence, disease-free survival, or overall survival

ACOSOG, American College of Surgeons Oncology Group; *ALND,* axillary lymph node dissection.

TABLE 2: Tumor characteristics and responsiveness to neoadjuvant chemotherapy

Patient and clinical characteristics	Increased likelihood of pCR	Decreased likelihood of pCR
Age	<40 years	>60 years
Tumor size	<2 cm	>4 cm
Histologic features	Ductal	Lobular
Grade	High	Low
Ki67 protein level	High score >20	Low score <20
Estrogen receptor	Negative	Positive
Her2/neu	Positive	Negative

pCR, Pathologic complete response.

bimonthly clinical exams. If the clinical response is ambiguous, the breast can be imaged with ultrasonography or mammography. Evaluation of treatment response during or after neoadjuvant chemotherapy is also an accepted indication for breast magnetic resonance imaging (MRI). If the patient is receiving chemotherapy, the authors normally wait 2 to 3 weeks after the last dose of therapy or until the white blood cell count is within normal range before surgery is performed. For neoadjuvant endocrine therapy, no waiting period is necessary before surgical resection.

After the completion of systemic therapy, the surgeon and patient must decide whether a lumpectomy is feasible. Imaging with ultrasonography, mammography, or MRI, or a combination of these, can help guide this decision, but the ultimate surgical goal is to achieve negative margins, remove all malignant calcifications, and produce a cosmetically acceptable result. To achieve negative margins, a second margin excision may be necessary. In women with larger breasts, an oncoplastic approach can be used to achieve acceptable cosmesis after a larger resection. If negative margins cannot be achieved, a mastectomy with or without reconstruction should be performed.

If metastatic disease to the axilla is diagnosed before the initiation of chemotherapy, either through sentinel lymph node biopsy or through image-guided biopsy, the standard of care is to perform a lymph node dissection at the time of the tumor resection after the completion of neoadjuvant systemic therapy. The results of ACOSOG's Z1071 study, presented in abstract form at San Antonio Breast Cancer Symposium 2012, demonstrated that with at least two nodes recovered in a sentinel lymph node biopsy after neoadjuvant chemotherapy, clinicians can accurately assess tumor response in the axilla and can reasonably assess nodal status in node-positive cases. Because neoadjuvant chemotherapy eradicated nodal disease in 40% of patients in this study, further research will dictate whether an axillary lymph node dissection can be omitted if the sentinel lymph node is negative in these patients after systemic therapy. Until that information is available, the authors recommend an axillary node dissection for most patients who had node-positive disease before neoadjuvant chemotherapy and absolutely when nodal disease persists after neoadjuvant chemotherapy.

ADJUVANT THERAPY

Endocrine Therapy

Estrogen and progesterone receptor–positive tumors constitute 75% of all breast cancers. Stimulation of these receptors by estrogen is a critical step in the development of breast cancer. Three treatment options exist to target ER/PR receptors: tamoxifen, aromatase inhibitors, and ovarian suppression or ablation.

Defining ER/PR-positive breast cancers has been a controversial topic because of the heterogeneity of expression. It is now understood that any degree of positivity qualifies patients for estrogen-targeted treatment, although the greater the degree of expression of estrogen and progesterone receptors, the greater the response to treatment.

Premenopausal Patients

Approximately one fifth of all new cases of breast cancer occur in women younger than 50 years of age, and 60% of these cases are ER-positive. Options for these patients include tamoxifen, ovarian suppression or ablation, or a combination of ovarian suppression with tamoxifen. Tamoxifen is a selective estrogen receptor modulator, and it inhibits the growth of breast cancer cells by competitively binding to the estrogen receptor. It should be offered for at least 5 years. If it is tolerated well and the tumor is aggressive, tamoxifen can be given for up to 10 years.

The benefits of tamoxifen in the adjuvant setting were clearly demonstrated from the 2011 Early Breast Cancer Trialists Collaborative Group's (EBCTCG's) meta-analysis of randomized trials. In ER-positive patients, breast cancer mortality was reduced by 30% in the first 15 years of follow-up when tamoxifen was used in the adjuvant setting for 5 years. Breast cancer recurrence was reduced by 39%. This benefit was seen in both premenopausal and in postmenopausal patients. Side effects of tamoxifen are a nonsignificant increase in stroke-related deaths and an increase risk of uterine cancer (3.8% vs 1.1% in the control group). There was a trend toward a lower incidence of cardiac deaths.

Ovarian suppression in addition to tamoxifen has shown benefit in reducing rates of breast cancer recurrence and mortality. Ovarian suppression can be accomplished with the use of luteinizing hormone–releasing hormone (LHRH) agonists. For premenopausal women, the 2007 EBCTCG meta-analysis showed that LHRH agonists alone showed a trend toward reducing recurrence (28% relative reduction, $P = 0.08$) in comparison with no further systemic treatment. When LHRH agonists were administered with tamoxifen, the risk of both recurrence and death was significantly decreased.

In a more recent trial, the North American Intergroup trial INT 0101, premenopausal patients with node-positive disease were randomly assigned to receive one of three protocols: (1) chemotherapy alone: cyclophosphamide, doxorubicin, 5-fluorouracil (CAF); (2) CAF followed by 5 years of an LHRH agonist, goserelin; or (3) CAF with both goserelin and tamoxifen. With a median follow-up period of 9.6 years, addition of tamoxifen and goserelin to CAF improved disease-free survival but not overall survival. There was no benefit to the addition of LHRH agonists to chemotherapy without tamoxifen in premenopausal women. Thus the role of LHRH agonists alone or with chemotherapy but without tamoxifen requires further investigation. There is proven benefit to administering LHRH agonists over tamoxifen and chemotherapy or tamoxifen alone. In the ongoing Suppression of Ovarian Function Trial (SOFT), treatment with tamoxifen alone is being compared with ovarian suppression plus either tamoxifen or exemestane.

For adjuvant endocrine treatment in premenopausal women with ER-positive breast cancer, current guidelines recommend the use of tamoxifen alone or in combination with ovarian suppression or ablation for at least 5 years. Aromatase inhibitors are contraindicated in premenopausal women.

Postmenopausal Patients

Standard of care for postmenopausal women with ER/PR-positive breast cancer is at least 5 years of adjuvant therapy with an aromatase inhibitor. Aromatase inhibitors decrease plasma levels of estrogen by inhibiting the synthesis of estrogens from androgenic substrates. The benefit of aromatase inhibitors over tamoxifen in postmenopausal women was demonstrated in the 2010 EBCTCG meta-analysis, which showed a reduction in both breast cancer recurrence and mortality when aromatase inhibitors were used instead of tamoxifen. There are several aromatase inhibitors and they all have similar efficacy in the adjuvant setting; no particular agent is preferred. The optimal duration of adjuvant aromatase inhibitor therapy is at least 5 years, but this duration is still being evaluated in ongoing trials. For women who do not tolerate, have a contraindication to, or decline aromatase inhibitor therapy, tamoxifen for 5 years is recommended. Women taking an aromatase inhibitor may have difficulty with joint pain, which is the most common reason for discontinuation. They should have a dual energy x-ray absorptiometry (DEXA) scan at initiation of therapy and every 1 years to evaluate bone density because progression of osteoporosis is a known side effect. Addition of a bisphosphonate to the adjuvant regimen can decrease the osteoporosis risk, as well as decrease risk of bone metastasis.

Adjuvant Chemotherapy

Molecular and Genomic Profiling

Molecular profiling has one of the longest track records as therapy for breast cancer. With the advent of measureing the presence or absence of estrogen and progesterone receptors, medicine could be personalized with antiendocrine therapy for patients who had the appropriate tumor-based targets for response. The addition of *Her 2 neu*–targeting agents and the biologic agent trastuzumab (Herceptin) further refined this patient- and tumor-specific approach to adjuvant therapy.

Genomic profiling is now used for risk stratification and therapeutic decision making. For women with ER-positive breast cancer, genomic profiling may be helpful in selecting which patients should receive adjuvant chemotherapy. Genomic profiling should not be used in patients already determined to benefit from chemotherapy or in patients with multiple comorbid conditions who would be unable to tolerate chemotherapy. Patients must be cautioned that for a favorable recurrence score, chemotherapy can be omitted only if the patient commits to 5 years of antiendocrine therapy.

The best validated prognostic molecular test is the Oncotype DX (Genomic Health, Redwood City, Calif), which is used to analyze 21 genes and has been on the commercial market since 2003. One of its benefits is that paraffin-embedded fixed tissue is used, and the test can be ordered at any time in the diagnostic process. It provides a recurrence score that is predictive of responsiveness to chemotherapy and relapse rate. The activity of 16 genes and 5 control genes on breast cancer tissue is measured, and a proprietary mathematical formula is used to develop a single recurrence score to predict the risk of distant relapse despite 5 years of tamoxifen therapy. The recurrence score was validated with the use of tissue samples and the clinical database from the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 study, which was a prospective randomized controlled trial in which the adjuvant treatment of tamoxifen alone was compared with tamoxifen plus chemotherapy in patients with ER-positive, node-negative early-stage breast cancer. The individual recurrence scores are further stratified into low-risk (score, <18), intermediate-risk (score, 18 to 30), or high-risk (score, >30) groups. The rates of distant recurrence at 10 years were 7%, 14%, and 31%, respectively, in these groups. Not only does the Oncotype DX test provide prognostic information, but it also demonstrated that there was no additional benefit to adding chemotherapy to the treatment regimen of a woman in the low-risk group. Other studies have shown similar scores and results when aromatase inhibitors are used instead of tamoxifen for postmenopausal women.

The true cutoff for the recurrence score number that defines who would benefit from chemotherapy is in the process of further refinement. The Trial Assigning IndividuaLized Options for Treatment

(Rx) (TAILORx) is an evaluation of differences in response for women with recurrence scores from 11 to 25. In this study, patients with ER-positive, node-negative, *Her 2 neu*–positive cancer and recurrence scores in the range of 11 to 25 are randomly assigned to receive either endocrine therapy alone or chemotherapy followed by endocrine therapy.

Oncotype DX has also expanded testing to patients who are ER positive with one to three positive lymph nodes. The study set which validated this application was much smaller, with 367 participants. A retrospective analysis of the NSABP B-28 trial presented at the 2012 Breast Cancer Symposium calculated the Oncotype recurrence score in 1065 node positive, ER/PR+ patients who had received chemotherapy plus adjuvant TAM. The recurrence score was a significant independent predictor of disease free and overall survival. Since all of these patients had received chemotherapy, the data suggests that Oncotype DX may be useful in assessing the risk of locoregional recurrence and therefore may guide the decision of adjuvant radiation therapy. The final published results from this NSABP study will have to be reviewed prior to using the Oncotype in node positive ER+ patients.

Another molecular profiling product is the Amsterdam 70-gene profile, Mammaprint (Agendia, Amsterdam, Netherlands), in which a microarray analysis of gene expression is used on breast cancer tissue. It is used to determine the prognosis of patients with breast cancer and can be used for all tumors, including node-positive, *Her 2 neu*–positive, and ER/PR-negative disease. A low score is correlated with an increased risk of distant metastasis at 10 years, although it does not provide information on the responsiveness to chemotherapy. Although this test previously required fresh tissue, paraffin-embedded tissue can now be used, which has extended the clinical situations in which the test can be performed. The clinical utility of this test is still unclear. A large international study, Microarray In Node Negative Disease May Avoid Chemotherapy (MINDACT), is underway to test node-negative tumors with the Mammaprint. Patients with discordant clinical and genomic characteristics are randomly assigned to either receive or not receive chemotherapy. The results of this trial are still pending.

Several other molecular tests are in use. All breast cancer molecular tests should be used to augment, not replace, known prognostic clinical factors. Despite the ability of these tests to assign prognosis or responsiveness to chemotherapy, they do not assist in determining the optimal chemotherapeutic agent for individuals. Current guidelines indicate that adjuvant therapy should be considered on the basis of clinical and tumor characteristics, life expectancy, and comorbid conditions.

Chemotherapy

Several regimens of adjuvant chemotherapy are accepted for the *Her 2 neu*–negative tumor. These agents are usually represented by their first letter, and the medical record often looks like alphabet soup. An early standard—cyclophosphamide, methotrexate, and 5-fluorouracil—gave way to regimens based on anthracycline (doxorubin or epirubicin) and a taxane (Taxol and Taxotere). More recently, the regimen of docetaxel plus cyclophosphamide has been added to the menu of options because it confers excellent survival and fewer long-term sequelae. There also is no single standard dosing regimen for these drugs. The recent Eastern Cooperative Oncology Group (ECOG) 1199 trial showed that out of four possible dosing strategies, doxorubicin plus cyclophosphamide followed by 12 weekly doses of paclitaxel proved to be the superior regimen in terms of both disease-free and overall survival rates, at the cost of an increase in peripheral neuropathy. The duration of this regimen is approximately 4 months. Dose-dense chemotherapy is another schedule commonly utilized for early-stage breast cancer. This decreases the time interval between cycles of doxorubicin plus cyclophosphamide from the traditional 3 weeks to 2 weeks. This schedule has been associated with an improvement in disease-free survival rates but more on-treatment side effects. Patients with triple-negative tumors derive the greatest benefit.

The role of anthracyclines in treating early-stage breast cancer has become controversial. It is unclear whether adding a taxane to the standard regimen decreases the need for an anthracycline in certain patients. Anthracyclines have been associated with increased cardiac toxicity, especially in patients with a history of either cardiac disease or radiation therapy. Patients are now living longer as breast cancer survivors, and the seriousness of cardiac toxicity should not be minimized. In US Oncology Adjuvant Trial 9735, patients with stages I to III *Her 2 neu*–negative cancers were randomly assigned to receive either a regimen of docetaxel plus cyclophosphamide or a regimen of doxorubicin plus cyclophosphamide. This trial has had a median follow-up period of 7 years, and docetaxel plus cyclophosphamide improved disease-free survival (81% vs 75%) and overall survival (87% vs 82%).

Her 2 neu–Targeted Therapy

Approximately 20% of all breast cancers demonstrate amplification of the *Her 2 neu* oncogene. Women with stages I to III breast cancer and *Her 2 neu* overexpression should be considered for adjuvant treatment with chemotherapy and trastuzumab.

Before the use of trastuzumab, several studies had shown that patients with *Her 2 neu*–positive tumors smaller than 1 cm have a higher risk of recurrence than women with *Her 2 neu*–negative tumors of the same size. The current National Comprehensive Cancer Network guidelines recommend that trastuzumab and chemotherapy be administered for node-negative, *Her 2 neu*–positive tumors larger than 6 mm (stage T1b) and for all node-positive tumors.

Trastuzumab is the only *Her 2 neu*–directed agent to result in a survival benefit when administered with chemotherapy in the adjuvant setting. In a joint analysis of data from the North Central Cancer Treatment Group's (NCCTG's) N9831 trial and the NSABP's B-31 trial, treatment of *Her 2 neu*–positive disease with chemotherapy alone (doxorubicin plus cyclophosphamide followed by paclitaxel) was compared with chemotherapy with trastuzumab; the latter produced an improvement in disease-free survival and a 39% significant reduction in death.

Trastuzumab does increase the risk of congestive heart failure and decreases left ventricular ejection fraction. The choice of which chemotherapy regimen to administer with trastuzumab depends on the patient's preexisting cardiac condition. Some regimens include anthracyclines (anthracycline, carboplatin. and taxotere [ACT]) and others do not (taxotere carboplatin: docetaxel plus cyclophosphamide). In comparison with ACT and trastuzumab, docetaxel plus cyclophosphamide with trastuzumab was found to produce a higher incidence of congestive heart failure (0.4% vs 2%) and a lower incidence of sustained loss of mean left ventricular ejection fraction (18.6% versus 9.%; Table 3). Because cardiac toxicity is known to be associated with trastuzumab alone and when combined with anthracyclines, there is a shift toward regimens that do not include anthracyclines, inasmuch as they appear to be equivalent in efficacy.

Trastuzumab is administered intravenously concomitantly with chemotherapy and then after the completion of the chemotherapy, for a total of 52 weeks. No data support the use of trastuzumab with endocrine therapy instead of chemotherapy for patients with triple-positive disease. Endocrine therapy should be administered with trastuzumab after the completion of chemotherapy.

Lapatinib is an oral *Her 2 neu*–directed agent. The current data show that there is no role for lapatinib in the adjuvant setting after chemotherapy for stages I to III breast cancer. Whether the combination of lapatinib plus trastuzumab with chemotherapy will improve survival in the adjuvant setting is currently being investigated in the Adjuvant Lapatinib and/or Trastuzumab Treatment Optimization (ALTTO) study.

TABLE 3: Timing and major side effects of systemic therapy

Systemic agent class: specific agent	Time of treatment	Side effect
Taxanes: docetaxel, paclitaxel	Neoadjuvant, adjuvant	Cutaneous reaction Motor and sensory neuropathy Embryo-fetus toxicity Myelosuppression
Anthracyclines: doxorubicin (Adriamycin), epirubicin	Neoadjuvant, adjuvant	Cardiomyopathy, congestive heart failure Myelosuppression
Carboplatin	Neoadjuvant, adjuvant	Neuropathy Myelosuppression
Trastuzumab	Neoadjuvant, adjuvant	With doxorubicin: cumulative risk of congestive heart failure; decreased left ventricular ejection fraction Cardiomyopathy, embryo-fetus toxicity, pulmonary toxicity
Aromatase inhibitors: anastrozole, exemestane, letrozole	Neoadjuvant, adjuvant	Arthralgias, myalgias, osteoporosis, embryo-fetus toxicity
Tamoxifen	Adjuvant	Blood clots, endometrial cancer, ovarian cysts, embryo-fetus toxicity

SUMMARY

The array of systemic options and treatment regimens available to patients with breast cancer is progressing rapidly. These options include endocrine, cytotoxic, and targeted agents that can now be administered with improved efficacy and less toxicity. Molecular profiling has become a valuable asset in creating a treatment plan. Patients who will benefit most from chemotherapy or targeted biologic agents can be identified and treated accordingly. In contrast, patients who derive minimal benefit from chemotherapy can now avoid this toxicity and be treated instead with antiendocrine therapy. Determining the appropriateness of neoadjuvant therapy for a particular patient can improve surgical outcomes and provide prognostic information.

For surgeons, an understanding of how these therapies will affect patients' local control options is important. The authors recommend that each patient with cancer be seen by a multidisciplinary team to allow discussion of these various options. Sometimes these teams practice in one location, but often the multidisciplinary approach requires close collaboration among colleagues who do not practice in physically adjacent spaces. Close coordination and integration of breast cancer specialists through a multidisciplinary team leads to improved outcomes for patients. A dialogue between diagnostic specialists (imagers, pathologists) and therapeutic specialists (breast and plastic surgeons, radiation and medical oncologists) can lead to the optimal treatment strategy. The most significant advances in breast cancer have resulted from physicians' ability to provide an individualized treatment plan, and this can be realized only through a multidisciplinary approach.

The Management of Recurrent and Disseminated Breast Cancer

Edwin O. Onkendi, MB, ChB, and
Judy C. Boughey, MD

INTRODUCTION

Invasive breast cancer remains the most common malignancy among females in the United States, constituting 30% of all new cancer cases and 15% of all cancer deaths among women. With the current advances in breast cancer screening, many breast cancers are diagnosed at an early stage, which, together with advances in neoadjuvant and adjuvant systemic and regional therapies, has resulted in most patients with breast cancer having longer survival than before. About 10% to 20% of stage I to III breast cancers recur locoregionally, with the risk of relapse higher with lymph node–positive and larger tumors. Despite this fact, no significant differences in disease-free survival, distant disease-free survival, or overall survival have been shown by multiple randomized controlled trials with long-term follow-up between mastectomy and breast conservation therapy (BCT; breast-conserving therapy, lumpectomy with adjuvant radiation therapy). The Early Breast Cancer Trialists' Collaborative Group (EBCTCG), however, performed an overview of randomized trials and showed that local recurrence and survival are linked. The EBCTCG estimates that for every 4 local recurrences prevented at 5 years, 1 death is prevented at 15 years.

BCT is known to be associated with higher rates of ipsilateral in-breast tumor recurrence (IBTR) compared with mastectomy. Isolated IBTR rates range from 8.8% at 20 years in the Milan study to 14.3% at 20 years in the National Surgical Adjuvant Breast and Bowel Project (NSABP-06) trial to 22% at 18 years in the National Cancer Institute study. The difference in IBTR rates across the studies is explained by the differing inclusion criteria and methods, specifically tumor sizes, and margin status. IBTR has been shown to be associated with poorer survival and distant metastasis. Advances in our understanding of tumor biology and improvements in early detection, operative techniques, systemic therapies, and radiation delivery have resulted in improvement in the locoregional control rates over historical studies.

RELAPSE PATTERNS AND DEFINITIONS

Breast cancer relapse can occur in various forms. The most common forms of relapse are:

1. Local recurrence (in-breast tumor recurrence [IBTR] or chest wall).
2. Regional recurrence (axillary, internal mammary, or infraclavicular lymph nodes).
3. Distant recurrence (metastasis to bone, lung, liver, brain, and other sites).

IBTR refers to breast cancer recurrence within the ipsilateral preserved breast after breast-conserving surgery. IBTRs are classified by location into:

1. True recurrence (a recurrence at the original lumpectomy site or within the boost volume of the preserved breast).
2. Marginal miss (a recurrence close to but not within the boost volume).
3. Elsewhere recurrence, or recurrence in other quadrants, other than the quadrant previously involved by the original breast cancer.

True recurrences and marginal misses constitute about 80% of IBTRs. True breast cancer recurrences and new ipsilateral primary breast cancer have been shown to have different natural histories and prognoses. These two entities can be distinguished based on histologic subtype, hormone receptor status, human epidermal growth factor receptor–2 (HER2) overexpression, tumor location, and discordant DNA flow cytometry. New ipsilateral primary breast cancer is associated with significantly better survival and lower rates of distant metastases than true recurrences. New ipsilateral primary breast cancer has been defined as tumor located more than 3 cm from the original primary tumor site (with breast imaging or clinical examination) that is of a different histology from the primary tumor or whose estrogen receptor (ER)/progesterone receptor (PR) or *Her 2 neu* status is different from the original primary tumor. On the other hand, a true recurrence has been defined as tumor located within 3 cm of the primary tumor bed or whose histologic subtype or ER/PR and *Her 2 neu* status is consistent with the primary tumor. Some authors have suggested that molecular classification is a reliable method of distinguishing these two entities.

Chest wall recurrence denotes recurrence that occurs in the preserved skin, nipple-areolar complex, subcutaneous tissue, remaining breast tissue, pectoral muscle, fascia, ribs, or intercostal muscles after any of the different types of mastectomy with or without reconstruction.

Regional recurrence refers to recurrence in the draining lymph nodes, usually axillary or supraclavicular and occasionally in the infraclavicular or internal mammary lymph nodes. Distant metastases most commonly involve bone or visceral organs (lung, liver, brain, and abdominopelvic organs).

THERAPEUTIC PRINCIPLES AND STRATEGIES

Ipsilateral Breast Tumor Recurrence After Breast-Conserving Therapy

Preoperative Considerations

IBTR after BCT is resectable in up to 85% of cases. When patients present with localized IBTR that is amenable to operative resection, mastectomy is the standard approach and can be performed once the patient has undergone staging with positron emission tomography (PET) scan or computed tomographic (CT) scan and bone scan to rule out distant metastases. Repeat breast-conserving surgery may be technically feasible. However, it is associated with a higher rate of re-recurrence, especially if the first recurrence occurred within 5 years of resection of the primary tumor, with 90% of these invasive. Many of the recurrences after 5 years following treatment of primary tumor are second primary cancers. Repeat breast-conserving surgery is also not recommended for these patients because repeat adjuvant breast radiation therapy to prevent future recurrence cannot be administered to the previously irradiated tissues. Patients who did not receive radiation after the initial breast-conserving surgery may be candidates for BCT with full-dose radiation of the whole breast, although data are limited. About 10% to 20% of patients are classified as inoperable because of advanced local or regional recurrences or

synchronous distant metastases. Patients with locally advanced recurrences (large or fixed tumors, skin or chest wall involvement, or inflammatory carcinomas) or regionally advanced disease should undergo neoadjuvant systemic therapy before consideration of surgical intervention. Skin recurrences are associated with higher incidence of distant metastases and uncontrolled local disease and a poor overall outcome.

Choice of Operation

Mastectomy is the standard treatment recommended for operable IBTR after BCT.

A standard simple/total mastectomy is often recommended because these patients have had previous breast radiation, which complicates options for immediate reconstruction. For patients who wish to pursue immediate reconstruction, discussion with a plastic and reconstructive surgeon and counseling of the patient regarding potential risks and complications associated with reconstruction in a radiated field is needed. Use of autologous tissue flap is recommended in these situations. The choice depends on patient preferences, extent of tumor, skin involvement, and timing of breast reconstruction. Skin-sparing mastectomy can be performed as long as there is no skin involvement. Use of nipple-sparing mastectomy in patients with IBTR and previous radiation has not been studied and lacks oncologic safety data.

The choice of incision depends on the type of mastectomy, location of the tumor, previous surgical scars, and skin involvement by tumor. For most cases, a standard simple mastectomy incision can be used. Care should be taken when designing the incision so the old surgical incision and any involved skin is resected along with the skin incorporated in the mastectomy incision where possible to avoid multiple scars on the chest wall.

Occasionally, patients treated with lumpectomy decline adjuvant radiation therapy and present with recurrent disease in the breast. In these cases, the lack of previous radiation simplifies the management. Mastectomy remains the standard recommendation. Although repeat breast conservation can be performed, the oncologic safety of this approach is not established. In addition, depending on breast size, tumor size, and extent of previous lumpectomy, cosmesis may be challenging with a second lumpectomy in the same breast. If lumpectomy is performed for recurrence, clips should be placed in the lumpectomy bed to mark the cavity for the delivery of the radiation boost. Adjuvant whole-breast radiation is strongly recommended, and patients who remain unprepared to consider adjuvant radiation are better served with mastectomy.

Technical Factors During Mastectomy for In-Breast Tumor Recurrence

In patients who have previously undergone breast-conserving surgery and adjuvant breast radiation, care should be taken during the development of the skin flaps because of radiation-associated microvascular changes that result in a tenuous blood supply to the skin and predispose the flaps to a higher risk of flap ischemia and necrosis. Because of the fibrosis from the previous radiation, the plane between the breast tissue and subcutaneous tissue may be harder to visualize. Care is necessary in the area of the previous lumpectomy scar to avoid skin flap necrosis. Attention is also required in the area of the recurrent tumor to ensure adequate margins are achieved, with resection of the skin overlying the tumor or the underlying muscle if needed. With dissection of the breast from the underlying pectoralis muscle, this plane is often fibrosed from the previous radiation and requires additional attention to avoid leaving breast tissue behind or damaging the muscle.

Complications and Their Prevention

An increased risk of seroma and wound healing complications is found in patients who have had prior breast radiation. The surgeon should attempt to minimize the risk of these complications. The risk of seroma formation may be reduced with use of quilting sutures, which involves mastectomy flap fixation with absorbable sutures.

Because of the microvascular changes that occur after breast radiation, there is an increased risk of skin flap necrosis. Meticulous surgical technique during mastectomy should be maintained to minimize this risk. SPY angiography (Novadaq Spy angiography system; Novadaq Technologies, Inc, Concord, Ontario, Canada) may be performed to evaluate breast cutaneous blood flow before surgery to assist in operative planning or during surgery to evaluate mastectomy flap viability and perfusion after mastectomy before reconstruction (Figure 1). This technique has been described in the literature for evaluation of reconstructive flaps and coronary artery bypass grafts. It is performed with intravenous injection of 5 mL of indocyanine green and then use of the SPY angiography camera to evaluate the perfusion of the mastectomy flaps. Preoperative SPY images usually show the decreased blood flow to the mastectomy flaps on the radiated side compared with the contralateral nonradiated side (see Figure 1). SPY angiography can be used to guide plastic surgeons regarding the appropriate volume of fluid to place in an expander and minimize risk of skin flap necrosis.

Recurrence After Mastectomy

Preoperative Considerations

Breast cancer recurrence after mastectomy is less common than recurrence after breast-conserving surgery. However, local recurrences after mastectomy can be more difficult to manage and are associated with a higher rate of distant metastasis and grave prognosis. Feasibility of resection should be assessed with physical examination, ultrasound scan, and magnetic resonance imaging (MRI). Local

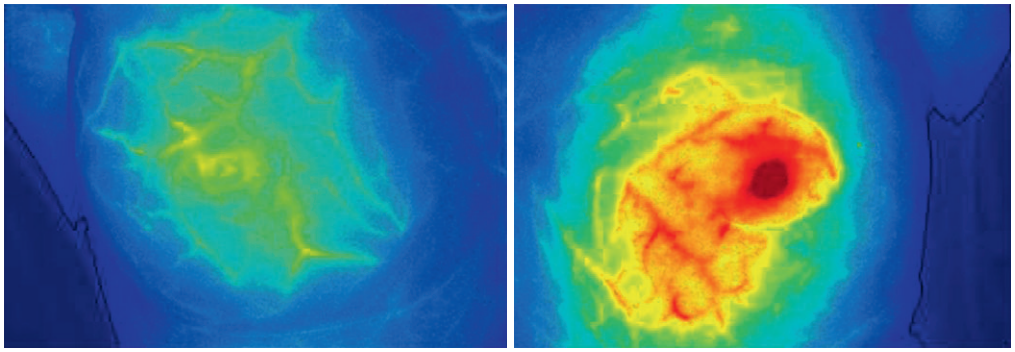

FIGURE 1 SPY angiography shows perfusion of breast skin. This patient had a history of lumpectomy and radiation on the right. In comparison of the perfusion on the right with the left before any surgical intervention, the SPY angiography clearly documents decreased perfusion on the side with the previous radiation.

recurrence may involve the skin, chest wall, muscle, or ribs and requires wide local excision of the involved structures. Preoperative evaluation should include a multidisciplinary team discussion including medical and radiation oncology, breast surgeon, and plastic surgeon. The patient should be evaluated for distant disease with use of PET scan and additional imaging as indicated. Systemic neoadjuvant chemotherapy or hormonal therapy or both should be considered for large recurrences to decrease the extent of surgery necessary. After systemic therapy, if no evidence of distant disease is found, curative resection should be considered if complete resection is feasible. These patients often end up with large wound defects after excision of the recurrence and may require input from a plastic surgeon to close the resulting wounds. Therefore, before surgery, the surgeon should carefully estimate the extent of resection that will be required. A thoracic surgeon should be involved if the tumor involves the bony chest wall and resection of involved rib cage is anticipated.

Technical Tips

Patients with skin or chest wall recurrence require wide resections to obtain negative margins; closure of the resulting wound may be difficult primarily depending on the size of the lesion and laxity of the skin at the mastectomy site and any prior radiation to the area. Often the recurrent disease, especially recurrence in the skin, may extend further histologically than can be seen with visual and imaging evaluation of the chest wall. In planning the incision either before or during surgery, multiple punch biopsies of skin areas beyond those areas that are hyperemic or contain petechiae or other suspicious skin changes may be performed with pathologic analysis for disease. After resection to grossly normal margins, intraoperative frozen analysis is helpful to guide the intraoperative decision making regarding further resection of the adjacent tissue and skin and evaluation of the deep margins.

In patients in whom resection resulted in large skin defects, different options exist for achieving wound closure (Figure 2, *A*). The goal is to achieve closure of the wound with skin to allow for subsequent adjuvant radiation in many cases. These options include local skin primary closure, local advancement flaps, DermaClose device-assisted delayed primary closure (DermaClose RC, Wound Care Technologies, Inc., Chanhassen, Minn), skin grafts, local vascularized pedicle flaps, and free flaps.

Local advancement skin flaps can be created by undermining the skin and subcutaneous tissues to the clavicle superiorly, the sternal border medially, the posterior axillary line posteriorly, and onto the abdomen inferiorly. After this mobilization, the wound edges may be temporarily approximated with clamps. If too much tension arises during this process, the skin flap perfusion may be assessed with the SPY angiography described previously and tense areas of skin with poor perfusion should be identified and tension decreased in these areas. Well-perfused areas may then be approximated with interrupted vertical mattress sutures starting in the peripheries. Often, a defect remains in the center of the wound that cannot safely be approximated. In this case, a DermaClose device may be applied to this defect and appropriate tension applied (Figure 2, *B*). SPY angiography may again be used to reassess the perfusion of the skin flaps and the wound edges. The tension of the DermaClose may be progressively increased over several days to approximate the wound edges to facilitate subsequent delayed primary closure (Figure 2, *C*).

When a positive deep margin is found at the level of the ribs, rib resection may be necessary (Figure 3, *A*). This is associated with a high rate of pneumothorax, usually from parietal pleural disruption.

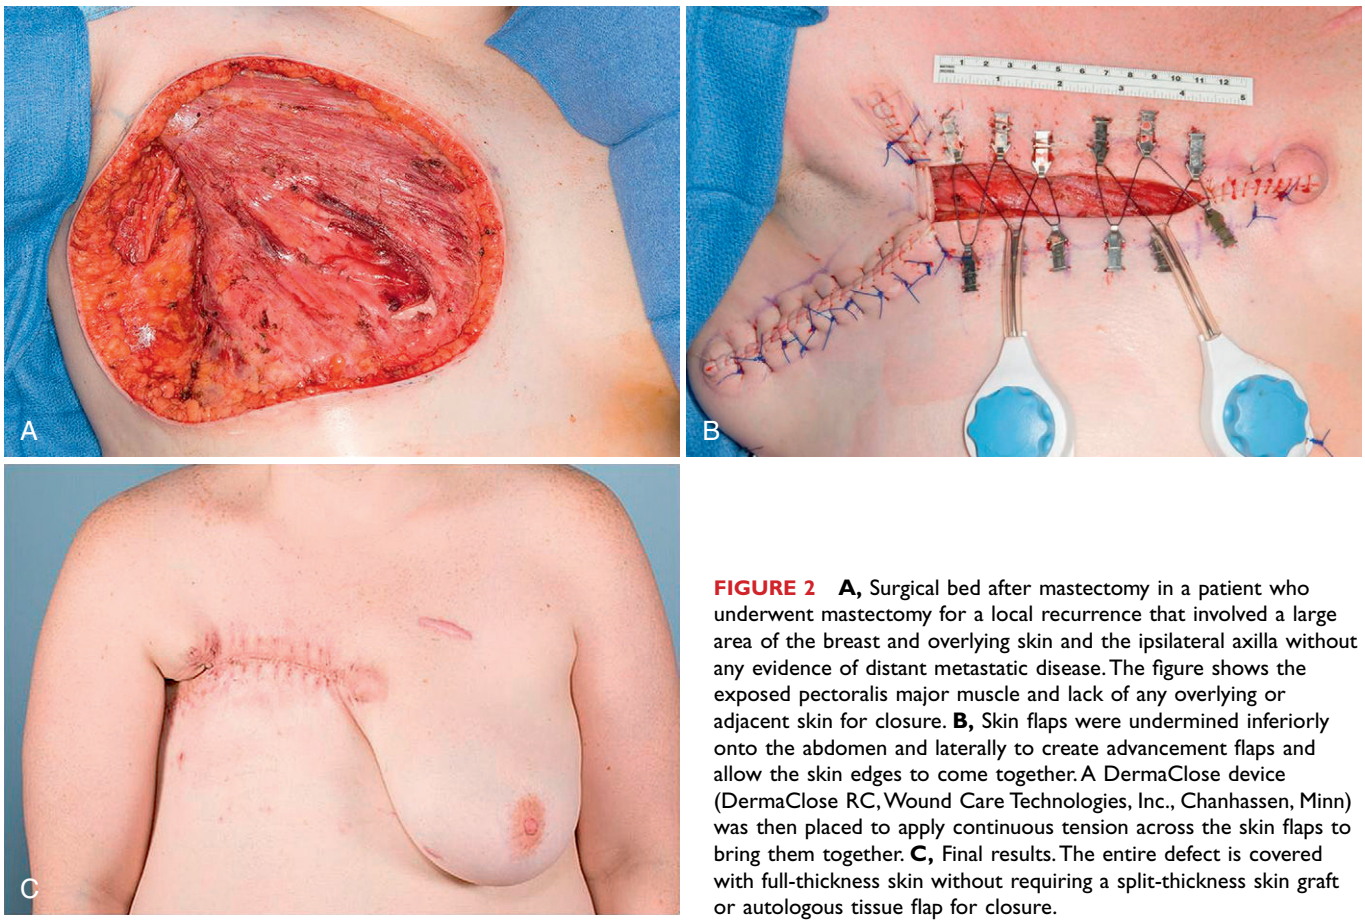

FIGURE 2 **A,** Surgical bed after mastectomy in a patient who underwent mastectomy for a local recurrence that involved a large area of the breast and overlying skin and the ipsilateral axilla without any evidence of distant metastatic disease. The figure shows the exposed pectoralis major muscle and lack of any overlying or adjacent skin for closure. **B,** Skin flaps were undermined inferiorly onto the abdomen and laterally to create advancement flaps and allow the skin edges to come together. A DermaClose device (DermaClose RC, Wound Care Technologies, Inc., Chanhassen, Minn) was then placed to apply continuous tension across the skin flaps to bring them together. **C,** Final results. The entire defect is covered with full-thickness skin without requiring a split-thickness skin graft or autologous tissue flap for closure.

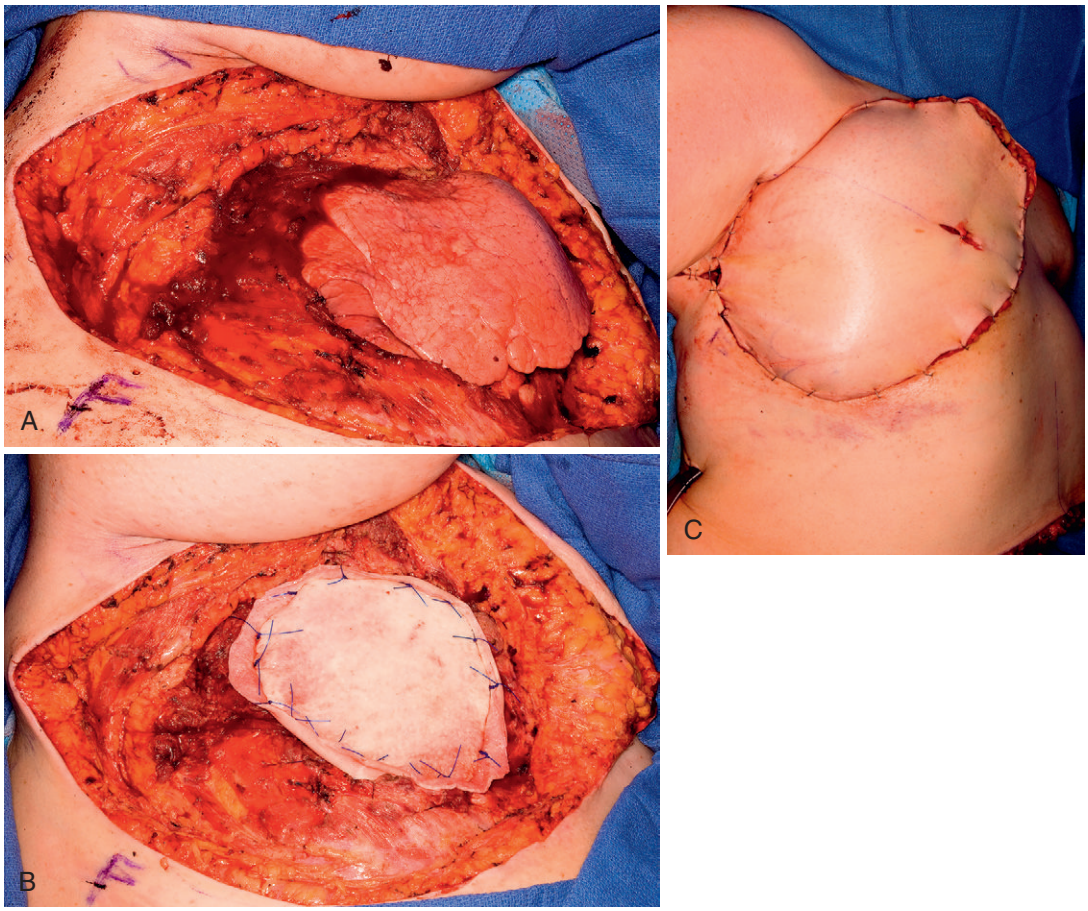

FIGURE 3 **A,** Resection of local recurrence includes skin, muscle, and en bloc resection of underlying ribs, resulting in exposed lung. **B,** Coverage of chest wall defect with mesh. **C,** Closure of soft tissue defect with use of a transverse abdominis musculocutaneous (TRAM) flap.

It may also be associated with hemothorax. A chest tube should be placed if there is disruption or en bloc resection of the parietal pleura. In this case, however, the cause of a pneumothorax is external atmospheric air gaining entry into the pleural space and not a visceral pleural leak, unless a visceral pleural disruption is known to have occurred. Therefore, airtight closure and dressing help prevent persistence of the pneumothorax. The resulting chest wall defects after en bloc resection of ribs with exposed lung may be closed with mesh, typically a biologic mesh (Figure 3, *B*), and covered with a local advancement flap, pedicled flap, or free flap (Figure 3, *C*).

Nodal Staging of Recurrent Breast Cancer after Breast Conservation or Mastectomy

Ability to perform repeat nodal staging at the time of recurrence depends on the extent of the previous nodal surgery performed for the index breast cancer and prior breast surgery and radiation therapy received. Physical examination and ultrasound scan examination of the regional nodal basins to include ipsilateral axilla, supraclavicular nodal basin, and internal mammary nodes is recommended with fine-needle aspiration or core needle biopsy of any suspicious lymph nodes. Patients with positive axillary lymph nodes should undergo axillary lymph node dissection.

In patients with clinically negative lymph nodes (i.e., no palpable lymph nodes and sonographically negative nodes), sentinel lymph node (SLN) mapping should be considered and has been shown to be feasible, although limited data are found on the false-negative rate in this situation.

SLN can provide valuable information to assist in planning adjuvant therapy and potentially avoiding the morbidity of axillary lymph node dissection (ALND). However, previous breast surgery and radiation with SLN surgery or ALND may have interfered with the native lymphatic drainage patterns and resulted in contralateral axillary drainage or extra-axillary drainage to the internal mammary or other nodal basins (Figure 4).

Therefore, a preoperative lymphoscintigraphy with imaging should be performed to map out the lymphatic drainage of the current tumor, even in patients who have previously undergone an ipsilateral ALND. Blue dye injection in addition to radiolabeled colloid should be used during surgery to assist in lymph node mapping.

Studies have shown that SLNs could be identified in 65% of patients with IBTR after BCT. SLNs were identified in 70% of patients in whom less than 10 lymph nodes (LNs) had been removed during the initial surgery, and the SLN success rate was 67% if more than 10 LNs had been removed at the initial surgery. The incidence of alternative lymphatic drainage (extra-axillary or internal mammary) increased as the number of axillary lymph nodes removed during the initial surgery increased or if mastectomy or radiation was part of the initial treatment. A similar study from Memorial Sloan-Kettering Cancer Center reported success in identification of a SLN in 75% of patients who had less than 10 LNs removed at the initial surgery and 44% in those who had had more than 10 LNs removed. SLN identification rates in the literature in patients with local recurrence after initial mastectomy range from 40% to 50%. In patients with a previously undissected axilla with large tumors and high-risk disease,

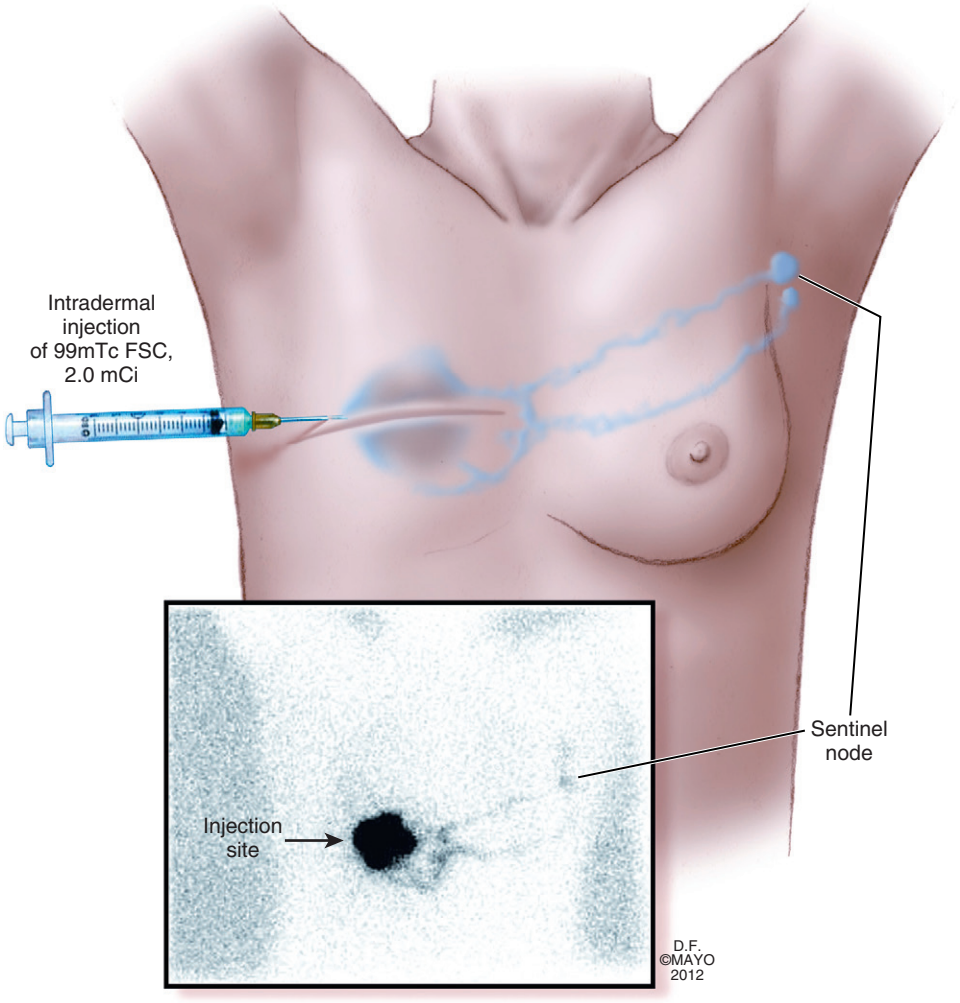

FIGURE 4 Injection at the site of recurrent breast cancer after previous right mastectomy with lymphoscintigraphic mapping showing drainage to the contralateral (left) axilla. *(Courtesy of Mayo Clinic.)*

ALND can be considered given the lack of false-negative data on SLN in this situation.

Adjuvant chemotherapy or hormonal therapy should be strongly considered. If the patient has not had prior radiation therapy, adjuvant radiotherapy should also be considered in addition to systemic therapy. In patients with unresectable tumors, palliative chemotherapy may be the only option.

Lymph Node Recurrence

The incidence of axillary and supraclavicular lymph node recurrences in patients who have undergone previous axillary lymph node dissection is 0.7% and 1.3%, respectively, at 7 years. In the presentinel lymph node era, the incidence rate of axillary nodal recurrences in patients who did not undergo ALND was about 20%. In the current sentinel lymph node sampling era, patients with SLN-negative disease had nodal recurrences develop less than 1% of the time.

On the basis of the results of the American College of Surgeons Oncology Group (ACOSOG) Z0011 randomized controlled trial, the use of ALND in patients with a positive SLN is decreasing. ACOSOG Z0011 enrolled patients with clinical T1 or T2 breast cancer treated with breast-conserving surgery with one or two positive SLNs and receiving whole-breast radiation and randomized them to either completion ALND or no further axillary surgery (SLN alone without any specific axillary treatment). This study showed no significant difference in the rate of ipsilateral axillary nodal recurrences in patients with positive SLNs who underwent ALND (0.5% at 6.3 years) compared with those with positive SLNs who did not undergo ALND (0.9% at 6.3 years). There was also no difference in survival between the two groups.

Patients who present with axillary recurrence and who were previously SLN-negative or those who did not undergo ALND should undergo axillary lymph node dissection. For patients with axillary recurrence treated with a prior ALND, a redo axillary dissection can be performed if residual tissue is present, or a localized excision of the recurrent disease is possible in cases with minimal residual axillary tissue. Patients with nodal recurrence benefit from subsequent adjuvant systemic therapy and radiation therapy if not contraindicated based on previous radiation fields.

Technical Tips

Axillary Lymph Node Dissection

The incision from the previous sentinel node surgery or previous axillary dissection should be used if present and extended as needed for adequate exposure in the axilla. If no prior scar is found, a curvilinear or a lazy S incision 1 cm below the hair-bearing portion of the axilla is used. The extent of the previous axillary surgery and the amount of scar tissue present affect the complexity of dissection. Paralytics should be avoided so the nerves can be easily identified, and dissection should be performed slowly and meticulously to avoid damage to the nerves. The nerves can be difficult to identify and may

not be in their usual anatomic location depending on scarring from prior surgery and any prior radiation. Use of clips and scissors rather than electrocautery is recommended.

Superior and inferior subcutaneous flaps are created, and the axilla is entered by incising the clavipectoral fascia. Adequate exposure is obtained with medial and cephalad retraction of the pectoralis major muscle. Two other retractors are used to triangulate the wound. The next step should be to define the axillary dissection borders and identify the important structures. The borders of axillary dissection are the axillary vein superiorly, the pectoralis muscles superomedially, the latissimus dorsi posterolaterally, and the serratus anterior and fascia medially. The initial dissection of the axilla should begin with the identification of the axillary vein superiorly. The medial pectoral nerve is then identified and preserved. The surgeon should avoid dissection cephalad to the inferior border of the axillary vein. Dissection is begun along the inferior border of the axillary vein with ligation or clipping of small venous or lymphatic vessels. The thoracoepigastric vein should then be identified because it is a very important landmark to identify and protect the thoracodorsal neurovascular bundle, which usually lies deep to this vein. The thoracoepigastric vein may invariably be ligated. The thoracodorsal neurovascular bundle is isolated and preserved. Dissection continues along the pectoralis minor muscle to the chest wall, with identification and protection of the medial pectoral nerve. Dissection along the pectoralis minor muscle to the chest wall with retraction of this muscle medially allows the level II lymph nodes to be dissected away and the intercostobrachial nerves to be identified coursing from the chest wall laterally. The long thoracic nerve of Bell enters the axilla deep to the axillary vein and courses posterior to the intercostobrachial and along the lateral border of the serratus anterior deep to the superficial fascia. It is identified deep to the serratus anterior fascia on the medial chest wall and should be preserved. Sometimes, in the lower axilla, a small vein that is a tributary of the thoracodorsal vein may course from the long thoracic nerve and help in identification. Once these major structures have been identified, one is then ready to proceed to removal of the axillary nodal tissue. With the thoracodorsal neurovascular bundle and the long thoracic nerve kept visible at all times, the fibrofatty tissue between them that contains the axillary nodes is bluntly dissected from the axilla, starting from the inferior border of the axillary vein and proceeding caudally and off the subscapularis muscle with skeletonization of the thoracodorsal neurovascular bundle and ligation of the multiple arterial and venous branches from and into the fibrofatty tissue, respectively. All visible and palpable lymph nodes, normal and abnormal, should be removed, with care taken to clip the small lymphatic channels to minimize lymphocele formation. The specimen is amputated and submitted for pathologic analysis.

In cases with significant scarring, an alternative approach is to dissect laterally to identify the latissimus dorsi muscle first. From here, enter the axilla and identify the thoracodorsal nerve, vein, and artery. Access from this direction can be helpful if there is scarring around the axillary vein and less scarring laterally in the axilla. From here, the thoracodorsal bundle can be followed cephalad to where the thoracodorsal vein enters the axillary vein, with care to preserve the adjacent thoracodorsal nerve. Inferiorly in the axilla, a tributary of the thoracodorsal vein, which crosses over to the serratus muscle, enters the muscle at the level of the long thoracic nerve of Bell, and aids identification of the long thoracic nerve.

Internal Mammary and Supraclavicular Lymph Node Metastasis

An isolated breast cancer recurrence that involves an internal mammary lymph node occurs rarely (<1%). Although no consensus exists regarding the management of internal mammary node recurrences, randomized controlled trials have shown that radiation or resection of internal mammary lymph node recurrences is not associated with improved survival. Internal mammary and supraclavicular nodal disease can often be treated with systemic therapy and radiation, although sometimes surgical resection of these nodes may be recommended and multidisciplinary discussion is important.

Metastatic Breast Cancer

Patients with metastatic breast cancer should be managed by a multidisciplinary team that includes a medical oncologist, radiation oncologist, breast surgical oncologist, plastic surgeon, palliative care specialist, psychosocial support, pathologist, and radiologist.

Intact Primary Tumor in Patients with Metastatic Breast Cancer

Approximately 5% of women in the United States with breast cancer have stage IV disease at diagnosis. Considerable interest is now found in changing the traditional approach to these patients, which has been primarily systemic chemotherapy, with operative resection used only as a palliative procedure in cases with locally advanced disease (toilette mastectomy). Current data show that one third to one half of patients with stage IV breast cancer undergo surgical resection of the primary tumor, and retrospective studies have shown an improved survival in these patients compared with patients in whom the primary tumor is not resected. All of these studies have intrinsic selection bias, which makes interpretation of these data complex. The hypothesis is that uncontrolled local disease may act as a source of continued systemic seeding for distant metastasis.

The treatment options for patients with stage IV disease with an intact breast primary include the traditional approach of systemic chemotherapy only, with local therapy of the breast primary limited to those patients that develop uncontrolled local disease. Alternatively, in recent years, interest has been seen in early local operative resection of the intact primary to free margins supported by data from retrospective studies and experiences from other cancers like colon cancer and renal cell cancer. As a result, prospective clinical trials are underway to gather data regarding benefit of resection of the primary tumor in patients with stage IV breast cancer.

Given that the data so far have only been from retrospective studies, randomized trials are needed to provide better unbiased data. One such randomized trial by the Eastern Cooperative Oncology Group (ECOG; NCT01242800) is ongoing and will look at whether patients with intact primary breast cancer with stage IV disease who receive optimal systemic therapy with no evidence of progression receive a survival benefit from early local therapy of the primary disease (surgery and radiotherapy of the primary tumor after induction systemic chemotherapy) compared with those who receive only palliative local therapy and systemic therapy. Other ongoing randomized controlled trials include one sponsored by Turkish Federation of the National Societies for Breast Diseases (NCT00557986) and another by Tata Memorial Hospital, India (NCT00193778). The results of these randomized controlled trials will better define the criteria for early local therapy and the survival benefit achieved.

Isolated Distant Metastatic Disease

The mainstay of treatment of stage IV breast cancer is systemic chemotherapy. Metastasectomy may be feasible and may render patients disease free in a highly select group of patients. Ability to resect metastatic disease is dependent on extent of metastatic disease (number of foci of metastasis and number of sites of metastatic disease).

Hepatic Breast Cancer Metastases

The liver is the third most common site for breast cancer metastasis, after bone and lung. About 10% to 15% of patients with newly diagnosed metastatic breast cancers have hepatic metastases, with about 5% of these having isolated hepatic metastases as the only site of

distant metastasis. Systemic chemotherapy is the standard treatment often with a palliative intent. However, recent studies have shown that resection of hepatic breast cancer metastasis does improve survival. Only a highly select group of patients are candidates for hepatic metastasectomy; these are patients with hormone-receptor positive tumors, with a disease-free interval of more than 1 year, who have a good response to chemotherapy and undergo subsequent surgical resection with negative margins. Five-year survival rates after R0 resection of hepatic metastases range from 34% to 37%, with recurrence-free rates from 12% to 22%. The morbidity and mortality of hepatic resection is 1% to 5% and less than 1%, respectively. Given that these patients are usually on systemic chemotherapy, and hormonal therapy in some cases, the exact survival benefit of metastasectomy may be difficult to filter from that achieved from systemic therapy without a randomized controlled trial.

Pulmonary Metastases

Lung is one of the most common sites of breast cancer metastasis, along with bone. About 15% to 25% of patients present with isolated lung metastases. A select number of patients may benefit from combined operative resection of metastases along with systemic chemotherapy and hormonal therapy. From existing literature, factors that have been shown to be associated with better survival after lung metastasectomy of breast cancer are a long disease-free interval between the primary tumor and the appearance of metastases (>3 years), R0 resection, estrogen receptor–positive disease, and solitary metastases. Of these, a long disease-free interval was the most consistent, likely indicating an indolent type of breast cancer. Overall survival rates at 5 and 10 years have been reported to be 38% and 22%, respectively, by Friedel's study of 467 patients in the International Registry of Lung Metastases, and 54% and 40% from Yoshimoto's study of 90 patients. For the same reasons as stated previously, it is difficult to single out the survival benefit obtained by addition of metastasectomy to the traditional chemotherapy in these patients and further studies are needed to better define this.

Male Breast Cancer

Rosemarie Hardin, MD, and
Theodore Tsangaris, MD

OVERVIEW

Carcinoma of the male breast is an exceptionally rare entity and accounts for less than 1% of all breast cancers and 0.1% of cancer mortality in men. The American Cancer Society estimates that in 2012, 2190 new cases of invasive breast cancer will be diagnosed in men and 410 men will die of breast cancer. Male breast cancer (MBC) warrants special consideration to foster prompt diagnosis and institution of appropriate therapies. Because of low clinical acuity and suspicion in men with breast symptoms, breast cancer tends to be diagnosed at later stages, with at least half of the cases presenting with stage 2 or higher breast cancer. It is not surprising then that approximately half of patients have regional spread of disease to the axillary lymph nodes at the time of diagnosis. Fortunately, the 5-year survival rates are similar across stages, comparable with women, although the overall survival rate in men tends to be lower than in women. This is thought to be largely because of the older age at diagnosis and resulting increased comorbidities.

Given the rarity of this disease, whether male breast cancer has its own distinct biology is difficult to ascertain. Treatment strategy for male breast cancer and determination of prognosis is extrapolated from our understanding of female breast cancer, with adjustments made for differences in anatomy and hormonal variations in men.

RISK FACTORS

Because of the rarity of this disease, establishment of causative links to development of MBC has been challenging. Similar to female breast cancer, the risk of MBC is increased twofold to threefold in patients with a positive family history of breast cancer and can be significantly higher in those with a known genetic predisposition. The most familiar gene mutation responsible for MBC is the *BRCA 2* gene. However, many other genetic mutations and syndromes can predispose to MBC, including mutations in the *AR* gene, cytochrome p45017 *(CYP17), PTEN* tumor suppressor gene associated with Cowden syndrome, *CHEK2* gene, and Klinefelter's syndrome (XXY karyotype).

Inherited MBC is most commonly associated with the *BRCA 2* mutations, which account for approximately 40% of MBC. The lifetime risk of development of male breast cancer in a *BRCA 2* carrier is approximately 7%, which is 80 to 100 times that of the normal population. *BRCA 1* can also predispose to MBC, but at a much lower risk of approximately 1%, and can account for approximately 4% of MBC cases. Other risk factors for the development of MBC include alterations in the estrogen-testosterone ratio, history of radiation exposure, and some occupational hazards. It is speculated that men who are exposed to high-temperature environments may be predisposed to early testicular failure and that the resulting estrogen-testosterone imbalance may predispose to breast cancer.

Increased estrogen exposure or androgen insufficiency can predispose men to breast cancer. The most well-known associated syndrome with such a hormonal imbalance is Klinefelter's syndrome (XXY), which accounts for 3% of MBC cases. Males with this syndrome have testicular dysgenesis, gynecomastia, low testosterone levels, normal to low estrogen levels, and increased gonadotropin levels. This condition results in a high estrogen to androgen ratio,

leading to a fiftyfold increased risk of development of breast cancer. Interestingly, this can be the outcome of abnormal hormonal stimulation resulting in proliferation of mammary duct epithelium or it may result from increased estrogen from the conversion of exogenous therapeutic testosterone in adipose tissue.

Men with undescended testes, congenital inguinal hernia, or orchitis or who have undergone orchiectomy are also at increased risk. Interestingly, obesity increases the estrogen-testosterone ratio and is considered a risk factor for MBC. Other considerations are increased estrogen levels in patients with cirrhosis with liver failure, in men treated for prostate cancer, and in transsexuals taking exogenous estrogens.

PRESENTATION

Male breast tissue is predominately made up of ductal elements, stroma, adipose tissue, and subcutaneous fat. Lobular tissue, which in women is responsible for lactation, is usually absent in males unless they have increased estrogen exposure. Normal male breast anatomy lacks terminal lobules found in females; therefore, lobular carcinomas are rarely if ever encountered. Most male breast cancers are low-grade and intermediate-grade invasive ductal cancer; the remaining cases present with ductal carcinoma in situ (DCIS). Paget's disease and inflammatory breast cancer, rare entities in female patients, have been reported to occur in male patients as well. Most MBCs are hormone receptor positive and *Her 2 neu* negative, which translates into better prognosis if detected early.

Most men with breast cancer present at older ages compared with women with breast cancer, with the peak incidence occurring between ages 68 and 71 years, with a painless breast mass, localized to the subareolar area. It is sometimes difficult to discern this from changes associated with gynecomastia. However, gynecomastia tends to be bilateral and can be associated with tenderness. The tissue tends to remain soft and mobile as opposed to the firm lesions associated with malignancy. Of note, no definitive link between gynecomastia and MBC has been proven, and at present, gynecomastia is not considered a risk factor for the development of carcinoma. Other findings suggestive of breast cancer in females may be evident on examination, including regional lymphadenopathy, nipple retraction, or nipple discharge. Nipple discharge, if present in men, should alert the physician to a more ominous finding. Given the smaller amount of breast tissue in men, cancers can involve the local adjacent tissues, specifically the overlying skin and chest wall musculature.

DIAGNOSIS

The evaluation of a palpable breast abnormality in a male should proceed in a similar manner as with female patients (Figure 1). A careful history and physical examination is conducted. Physical examination should include both breasts, the chest wall, and the regional nodal basins. This is followed by diagnostic imaging with mammography and ultrasound scan. Mammography has been shown to be 92% sensitive and 90% specific for detection of male breast cancer. Mammography remains the diagnostic tool of choice in men presenting with breast symptoms. Given the rarity of MBC, it is not justified as a screening modality except for those at particularly high risk, such as those with the *BRCA 2* mutation. Ultrasound scan can help to better delineate palpable abnormalities, assess involvement of underlying musculature, and accurately assess regional nodal basins for nodal disease. It follows that any palpable lesion identified should be biopsied with image-guided core biopsy for confirmation of pathologic diagnosis and receptor status of malignant tumors. Patients with palpable lymphadenopathy or suspicious nodes identified on ultrasound scan should undergo fine-needle aspiration to determine management strategy. Evaluation of distant metastases follows the same strategy as for women and should be based on clinical assessment of symptoms suggestive of metastatic spread or in cases of locally advanced disease.

Of note, given the rarity of male breast cancer, a careful family history should be obtained and patients should be strongly considered for genetic counseling and testing. This test is performed to determine risk of development of additional cancers in the male patient, with heightened awareness of other cancer screenings that may be warranted, and also provides useful information to family members regarding their associated risk and possible preventative strategies. Male relatives discovered to have the *BRCA* mutation should be followed as high-risk cases and should closely adhere to strict surveillance programs with consideration of screening mammography for early detection. Given the rarity of MBC, little data exist regarding prophylactic surgery. However, it can be discussed with men who are *BRCA 2* carriers for risk reduction in the same manner as female BRCA mutation carriers. Interestingly, males who have a family history of breast cancer and whose female relatives are proven to be *BRCA+* are sometime not informed of these genetic test results. This is an important consideration in counseling female patients who undergo genetic testing.

TREATMENT

Although many surgical options are available for women diagnosed with breast cancer, the options available to men are more limited. If women are deemed candidates for breast conservation, they are often offered lumpectomy with sentinel lymph node biopsy (SLNBX) followed by radiation; and those that require mastectomy can be offered skin-sparing mastectomy to facilitate reconstruction and nipple-sparing mastectomies that offer a pleasing cosmetic outcome. The anatomy of the male breast does not necessarily lend itself to breast conservation, with lesions that are typically located deep in the subareolar tissue, and the cosmetic outcome is improved with mastectomy. However, there is no specific contraindication to breast conservation in men if so desired and if it can be accomplished without disfigurement. Men do not undergo reconstructive procedures; therefore, skin-sparing and nipple-sparing mastectomies are not considered. Men diagnosed with breast cancer typically undergo total mastectomy. Axillary staging is an important component of surgical management, as studies have shown that men who underwent mastectomy without axillary dissection developed nodal recurrence and had poorer prognosis. Therefore, sentinel lymph node biopsy is appropriate in men and follows the same algorithm as used in female patients.

The decision for local radiation therapy follows the same guidelines as for women. This includes patients who present with large tumors, have microscopically positive margins that cannot be surgically improved, and who have four or more positive lymph nodes. Decision for systemic therapy is considered for the patients with advanced disease who are at risk of recurrence and death from breast cancer.

Given that most male breast cancers are hormonally sensitive, adjuvant hormonal manipulation is a crucial adjuvant therapy, with tamoxifen reducing the risk of recurrence. Similar to women, tamoxifen can lead to hormonal changes in men and is poorly tolerated by some. These changes include hot flashes, mood changes, and decreased libido and are present in approximately 20% of men. They are likewise at risk of venous thromboembolism. These side effects are in part responsible for the low compliance with hormonal therapy reported in male patients with breast cancer.

Patients with metastatic disease are managed in the same fashion as female patients. Given that most MBCs are estrogen receptor positive, hormonal therapy is often considered first-line therapy in the metastatic setting. Tamoxifen has established efficacy with a 50% response rate in metastatic male breast cancer. For males who are estrogen receptor negative who present with rapid progression of disease, chemotherapy can be considered for palliation. Trastuzumab

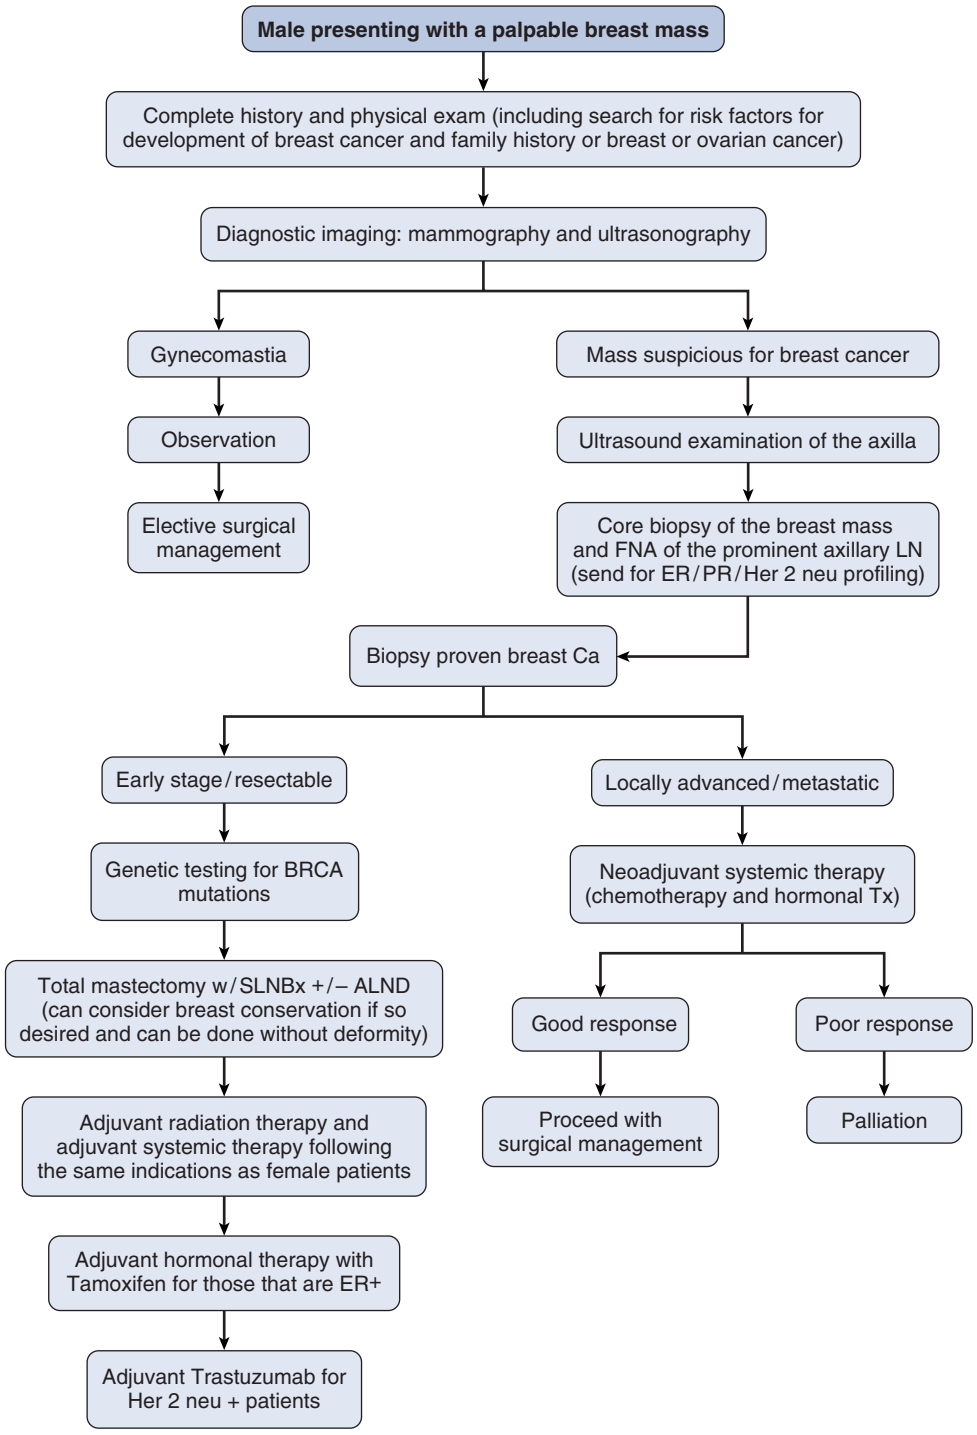

FIGURE 1 Treatment algorithm for a male with a palpable breast mass. *ALND,* axillary lymph node dissection; *ER,* estrogen receptor; *FNA,* fine needle aspiration; *LN,* lymph node; *PR,* progesterone receptor; *SLNBX,* sentinel lymph node biopsy.

should be considered in those that are *Her 2 neu* positive, extrapolating from evidence in female patients.

PROGNOSIS

As with female breast cancer, staging follows the American Joint Committee on Cancer tumor node metastasis (TNM) staging system. Tumor size, grade of tumor, presence of lymph node metastases, and distant disease determine outcome. As in women, predictors of locoregional failure include positive margins, increased tumor size, and involvement of the axillary lymph nodes. Estrogen, progesterone status, and overexpression of *Her 2 neu* also help to predict prognosis and guide adjuvant therapies.

Even in those patients who do not have a genetic predisposition, those diagnosed with male breast cancer are at risk for subsequent cancers, which can include contralateral breast cancer, melanoma, and prostate cancer among others. Close follow-up for health maintenance is especially crucial for these patients.

The diagnosis, surgical treatment, and use of adjuvant therapies for patients diagnosed with male breast cancer remain largely extrapolated from our experience with female breast cancer patients; fortunately, this has been met with success. However, as MBC is increasingly recognized with treatment modifications accounting

for differences in anatomy and hormonal balance, our knowledge regarding this disease will be broadened. This will advance our understanding of the disease and help to better determine optimal male specific treatment algorithms.

Breast Reconstruction Following Mastectomy: Indications, Techniques, and Results

Hakim K. Said, MD, FACS, Sara H. Javid, MD, Shannon Colohan, MD, Otway Louie, MD, David W. Mathes, MD, Benjamin O. Anderson, MD, and Peter C. Neligan, MD

Early treatment of breast cancer centered on removal of disease, prevention of recurrence, and life expectancy. Since then, early detection and multimodal treatment have proven very effective, and breast cancer is currently one of the most curable forms of cancer. Survival without breast restoration, however, has a dramatic negative impact on self-image and lifestyle. Advances in the quality of care have focused on quality of life after treatment, particularly on returning women to their former lives before they were diagnosed with cancer. Today, the options for restoring a breast are better than ever, with natural tissues, organic matrices, or synthetic implants, especially when used in novel combinations.

INDICATIONS

The surgical treatment options for both noninvasive (ductal carcinoma in situ) and invasive breast cancer include breast-conserving surgery (lumpectomy) and mastectomy. Approximately 70% of patients with early-stage invasive breast cancer are candidates for and elect breast-conserving surgery, but many will require or choose mastectomy due to the extent of malignant disease in the breast, prior radiotherapy exposure, contraindication to or desire to avoid radiotherapy, and/or risk reduction for subsequent breast cancers. Various technical approaches to mastectomy differ primarily with respect to the amount of the skin envelope that is preserved.

A non–skin-sparing ("standard") mastectomy is performed when a patient does not desire or cannot undergo immediate reconstruction. A wide elliptical incision is made, excising the nipple areolar complex (NAC) and the skin overlying the tumor, ultimately leading to a long transverse or oblique scar. The goal should be to minimize postoperative skin redundancy that might interfere with the wearing of a prosthesis. In contrast, in a skin-sparing mastectomy, the breast is removed through a much smaller circumareolar incision narrowly encompassing the NAC in order to preserve the skin envelope for the reconstructed breast mound. A newer variation of this skin-sparing approach is the "nipple-sparing," or "total skin-sparing," mastectomy. The nipple-sparing mastectomy, previously termed the *subcutaneous mastectomy* in the 1970s and 1980s, was an operation that fell into disrepute out of concern that excessive fibroglandular tissue would be left behind the NAC, but it is now being reevaluated for the purpose of cancer prophylaxis and in carefully selected breast cancer cases.

Because the perfusion to the skin and the nipple comes primarily from the breast that must be removed, the remaining skin may be relatively ischemic and prone to healing challenges. As the mastectomy plane grows closer to the skin, the chance increases of causing damage to the subdermal plexus that is the only remaining source of perfusion. Whereas in a standard mastectomy, this ischemic central breast skin would be removed, in skin-sparing mastectomy, most of these skin flaps are preserved. Nipple-sparing mastectomy leaves essentially all the breast skin intact, regardless of how far away the nearest intact blood vessels lie. This further increases the amount of ischemic skin, the chance of healing problems, and the risk of complications after either of these kinds of mastectomy. Reliably preserving an intact and undamaged subdermal plexus is a challenge in skin-sparing mastectomy, and critically important in nipple-sparing mastectomy, in order to avoid complications after mastectomy. Moreover, while leaving fibroglandular tissue behind poses an oncologic risk, excessively thinning the dermal subcutaneous tissue negatively impacts the appearance and quality of the reconstructive outcome.

In general, both skin-sparing and nipple-sparing mastectomies are only performed in the setting of breast reconstruction, whether that reconstruction is performed during the same operation or shortly thereafter as a separate procedure once the skin has recovered and the surgical pathology results are known.

Several studies have demonstrated that post-mastectomy breast reconstruction affords several benefits, including improved body image, psychological health, and reduced concern for cancer recurrence. Although most patients are eligible to undergo reconstruction in a "delayed" fashion following completion of their breast cancer treatment, many patients are eligible to begin reconstruction at the time of their mastectomy ("immediate" reconstruction). The decision to proceed with immediate reconstruction depends on patient and disease factors, as well as treatment-related factors. In some cases, the mastectomy is performed as a separate procedure, with reconstruction to be performed a few weeks later ("delayed-immediate"), in order to allow pathologic examination of the specimen before proceeding with the reconstructive procedure.

Immediate reconstruction, with either a prosthetic device or autologous tissue, requires a preserved skin envelope with a skin-sparing mastectomy. The majority of patients with early-stage (0, I, II) breast cancer can undergo this approach. Immediate

reconstruction is contraindicated in a patient with skin involvement, such as skin ulceration (T4b) or inflammatory (T4d) breast cancer. In addition, if a patient is expected to require post-mastectomy radiation therapy (PMRT), such as those with locally advanced (stage III) cancers, immediate reconstruction with autologous tissue is to be avoided to prevent the deleterious effects of radiation on the reconstruction. However, in such cases, skin-sparing mastectomy with immediate reconstruction using a temporary prosthesis (tissue expander) is often possible, with the understanding that this expander may need to be deflated prior to radiation. Other relative contraindications for immediate reconstruction include active smoking history and medical comorbidities such as morbid obesity or cardiopulmonary disease.

RECONSTRUCTIVE TECHNIQUES

Women who elect to undergo reconstruction have two main reconstructive options: prosthetic devices (tissue expanders, implants) or autologous tissue reconstruction using tissue transferred from a distant donor site to the chest wall. The choice can sometimes be driven by the breast cancer treatment plan, such as patients who will require PMRT, which largely eliminates the option of immediate autologous reconstruction. More commonly, reconstruction reflects the patient's choice and the reconstructive surgeon's recommendation. For instance, very slender women may not have ample donor tissue available for autologous reconstruction, and women with a history of prior radiation (e.g., mantle radiation for lymphoma) may not be candidates for implant-based reconstruction because of the significantly higher risk of implant complications in a radiated setting.

Implants

Implants are selected by many women because of the desire to avoid a second surgical scar and recovery associated with the donor site or because it entails less extensive surgery. Downsides of implant-based reconstruction include higher risk of infection due to presence of a foreign body, risk of capsular contracture, and risk of leak or rupture, which would require removal or replacement.

Two Stages

Historically, the two-stage implant approach is the earliest form of breast reconstruction, although implants have gone through many iterations. Today the great majority of implants are placed in two stages. First, an adjustable implant called an *expander* is placed subpectorally, either deflated or partially filled. Typically, over the next 3 months, the expander is inflated with saline on a weekly basis to reach an appropriate goal size. At that point, the expander is replaced by a softer and more aesthetic implant, saline or silicone. Although in the United States, between 1994 and 2007, a moratorium prohibited use of silicone gel implants, elsewhere in the world their use has continued. In 2007, the safety data were convincing enough to warrant rerelease of silicone gel implants on the U.S. market. Subsequent studies have documented significantly improved patient satisfaction and better aesthetic outcomes in the setting of breast reconstruction using silicone gel implants versus saline implants. Most patients currently choose the silicone implants, and the outcomes are closer to the results obtained with autologous reconstruction (Figure 1).

One Stage

An alternative to this approach is one-stage reconstruction using a permanent silicone implant placed subpectorally at the time of the mastectomy. This reduces the number of surgeries required but poses several risks. First, there must be sufficient skin redundancy after mastectomy to permit construction of a full breast of the desired size. Second, the mastectomy skin must be of sufficient viability to tolerate the weight and expansion produced by a full-size implant. Third, the patient's desired goals in terms of the final implant must be explicitly known and achievable at this point. Many patients lose enough skin through mastectomy to reduce the volume that can be reached, or they have delicate skin flaps that would be compromised by or even necrose as a result of excessive tension from a full-size implant. Patients generally are better served by placement of an adjustable expander with a lower fill volume and a two-stage reconstruction. In addition, the second stage implant exchange allows the patient to choose her desired implant size and type and allows for another chance to adjust the pocket for a more optimal breast shape.

FIGURE 1 Implant reconstruction.

Tissue Matrices

Offered by a number of manufacturers, tissue matrices are organic substrates derived from human, porcine, or bovine origins, processed to produce an implantable organic scaffold. They are commonly placed in conjunction with an expander at the time of mastectomy as a "sling," which offloads the skin by bearing the weight of the implant. In addition, these matrices allow a significant degree of control over the size and shape of the implant pocket, including definitive positioning of the inframammary fold. Evidence suggests they may have a beneficial effect on capsular contracture rates, which are especially high among patients who have undergone radiation (Figure 2).

Autologous Methods of Breast Reconstruction

Some women do not like the idea of having implants, while others, for any number of reasons, may not be candidates for that type of reconstruction. The most common reason that a patient may not be eligible for implant reconstruction is because of a history of radiation. Using the patient's own tissues to reconstruct the entire breast is an attractive option for these patients. Natural tissue has the potential to provide durable reconstruction of the full breast volume, often without the vulnerability of implants, which can fail or require replacement eventually.

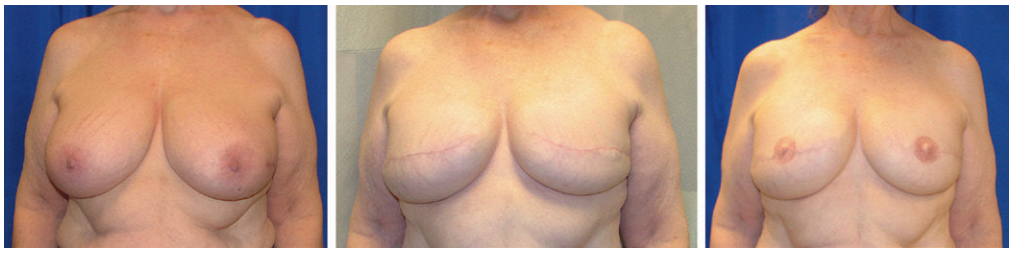

FIGURE 2 One-stage implant reconstruction with tissue matrix.

There are many ways to reconstruct a breast using autologous tissue. All involve incisions for harvesting tissues from various donor sites elsewhere on the body. These methods can be divided into three broad categories: (1) fat grafting, (2) pedicled flap reconstruction, and (3) free flap reconstruction. The last of these requires microsurgical skills.

Fat Grafting

The use of fat grafting in breast reconstruction is a relatively new technique. Fat grafting has been used in aesthetic surgery for a number of years. Structural fat grafting involves harvesting adipose tissue from other areas on the body through a series of tiny nick incisions. Small amounts of fat are carefully prepared and then injected in multiple planes into areas to be treated. Depending on the site, 30% to 70% of the fat injected with this technique can be retained and engrafted long-term. Overcorrection, subsidence, and retreatment are the keys to reaching the goal size with this method. It is an extremely useful technique for reconstruction of lumpectomy defects, where one treatment may be all that is necessary (Petit et al., 2011).

It has also gained favor for contour correction and volume adjustment in conjunction with implant reconstruction. Some of the issues associated with implants, such as implant rippling or edge step-off deformities, can be addressed easily with lipofilling using fat harvested from other sites of redundancy, without significant scars or deformity at the donor sites.

More recently, Khouri has introduced the concept of external expansion using a suction cup device worn by women called the Brava bra (BRAVA LLC, Miami, Fla). This expands the recipient site, creating an edematous mound that can accommodate larger volumes of fat injection. Typically, patients will undergo 3 to 4 sessions of fat grafting over a number of months, in conjunction with a regimen of external expansion before and after each surgery. With persistence, the entire breast mound can be reconstructed to a reasonable volume with repeated rounds of this method.

Pedicled Flap Reconstruction

A pedicled flap is one in which the vascular supply remains intact and is transferred into the breast from an adjacent region. The two most common pedicled flaps in use for breast reconstruction are the latissimus dorsi myocutaneous flap and the transverse rectus abdominis myocutaneous (TRAM) flap. Other flaps exist based on perforators from the thoracodorsal vessels and the intercostal vessels. These will be discussed later. Many of these flaps are also extremely useful for reconstructing partial mastectomy defects or defects resulting from lumpectomy.

The Latissimus Flap

The blood supply of the latissimus dorsi is from the thoracodorsal artery. Because of the favorable position of this pedicle, the latissimus muscle and its overlying skin can be pivoted on the pedicle and rotated from the back to the chest. The skin paddle of the latissimus can be oriented obliquely or transversely to hide the donor site scar under the bra line. In most cases, the latissimus flap is combined with placement of a breast implant, as there usually is insufficient bulk to create a breast mound. This is particularly useful in patients who have been through radiation treatments. The addition of nonradiated tissue from the back can make implant reconstruction possible in patients who otherwise might not be candidates for implants.

The TRAM Flap

Introduced by Hartrampf, the TRAM flap takes advantage of the blood supply of the abdominal skin. Based on the superior epigastric artery, an ellipse of lower abdominal skin and fat, along with underlying rectus abdominis muscle, is mobilized. This flap is tunneled from the abdomen into the chest, where it is folded and inset to reproduce the breast shape. The abdominal donor site is treated similarly to a tummy tuck, by undermining the upper abdominal skin and advancing it to facilitate closure. Critics of the pedicled TRAM flap point out that, with sacrifice of one or both rectus muscles, there is significant potential weakening of the abdominal wall and careful reconstruction of the abdomen to prevent future development of a ventral hernia is critical.

Free Flap Breast Reconstruction

Free flap breast reconstruction has undergone an evolution over the past 20 years. Because of concerns with abdominal wall integrity following pedicled TRAM flap reconstruction, the free TRAM was developed, based on the deep inferior epigastric vessels. The rationale was that less muscle could be harvested, and the expectation was that donor morbidity would be less. As our knowledge of vascular anatomy improved, the free TRAM became the muscle-sparing free TRAM, harvesting less and less muscle. Ultimately, with the introduction of perforator flaps, we learned how to dissect the vascular pedicle out of the rectus muscle with minimal disruption of the muscle and preservation of the segmental nerves. This evolved to become the deep inferior epigastric perforator (DIEP) flap (Figure 3). In each of these flaps, the major pedicle, the deep inferior epigastric artery, is divided and reanastomosed in the chest to the internal mammary vessels.

In patients who are not candidates for abdominal-flap breast reconstruction, either because of insufficient tissue availability or because of previous surgery, there are several other options. These include the transverse upper gracilis (TUG) flap (Figure 4), which includes skin and subcutaneous fat from the upper inner thigh, or the superior and inferior gluteal artery perforator (SGAP and IGAP) flaps. Each relies on a donor site and removal of excess tissue at a respective site on the patient. All of these flaps require advanced microsurgical expertise as well as an intimate knowledge of the vascular anatomy of the flap involved based on preoperative computed tomographic scan imaging evaluation. Each donor site also represents a particular set of benefits or drawbacks depending on the site and the patient.

Adrenal Incidentaloma

Alan P. B. Dackiw, MD, PhD

OVERVIEW/CLINICAL PROBLEM

An adrenal "incidentaloma" is an adrenal mass, usually measuring 1 cm or more in size, that is discovered incidentally during a radiologic examination performed for indications other than a suspected adrenal problem. The widespread use of abdominal ultrasonography, computed tomographic (CT) scanning, and magnetic resonance imaging (MRI) has resulted in the findings of adrenal incidentaloma, which necessitates the subsequent workup. Numerous autopsy studies have revealed that the overall frequency of adrenal adenomas is approximately 6%; abdominal CT identification has demonstrated similar numbers. The prevalence of adrenal adenomas increases with age. The probability of finding an unsuspected adrenal adenoma on abdominal CT scans in a patient between 20 and 29 years of age is approximately 0.2%, in comparison with approximately 7% in a patient older than 70 years.

The majority of adrenal incidentalomas are clinically nonfunctioning, benign adrenal cortical adenomas. Other frequently reported diagnoses include cortisol-secreting adrenal cortical adenoma, aldosteronoma, pheochromocytoma, adrenal cortical carcinoma, and metastatic carcinoma. In the evaluation of the adrenal incidentaloma, three important questions must be asked: (1) Is the mass functioning or nonfunctioning? (2) Is the mass benign or malignant? (3) If malignant, is it primary or secondary? If the clinician directs the history, physical examination, and laboratory evaluation to answering these three questions for each zone of the adrenal cortex and the adrenal medulla, all incidentally discovered massed will be thoroughly and correctly evaluated (Figure 1). Because these masses are discovered initially on abdominal imaging, the imaging characteristics and size in evaluation of these masses are discussed first.

IMAGING

Density/Hounsfield Unit Assessment

The primary goal of imaging is to distinguish among adrenal adenoma, adrenal carcinoma, and pheochromocytoma (Figure 2), as well as metastatic lesions. Imaging cannot, however, reliably distinguish between nonfunctioning and functioning adrenal adenomas. The diagnosis of an adenoma relies on the presence of lipid content in the adrenal lesion, which can be identified by density measurement on noncontrast CT scans or on in-phase and out-of-phase MRI. Alternatively, an adenoma can be identified by measuring contrast washout on CT scans. Lesions that have attenuation values below 10 Hounsfield units (HUs) on noncontrast CT scans and loss of signal on out-of-phase MRI are adenomas. The differential diagnosis can be further delineated by CT scans obtained immediately after intravenous administration of a contrast agent and then again after a 10-minute to 15-minute delay. Benign adrenal lesions are commonly enhanced up to 80 to 90 HUs and are washed out more than 50% on the delayed scan, whereas lesions such as metastatic tumors, carcinomas, or pheochromocytomas do not washout. Pheochromocytomas usually show enhancement to more than 100 HUs, which diagnostically distinguishes them from adenomas. On noncontrast CT scans, some benign adrenal lesions do not have attenuation values of less than 10 HUs and may have values of 20 to 40 HUs. This result is found in lipid-poor adenomas, often of smaller size. In these cases, a washout of more than 50% may enable the diagnosis of an adenoma. These masses may also be further evaluated by MRI; however, they may remain indeterminate.

Size

The size of the adrenal mass, as measured on CT scans or MRI, remains the single best indicator of malignancy. In a clinical review of six reported series, Copeland reported that 105 (92%) of 114 adrenal cortical carcinomas were more than 6 cm in diameter. In contrast, large adrenal adenomas (>6 cm) are relatively uncommon, although the exact frequency is unknown. In an important study, Ross and Aron assumed that 1% of adenomas were more than 6 cm in diameter and, on the basis of this assumption, calculated that fewer than 1 per 10,000 adrenal neoplasms smaller than 6 cm in diameter would be an adrenal cortical carcinoma (in the absence of CT characteristics suggesting malignancy, such as irregular borders and lack of homogeneity). They further estimated that the likelihood of adrenal cortical carcinoma increases to 35% to 98% in patients with an adrenal mass larger than 6 cm.

Ross and Aron's widely read 1990 article established the routine practice of operating on patients with nonfunctioning unilateral adrenal neoplasms greater than 6 cm in size and considering observation in patients with smaller lesions. However, there are reasonable concerns about this recommendation: (1) Their calculations were based on an estimate of the frequency of large (>6 cm) adrenal adenomas, a number that, although probably low, is unknown; (2) adrenal cortical cancer is an aggressive malignancy, and no data support the safety of observing an enlarging adrenal cancer (until it reaches 6 cm); and (3) small (<5 cm) adrenal cortical cancers have been documented in a number of reported series. Therefore, clinical reality suggests that few endocrine surgeons would merely observe a 4- or 5-cm unilateral adrenal mass (regardless of CT characteristics) in an otherwise healthy 40- to 50-year old patient.

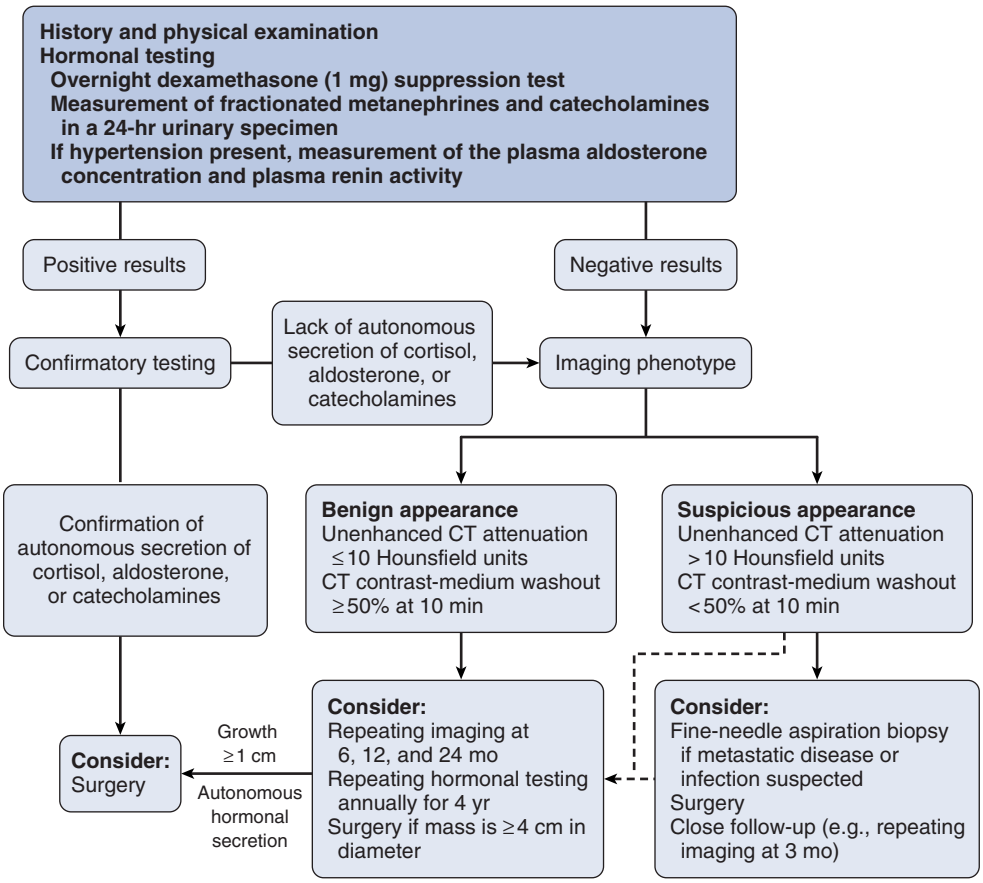

FIGURE 1 Algorithm for the evaluation of patients with an adrenal incidentaloma. *(From Young WF Jr: Clinical practice: the incidentally discovered adrenal mass,* N Engl J Med *356:601–610, 2007.)*

Indeed, updated clinical guidelines since have recommended operating on adrenal masses that are 4 cm in size or greater. This point was emphasized by the results of a multiinstitutional retrospective study of incidentally found (and nonfunctional) adrenal neoplasms reported by Terzolo and colleagues. Of the 210 patients in the study, 115 (55%) underwent adrenalectomy and adrenal cortical carcinoma was found in 15 patients (13% of patients who underwent surgery and 7% of patients with incidental adrenal neoplasms). Of the 15 cancers, 3 were smaller than 6 cm in diameter (2.6% of surgical patients and 1.4% of patients with incidental adrenal neoplasms). In all three of these patients, the radiographic characteristics suggested malignancy (i.e., inhomogeneous density, irregular shape and margins). Thus tumor diameter was highly correlated with the risk of cancer; for a diameter of 5 cm, the sensitivity was 93% and the specificity was 64% for identifying adrenal cortical carcinoma. Furthermore, if the 5-cm size criterion had been used as an indication for adrenalectomy, one carcinoma less than 5 cm (diameter, 3.7 cm) would have been observed among the 15 patients with cancer. The CT characteristics of this tumor, as noted previously, did provide an adequate indication for adrenalectomy.

Most guidelines now recommend surgical excision of adrenal neoplasms larger than 4 cm in diameter and those of any size with suspect imaging characteristics. The CT and MRI criteria assume greater importance in the evaluation of nonfunctioning tumors 3 to 5 cm in diameter. CT characteristics of malignancy include tumor inhomogeneity/heterogeneity, irregular shape, irregular margins, and hemorrhage with underlying mass, lack of fat suppression on MRI on T2 out-of-phase gradient imaging or heterogeneous signal intensity on T2-weighted MRI. As noted previously, MRI characteristics of malignancy include the signal intensity on T2-weighted images. Adenomas have low signal intensity in comparison to the liver (adrenal mass/liver ratio ≤1.4), cortical carcinomas and metastases are moderately bright (adrenal mass/liver ratio, 1.2 to 2.8), and pheochromocytomas usually are extremely bright (adrenal mass/liver ratio >3.0). However these ratios overlap in some cases, and thus size of the mass, other imaging characteristics, and the overall clinical picture must be considered.

Current practice is to recommend adrenalectomy for all biochemically confirmed functioning cortical neoplasms and those with suspect radiographic findings, regardless of tumor size. Nonfunctioning tumors 4 cm in size or larger with benign radiographic characteristics are considered for surgical resection if patient age and general health are acceptable. The radiographic assessment of tumor size cannot be the only consideration; nonfunctioning, radiographically benign adrenal cortical neoplasms approximately 4 cm in diameter necessitate individualized treatment that is based on patient age and comorbid conditions. For example, adrenalectomy is a reasonable recommendation in a healthy 50-year-old woman (adrenal cortical cancers cluster in the 40-year to 50-year age range and are more common in women) with a 3.8-cm to 4.0-cm unilateral nonfunctioning adrenal neoplasm. For such a patient, no data suggest that careful follow-up, no matter how frequent, can detect malignancy, if it were to exist, at a curable stage. Such a patient has a relatively long life expectancy, multiple serial CT scans or other abdominal imaging are needed, and the risk of death from disease is high if the adrenal cortical cancer is not cured at the first surgical procedure; therefore, adrenal resection is reasonable in this patient. In contrast, in a 75-year-old man with multiple comorbid conditions with a similar 4-cm unilateral nonfunctioning adrenal neoplasm, observation would probably be recommended unless radiographic criteria were strongly suggestive of malignancy.

Fine-needle aspiration (FNA) biopsy of an isolated adrenal mass should be performed only in patients with a history of cancer or if there is clinical, laboratory, or radiographic evidence of a primary extraadrenal malignancy and if biopsy findings would result in a change in the clinical management. There is no indication for adrenal

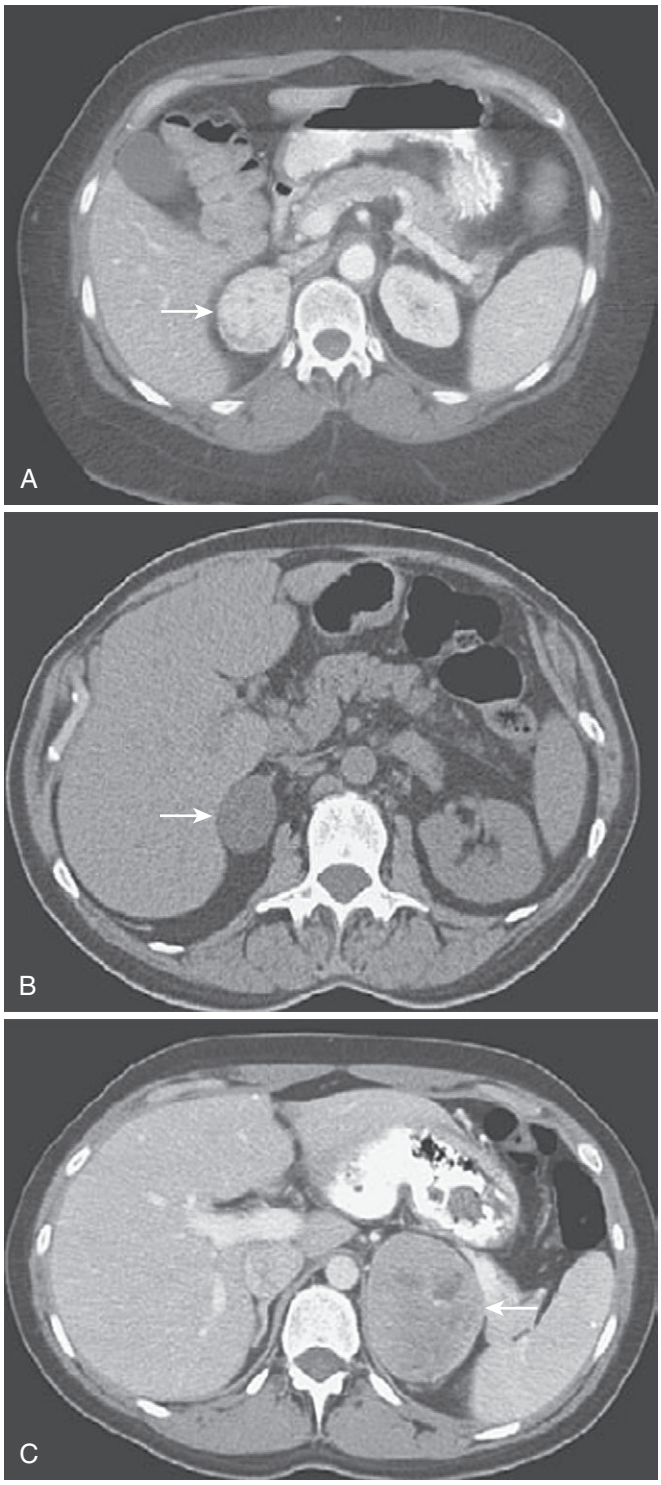

FIGURE 2 Imaging characteristics of adrenal masses: pheochromocytoma (**A**), benign cortical adenoma (**B**), and adrenocortical carcinoma (**C**). Imaging phenotypes and characteristics are as discussed in text. *(From Young WF Jr: Clinical practice: the incidentally discovered adrenal mass,* N Engl J Med *356:601–610, 2007.)*

biopsy in the absence of presumed metastasis to the adrenal glands. It is critically important to rule out pheochromocytoma before a biopsy is performed because of the risk that percutaneous biopsy may trigger severe hypertension in a patient with a catecholamine-secreting tumor. Furthermore, the manifestation of an occult metastatic cancer as a small, unilateral, asymptomatic adrenal mass is rare; thus, investigating all hormonally inactive adrenal masses to detect occult metastatic cancer would result in a large number of unnecessary fine-needle aspiration biopsies.

RAPID OFFICE BIOCHEMICAL EVALUATION (SUMMARY)

The diagnostic evaluation of a patient with a unilateral adrenal mass includes measurement of serum electrolyte levels to rule out hypokalemia secondary to aldosterone excess, an overnight l-mg dexamethasone suppression test, a 24-hour urine collection for 17-ketosteroids if a masculinizing or feminizing adrenal tumor is suspected, and a 24-hour urine collection to measure catecholamine (and metanephrine) concentrations if pheochromocytoma has not been ruled out. In the author's institution, rapid office evaluation begins with obtaining an afternoon blood sample for cortisol and electrolyte measurements and for plasma metanephrine, normetanephrine, and catecholamine measurements, and a 24-hour urine collection to measure vanillylmandelic acid, metanephrine, and catecholamine concentrations. Dexamethasone (1 mg) is then taken at 10:00 PM that evening, and the following morning at 8:00 AM, blood is obtained for plasma cortisol analysis. During the afternoon of the second day, patients return their timed urine collection specimen. If the patient's plasma cortisol level is not suppressed below 5.0 mcg/dL, the patient undergoes a second timed 24-hour urine collection, this time to measure the cortisol, 17-hydroxysteroid, and 17-ketosteroid concentrations.

CLINICAL EVALUATION

Cortisol Production (Zona Glomerulosa)

History/Symptoms

In documenting the history, the clinician should note weight gain, fatigue, depression, other emotional and cognitive changes, sleep disturbances, menstrual irregularities, high blood pressure, glucose intolerance, and easy bruising.

Physical Examination

On physical examination, the patient should be evaluated for hypertension, evidence of central obesity, supraclavicular fat accumulation, a dorsocervical fat pad ("buffalo hump"), facial plethora, thinned skin, purple striae, acne, ecchymoses, hirsutism, and proximal muscle weakness or wasting. Patients may offer photographs demonstrating changes in appearance over several years.

Biochemical Evaluation

Adrenal autonomy is best assessed by an overnight dexamethasone (1 mg) suppression test. Although the optimal cutoff value is controversial, a cortisol level greater than 5 mcg/dL or 138 nmol/L is an acceptable criterion for defining an abnormal result. If the result is abnormal, confirmatory testing should be performed, including midnight salivary cortisol measurements, adrenocorticotropic hormone (ACTH) measurement, 24-hour urine cortisol measurement, and possibly a 2-day dexamethasone suppression test.

Aldosterone Producing Adenoma (Zona Fasciculata)

History/Symptoms

Affected patients may have symptoms of nocturia, polyuria, muscle cramps, and palpitations, in addition to a history of hypertension often difficult to control with multiple medications.

Physical Examination

Physical examination will reveal hypertension (mild, moderate, or severe).

Biochemical Evaluation

Measurement of the plasma aldosterone concentration and plasma renin activity is the critical screening and diagnostic test. Patients may be hypokalemic or normokalemic. A ratio of plasma aldosterone concentration to plasma renin activity ratio that is 20 or higher and a plasma aldosterone concentration of 15 ng/dL are positive results. These levels and ratios can be determined while the patient is receiving antihypertensive drugs, with the exception of aldosterone antagonists such as spironolactone end eplerenone. If this screening test result is positive, the diagnosis can be confirmed by aldosterone suppression testing with either a saline infusion test or 24-hour urinary aldosterone excretion test while the patient maintains a high-sodium diet. To confirm that the adrenal mass (and not bilateral adrenal hyperplasia) is the source of aldosterone excess in patients with documented primary aldosteronism, adrenal venous sampling should be considered in patients with bilateral adrenal abnormalities on CT scans and in patients older than 40 years.

Sex Steroid Production (Zona Reticularis)

Measurement of 17-hydroxysteroid and ketosteroid levels are performed only in patients with suspected masculinizing or feminizing tumors.

Pheochromocytoma (Adrenal Medulla)

History/Symptoms

Patient may have no symptoms or may have episodic spells or paroxysms with classic symptoms that include headache, palpitations, and diaphoresis. Other symptoms reported are tremor and anxiety.

Physical Examination

Signs on physical examinations include hypertension (paroxysmal or sustained), evidence of orthostatic hypotension, pallor, and possibly retinopathy.

Biochemical Evaluation

Most pheochromocytomas secrete the catecholamines norepinephrine or epinephrine and, more rarely, dopamine. Routine testing for pheochromocytoma has included a 24-hour urine collection for catecholamines, total and fractionated metanephrines, and vanillylmandelic acid, as noted previously. In a 24-hour urine collection, a total metanephrine level above 1800 mcg in the appropriate clinical setting is highly suggestive of a pheochromocytoma, and a plasma metanephrine level exceeding three or four times normal is also highly suspect for a pheochromocytoma. The measurement of plasma free metanephrine and normetanephrine levels has the highest sensitivity (97% to 100%) and specificity (85% to 89%) and is often the best initial test in screening for pheochromocytoma. Because of the very high sensitivity of this test, if the result is negative, it is highly unlikely that the detected adrenal incidentaloma is a pheochromocytoma. If the result is positive, the diagnosis is corroborated by assessment of the patient history, a confirmatory 24-hour urine collection, the previously noted imaging phenotype, and possibly a nuclear medicine (metaiodobenzylguanidine [MIBG]) scan in select cases.

Adrenalectomy

Adrenalectomy is indicated in any patient with a hormonally active adrenal tumor, enlarging mass, or suspected malignancy. Adrenal tumors can be generally categorized as *functional* or *nonfunctional.* Most functional adrenal tumors are less than 6 cm in diameter, and patients with functional tumors are excellent candidates for laparoscopic adrenalectomy (Figure 3). Functional tumors include aldosterone- and cortisol-producing adenomas and pheochromocytomas. The main indication for performing an adrenalectomy with an open approach is the size of the tumor or mass in the adrenal gland. It may be technically feasible to remove larger tumors up to 14 cm with a laparoscopic approach; as a general rule, however, if a large adrenal tumor is suspected to be an adrenal cortical carcinoma preoperatively because of size and imaging characteristics, an open approach is recommended. These tumors are often soft, friable, and easily penetrable, with indistinct tissue planes. An open approach to these tumors is often safer, to avoid possible tumor disruption or violation of tissue planes that may occur with a laparoscopic approach.

PREOPERATIVE PREPARATION

The importance of documenting and diagnosing function of an adrenal neoplasm preoperatively cannot be overemphasized, inasmuch as the preoperative, intraoperative, and postoperative medical management of patients with hormonally active tumors is extremely important.

Pheochromocytoma

Patients with pheochromocytoma are treated preoperatively for 2 to 4 weeks with α-adrenergic blockade. Phenoxybenzamine, usually at 10 mg by mouth twice daily, has been the drug of choice at the author's institution, inasmuch as intraoperative blood pressure control has been good with this regimen. The addition of β-adrenergic blockade may prove necessary after institution of α-adrenergic blockade if hypertension is persistent or tachycardia ensues. Close intraoperative communication with anesthesiology colleagues cannot be overemphasized, with availability of nitroprusside, phentolamine, and adrenergic agents after tumor removal to control blood pressure intraoperatively.

Aldosteronoma

Patients with aldosterone-producing adenomas require electrolyte monitoring and correction before surgery, which may necessitate aggressive potassium replacement. This must be done with caution and closely monitored in patients who also may be receiving spironolactone or eplerenone. In some patients, it may be difficult to completely normalize potassium levels preoperatively.

Cortisol-Producing Adenoma (Cushing)

Affected patients may be treated preoperatively for a brief period (5 to 7 days) with ketoconazole in an attempt to decrease and eliminate

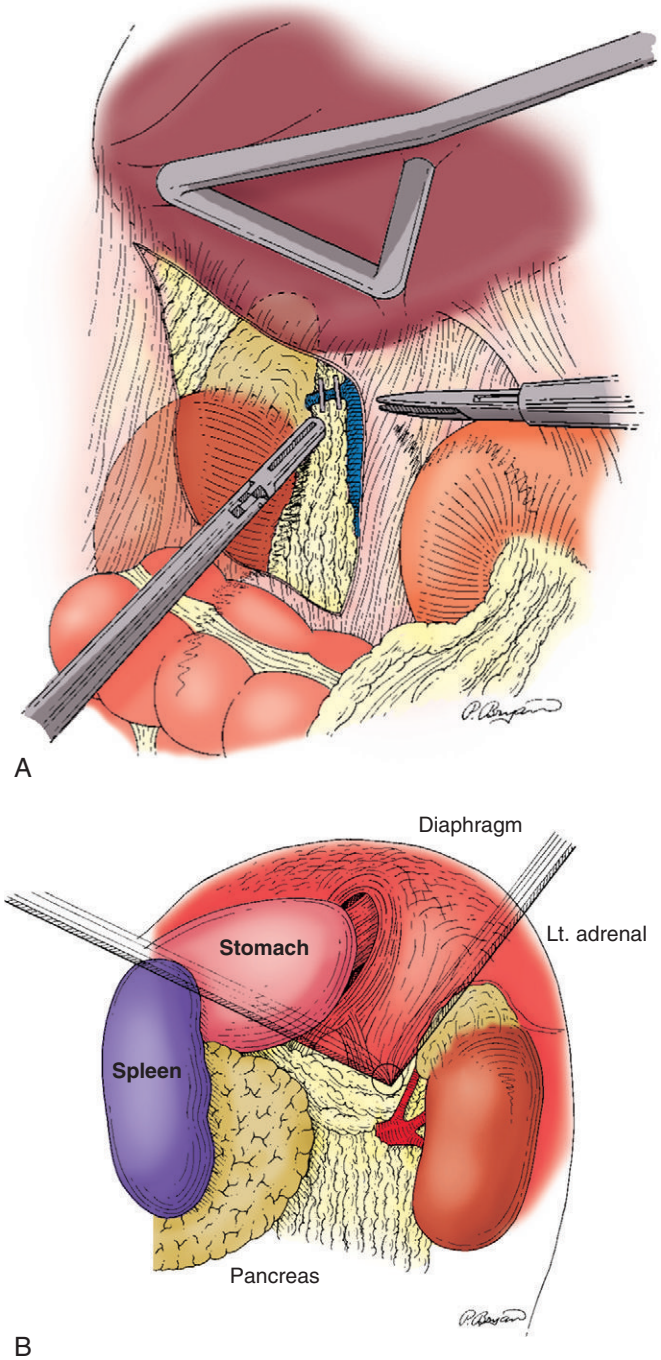

FIGURE 3 Laparoscopic adrenalectomy. *(From Dackiw APB: Laparoscopic adrenalectomy. In Cameron JL, editor:* Current surgical therapy, *10th ed, Philadelphia, 2011, Elsevier.)*

the significant hypercortisolemia perioperatively, which theoretically may affect blood vessel fragility and bleeding, as well as wound healing. Patients are treated with 100 mg of intravenous hydrocortisone at induction of anesthesia and after tumor removal, followed by a dose every 8 hours until oral replacement and taper begin.

OPERATIVE TECHNIQUE AND POSTOPERATIVE CARE

As noted previously, if a large adrenal tumor is suspected to be an adrenal cortical carcinoma preoperatively because of size and imaging characteristics, an open approach is recommended. The two main techniques used today for laparoscopic adrenalectomy are the lateral transabdominal approach popularized by Gagner and the posterior retroperitoneal approach popularized by Walz. Interestingly, laparoscopic left adrenalectomy and laparoscopic right adrenalectomy are two anatomically and technically distinct procedures (see Figure 3). The lateral transabdominal approach is the author's preferred approach (used in approximately 300 cases) for several reasons, except in certain clinical circumstances, such as in patients who have undergone multiple prior abdominal operations. These reasons include familiarity with laparoscopic intra-abdominal anatomy, the potential to remove larger tumors, and the ability to perform laparoscopy. Most patients who undergo laparoscopic adrenalectomy may be discharged 24 to 48 hours postoperatively. An ileus may persist for 24 to 48 hours. Patients with pheochromocytoma require postoperative hemodynamic monitoring in an intensive care unit, and those with Cushing's syndrome require postoperative stress-dose steroids, followed by an oral tapering dose often over several months for up to 2 years. Patients with aldosterone-producing adenomas often experience significant diuresis postoperatively and require close monitoring of their fluid balance and electrolytes because some may develop significant hyperkalemia.

The Management of Adrenal Cortical Tumors

Peter D. Peng, MD, Danielle A. Bischof, MD, Douglas Ball, MD, and Nita Ahuja, MD

OVERVIEW

The adrenal glands are paired retroperitoneal endocrine organs located superior to the kidneys. The left adrenal gland lies superomedial to the left kidney with venous drainage into the left renal vein, and the right adrenal gland lies superomedial to the right kidney and drains into the inferior vena cava. The adrenal cortex comprises 80% to 90% of the adrenal gland, and the zona glomerulosa, zona fasciculata, and zona reticularis are responsible for production of aldosterone, cortisol, and sex hormones, respectively.

Adrenal cortical tumors in patients referred for surgery generally fall into one of four categories: (1) incidentalomas; (2) functional hormone-secreting tumors that cause a clinical syndrome such as Cushing's syndrome, Conn's syndrome, or virilizing/feminizing syndromes; (3) adrenocortical carcinoma; or (4) adrenal metastasis. Evaluation of these patients should consist of a thorough history, physical examination, cross-sectional imaging, and functional evaluation that includes:

- Plasma renin activity (PRA), plasma aldosterone concentration (PAC), and PAC/PRA
- Serum adrenocorticotropic hormone (ACTH) *and* 24-hour urine cortisol *or* 1-mg dexamethasone suppression test *or* midnight salivary cortisol
- 24-hour urine catecholamines and metanephrines *or* plasma metanephrines

An adrenal protocol computed tomographic (CT) scan is the imaging modality of choice in the diagnostic assessment of adrenal masses. Lesion size, appearance of margins, heterogeneity, precontrast attenuation levels, percent washout on delayed images, and local extent of the lesion can distinguish lesions that are likely benign from malignant lesions and metastases. Magnetic resonance imaging (MRI) may also help differentiate an adenoma from an adrenocortical carcinoma or a metastasis and may be superior to CT scan in determination of local extent of the lesion and invasion of adjacent structures.

The role of image-guided percutaneous biopsies of the adrenal gland is limited because biopsy is unable to distinguish an adenoma from adrenocortical carcinoma. However, in patients with a history of malignancy, after a pheochromocytoma is ruled out, percutaneous biopsy may be useful to distinguish between a primary adrenal tumor and a metastatic lesion.

INCIDENTALOMA

The increasing use of cross-sectional imaging in medicine has resulted in the frequent incidental finding of adrenal masses in up to 5% of imaging studies. The evaluation and management of an incidentaloma focuses on (1) functional status and (2) likelihood of malignancy. As mentioned previously, the workup should begin with evaluation to determine whether the lesion secretes active endocrine hormones. Although history and clinical examination may provide some insight, biochemical evaluation is essential. *All functional lesions should be resected.*

Nonfunctional lesions should be evaluated for the likelihood of malignancy. Cross-sectional imaging with an adrenal protocol CT scan is useful to stratify the risk of malignancy. Empiric data have shown size to be an important criteria, with lesions less than 4 cm likely to be benign and those more than 6 cm with a significant probability of malignancy. The imaging phenotype of the lesion can also be helpful in determination of malignancy risk. Adrenal lesions have been shown to appear approximately 25% smaller on cross-sectional imaging when compared with pathologic analysis. Lesions with a precontrast density of less than 10 Hounsfield units are virtually all benign adenomas. Benign adenomas also typically display rapid washout, with more than 50% washout 10 minutes after contrast administration. Adrenocortical carcinomas, pheochromocytomas, and metastases typically have delayed washout, with less than 50% washout on delayed images. Some investigators have advocated for resection of all nonfunctional incidentalomas of more than 3 cm, and others believe that nonfunctional incidentalomas of more than 5 cm in size and those between 3 and 5 cm with imaging features not consistent with a benign adenoma should be resected. The authors recommend taking the imaging phenotype and patient factors, including age and comorbidity, into consideration when deciding on management for nonfunctional incidentalomas between 3 and 5 cm.

FUNCTIONAL HORMONE-SECRETING TUMORS

Functional hormone-secreting tumors are identified either through history and clinical examination or through the biochemical workup of an incidentally identified adrenal mass.

Aldosteronoma

Primary hyperaldosteronism accounts for 1% of all cases of hypertension and results in Conn's syndrome, which is characterized by hypertension, hypokalemia, and polyuria. Hypokalemia may result in muscle weakness, cramping, and periodic paralysis. The diagnosis is initially suggested through measurements of elevated PAC, depressed PRA, and PAC:PRA ratio greater than 30. A persistently elevated aldosterone value after salt loading (either a 2-L saline solution infusion over 4 hours or 2 days of oral sodium loading) confirms the diagnosis.

Cases of primary hyperaldosteronism are commonly caused by either an aldosteronoma (65%) or bilateral idiopathic hyperaldosteronism (25%); it is crucial to distinguish between the two because unilateral adrenalectomy in the setting of idiopathic hyperaldosteronism is not curative. High-resolution CT scanning and selective adrenal venous catheterization are used to distinguish the two diagnoses. Most clinically significant aldosteronomas are hypodense on CT scan, measuring 0.5 to 2 cm. In older patients, the risk of nonfunctional adrenal adenomas is increased, and many advocate for selective adrenal venous catheterization in patients over the age of 40 years with hyperaldosteronism to rule out bilateral hyperaldosteronism before surgery. If bilateral nodules, adrenal hypertrophy, or no lesions are found on CT scan, then selective adrenal venous catheterization with aldosterone sampling is essential to localize the lesion. Adrenal vein sampling is accomplished through measurement of aldosterone and cortisol levels in both adrenal veins and the inferior vena cava. Sensitivity of adrenal vein sampling is improved with ACTH infusion. The ratio of cortisol in the adrenal vein samples compared with inferior vena cava sample is used to confirm

successful cannulation of the adrenal veins. The aldosterone/cortisol ratios from both adrenal veins are then compared. Generally, an elevation of aldosterone/cortisol ratio of greater than fourfold on one side confirms lateralization and indicates a unilateral process amenable to cure through adrenalectomy. If the ratios are similar, bilateral hyperplasia should be suspected. Bilateral adrenal hyperplasia resulting in Conn's syndrome is treated with aldosterone antagonists and surgery is not indicated. Spironolactone is the most commonly used aldosterone antagonist; eplerenone is an alternative aldosterone antagonist that can be used in males who have development of gynecomastia on spironolactone.

Laparoscopic adrenalectomy is preferred for localized aldosteronomas. Blood pressure should be optimized before surgery through administration of spironolactone, and additional antihypertensive medications can be given as needed. Potassium levels should also be normalized before surgery with potassium replacement. After resection, hypokalemia is corrected in more than 95% of patients, and 75% have improvement in hypertension. Spironolactone should be discontinued after the operation.

Cushing's Syndrome

As described by Harvey Cushing in 1932, Cushing's syndrome is caused by glucocorticoid excess and is characterized by central obesity, moon facies, hypertension, polyphagia, polydipsia, easy bruising, and skin changes. The most common causes of Cushing's syndrome are exogenous steroid use, pituitary adenomas or hyperplasia (known as Cushing's disease), ectopic ACTH-secreting tumors (small cell lung cancer, bronchial carcinoid tumors, thymomas), and ACTH-independent adrenal tumors. ACTH-independent adrenal tumors directly hypersecrete glucocorticoids and include adrenal adenomas, adrenocortical carcinomas, and more rarely, primary pigmented nodular adrenal dysplasia and macronodular adrenal hyperplasia.

The initial biochemical workup for Cushing's syndrome shows elevated 24-hour urinary-free cortisol or elevated 1-mg dexamethasone suppression test results. The 24-hour urine-free cortisol test is the most sensitive and specific test for Cushing's syndrome. Further workup aims to characterize the disease as either pituitary, ectopic, or adrenal. Low plasma ACTH levels (<5 pg/mL) through feedback inhibition can distinguish ACTH-independent adrenal tumors, whereas high levels suggest pituitary or ectopic disease. The dexamethasone suppression test can help distinguish between Cushing's disease, ectopic ACTH-secreting tumors, and ACTH-independent adrenal tumors.

CT scan and MRI complement biochemical tests by localizing pituitary and adrenal lesions. Pituitary tumors can be resected transsphenoidally or irradiated. Occasionally, patients with ACTH-dependent Cushing's disease with failed transsphenoidal resection or radiation require bilateral adrenalectomy. For cases of adrenal Cushing's syndrome, high-resolution CT scan can differentiate a unilateral adenoma from bilateral hyperplasia. Adrenal Cushing's syndrome is most commonly caused by a unilateral adrenal adenoma, which is small and amenable to laparoscopic adrenalectomy. Ketoconazole can be used to control cortisol excess before surgery. For prevention of adrenal crisis, perioperative stress dose steroids should be initiated with hydrocortisone 100 mg intravenously (IV) every 8 hours and can be tapered to an oral dose after surgery. The contralateral adrenal gland may remain suppressed for several weeks after an operation, and gradual oral steroid tapers are recommended, with close monitoring for signs of adrenal insufficiency. Perioperative antibiotics are recommended because patients are more susceptible to infectious complications. Cases of bilateral nodular hyperplasia are very rare and should be initially treated with medical management, with bilateral adrenalectomy reserved for patients with severe Cushing's syndrome who have failed medical management. After bilateral adrenalectomy, patients must be maintained on lifelong glucocorticoid and mineral-corticoid replacement.

Virilizing/Feminizing Tumors

Virilizing or feminizing tumors are rare and secrete androgen or estrogens. Approximately 50% of androgen-secreting tumors are malignant, and all feminizing tumors are malignant. Women with virilizing tumors most commonly present with hirsutism, irregular menses, or other virilizing signs. The diagnosis of an androgen-secreting tumor is established with documented elevated serum testosterone and dehydroepiandrostenedione (DHEA-S) values, with an adrenal protocol CT scan that shows an adrenal mass. Estrogen-secreting adrenal tumors can result in feminization in men, characterized by gynecomastia, gonadal atrophy, and loss of libido. In women, feminizing tumors can result in precocious puberty or postmenopausal bleeding. Feminizing adrenal tumors are characterized by elevated serum estradiol levels with suppressed gonadotropins (follicular-stimulating hormone and luteinizing hormone) and an adrenal mass on CT scan. If the appearance of a virilizing tumor on CT scan is benign, it can often be safely removed laparoscopically with a low threshold for conversion to open if evidence of local invasion or other evidence of malignancy exists. Feminizing tumors and virilizing tumors with a CT scan appearance suspicious for adrenocortical carcinoma should be removed with an open approach (see Adrenocortical Carcinoma).

ADRENOCORTICAL CARCINOMA

With an incidence rate of less than two cases per million per year, adrenocortical carcinomas (ACCs) are rare and are associated with a poor prognosis. Sixty percent of patients with ACC present with symptoms of hormone excess. Most commonly, adults with hormone-secreting ACC present with glucocorticoid excess alone (45%) or with both glucocorticoid excess and androgen excess (25%). A minority of patients with hormone-secreting ACC presents with sex-steroid excess alone; aldosterone-secreting ACC is exceedingly rare. More than 40% of patients with ACC present with metastatic disease at the time of diagnosis and are not candidates for curative-intent surgical resection. On CT scans, ACCs tend to be heterogenous with irregular borders and areas of necrosis or hemorrhage (Figure 1). CT imaging of adrenal lesions with precontrast density of more than 20 Hounsfield units and delayed washout are more likely to be malignant. More than 90% of ACCs are greater than 6 cm in size on presentation.

Preoperative staging imaging, including CT scan, of the chest and abdomen should be obtained for all patients with adrenal lesions suspicious for ACC to identify distant metastases. The most common sites for metastatic adrenocortical carcinoma are lung, liver, peritoneum, and bone. Complete surgical resection of adrenocortical carcinoma is the cornerstone of curative intent therapy for patients with stage I-III disease (Table 1); this involves en bloc resection of any involved adjacent organs for patients with locally advanced disease. Invasion into the inferior vena cava should be considered regional disease, and consideration should be given to resection and thrombectomy, which may require cardiopulmonary or veno-venous bypass. Although the experience has been mixed, in some series, laparoscopic resection of adrenocortical cancer has been associated with increased rates of tumor rupture and positive margins and decreased time to recurrence. The authors, therefore, advocate for open resection of lesions that are highly suspicious for adrenocortical carcinoma.

The overall survival rate for adrenocortical carcinoma is poor, and mean survival times are 22 to 47 months. Survival is, however, stage specific and improved with R0 resection. The 5-year survival rate with complete resection of stage I and II tumors is 40% to 60%, but only 10% of patients with stage IV disease survive beyond 1 year. Even with complete resection, recurrence of ACC is common, with up to 85% of patient having local recurrence or metastatic disease develop. Complete resection of recurrent or metastatic disease may

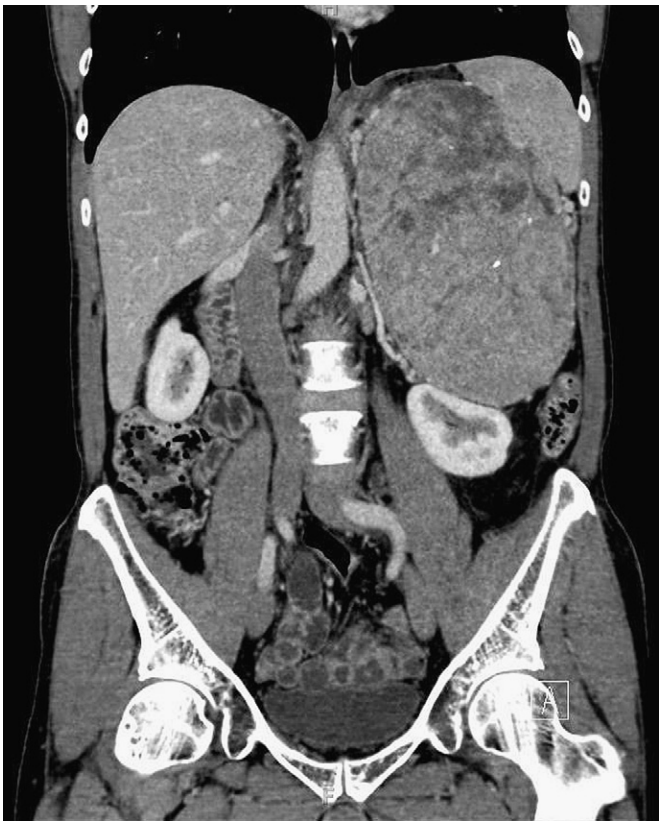

FIGURE 1 Left retroperitoneal mass replacing the left adrenal gland measures 18 × 15 × 11 cm with heterogeneous attenuation, central calcifications, and necrotic changes suspicious for adrenocortical carcinoma. On final pathology, the mass was described as an adrenocortical oncocytic neoplasm of indeterminate malignant potential, but it was treated as malignant given its size.

TABLE 1: Tumor node metastasis (TNM) staging for adrenocortical carcinoma

TNM
T1: <5 cm, no invasion
T2: >5 cm, no invasion
T3: Any size, locally invading (but not adjacent organs)
T4: Any size, locally invading adjacent organs
N0: No regional positive nodes
N1: Positive regional nodes
M0: No distant metastatic disease
M1: Distant metastasis present
Stage
I: T1N0M0
II: T2N0M0
III: T1N1M0, T2N1M0, T3N0M0
IV: T3N1M0, T4N1M0, TXNXM1

improve survival in selected patients and provides palliation from symptoms of hormone excess.

In retrospective studies, adjuvant mitotane has been shown to improve recurrence-free and overall survival in patients with resected adrenocortical carcinoma. Patients may have adrenal insufficiency develop during treatment with mitotane, and glucocorticoid and mineralocorticoid replacement is recommended. The role of adjuvant radiation in the management of adrenocortical carcinoma is controversial. On the basis of data from retrospective case series, adjuvant radiation has been suggested for patients with positive resection margins and those with stage III disease.

ADRENAL METASTASES

Adrenal masses in patients with a history of cancer are metastatic lesions in 30% to 75% of cases. The most common cancers that metastasize to the adrenal gland are lung cancer, renal cell carcinoma, melanoma, gastrointestinal cancers, breast cancer, lymphomas, and hepatocellular carcinoma. Features of adrenal metastases on CT scan include bilateral disease, irregular shape, heterogeneity, unenhanced attenuation of more than 20 Hounsfield units, and delayed washout after contrast administration. For confirmation of the diagnosis of a metastatic lesion, fine-needle aspiration can be undertaken once pheochromocytoma has been ruled out. Imaging should be undertaken to rule out extraadrenal disease, which precludes resection.

Adrenalectomy in selected patients with isolated adrenal metastases has been associated with improved survival in retrospective series. Metachronous presentation with a long disease-free interval has been associated with improved outcomes. Most adrenal metastases are small and well encapsulated; laparoscopic adrenalectomy is believed to be as effective as open resection for these lesions. En bloc resection is recommended for lesions with local invasion of adjacent structures. Survival and recurrence rates after resection of adrenal metastases vary according to disease histology.

LAPAROSCOPIC ADRENALECTOMY

Laparoscopic adrenalectomy has become the standard technique at many institutions for small, localized adrenal tumors with benign appearance on imaging and for adrenal metastases. Many surgeons advocate the open approach for lesions suspicious for adrenocortical carcinoma and those associated with extracapsular invasion or lymphadenopathy. Laparoscopic adrenalectomy can be performed through a lateral transabdominal or a posterior retroperitoneal approach. Patient outcomes with both approaches are comparable, with improved postoperative pain requirements, resumption of regular diet, and length of stay when compared with the open approach.

The lateral transabdominal approach is the most commonly used approach for adrenalectomy. After induction of general anesthesia, a Foley catheter is placed. In addition, an orogastric tube is placed to decompress the stomach and duodenum. The patient is then positioned in the lateral decubitus position, with the affected side up, on a beanbag (Figure 2). An axillary roll is placed, and the table is flexed to increase the space between the costal margin and the iliac crest. The patient's chest and legs are taped to the operating room table. A 10-mm port is first inserted just inferior to the costal margin at the level of the midclavicular line. A 10-mm 30-degree laparoscope is used. Two additional 5-mm working ports are introduced, flanking the camera port. All trocars should be at least 5 cm apart. A right adrenalectomy often requires placement of a fourth port for liver retraction. On insertion of trocars, a diagnostic laparoscopy is performed.

The right and left adrenalectomy differs in the exposure of the adrenal gland and the adrenal vein. The authors favor early identification and ligation of the adrenal vein when possible. For large adrenal lesions, this sometimes is not possible and the gland must be mobilized before identification and division of the vein. For a left adrenalectomy, mobilization of the colon inferiorly and the spleen medially allows access to the superior pole of the kidney and the adrenal gland (Figure 3). The lateral attachments of the spleen should be mobilized superiorly until the stomach is visible for adequate

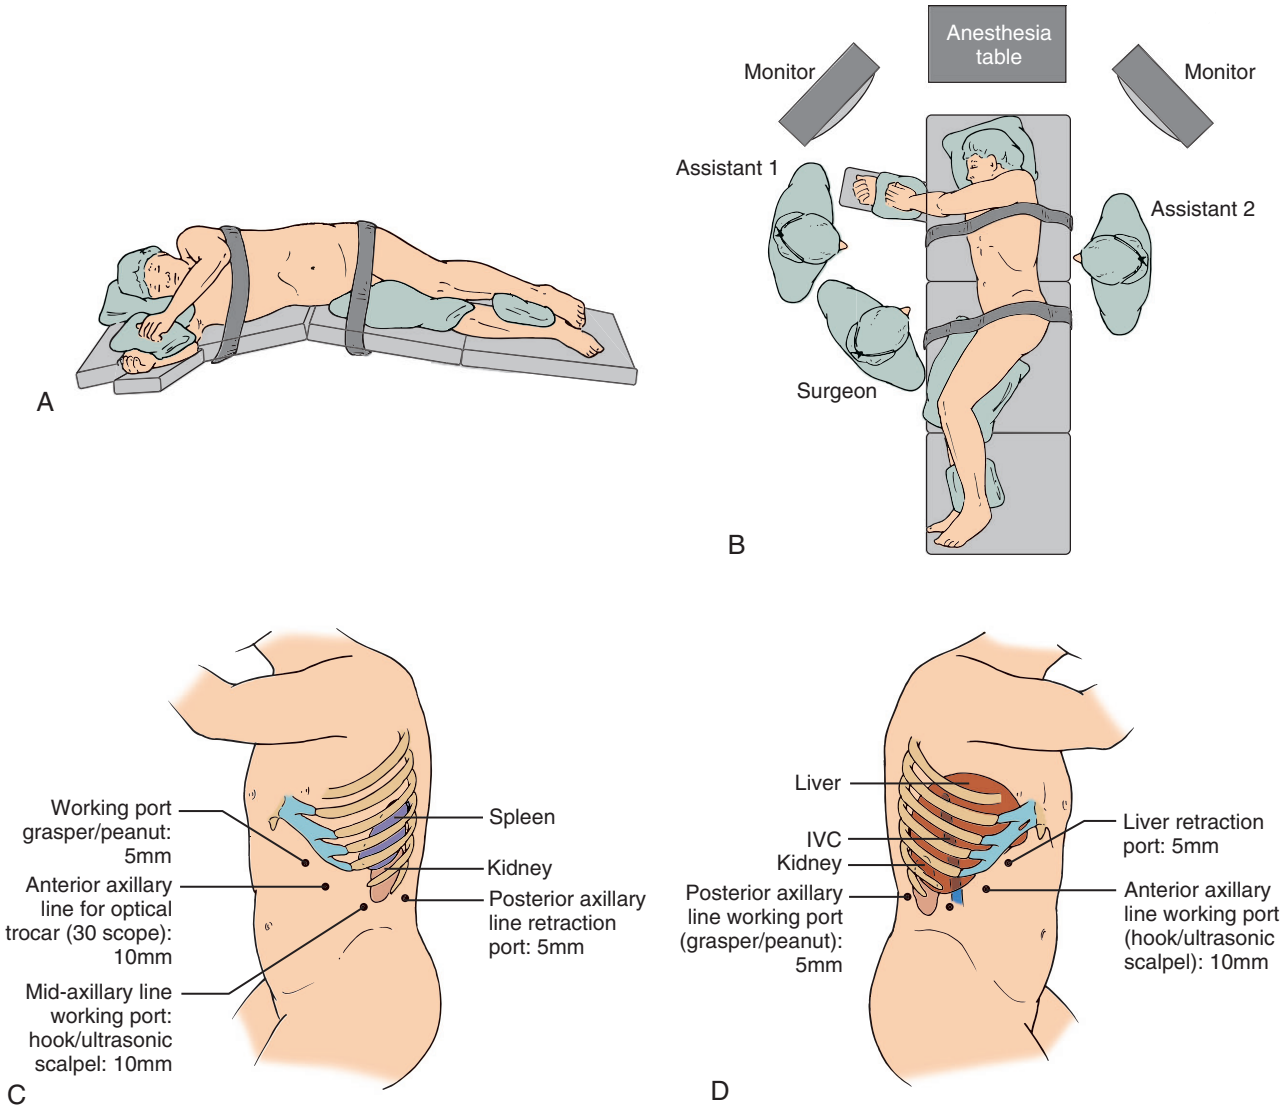

FIGURE 2 Positioning and trocar placement for laparoscopic adrenalectomy. The patient is in full lateral decubitus position, and the table is flexed to open up the flank. **A,** Patient positioning for a laparoscopic left adrenalectomy. **B,** Positioning of patient, surgical team and monitors for a laparoscopic left adrenalectomy. **C,** Trochar placement for a laparoscopic left adrenalectomy. **D,** Trochar placement for a laparoscopic right adrenalectomy. *IVC,* Inferior vena cava. *(*Current Surgical Therapy, *ed 10, Fig 129-3.)*

exposure of the retroperitoneum. The peritoneum is incised at the inferior aspect of the tail of the pancreas, and the plane between the tail of the pancreas and the adrenal gland and kidney is opened. The left adrenal vein is identified as it joins the left renal vein along the superior aspect of the left renal vein. The left adrenal vein is then isolated, clipped, and divided.

In a right adrenalectomy, a liver retractor is inserted to lift the right hepatic lobe anteromedially (Figure 4). The right triangular ligament and lateral hepatic attachments are divided so the right hepatic lobe can be retracted medially to allow visualization of the right adrenal gland. Dissection then begins in the plane between the lateral inferior vena cava and the right adrenal gland. This dissection is continued until the right adrenal vein is identified as it enters posterolateral aspect of the inferior vena cava. The right adrenal vein is short and broad. Dissection along the superior and inferior aspects of the right adrenal vein towards the adrenal gland can often lengthen the vein to facilitate clipping and division of the vein. The vein is then isolated, clipped, and divided (or stapled with an endoscopic vascular stapler). The plane between the lateral inferior vena cava and the medial aspect of the right adrenal is then further developed, with care taken to identify and ligate an accessory adrenal vein (generally superior to the main adrenal vein) when present.

For both approaches, after the adrenal vein is divided, the adrenal is then dissected out from surrounding retroperitoneal structures with a Harmonic scalpel (Ethicon Endosurgery, Cincinnati, Ohio). Adrenal arteries, which can be highly variable, are divided with the Harmonic scalpel or are clipped, depending on the size of the vessel. Minimized grasping of the adrenal is essential to avoid tumor rupture and nuisance bleeding. Once the adrenal gland is freed, it is placed in a specimen bag and extracted from the camera trocar site.

SUMMARY

The indications for operative resection of adrenocortical tumors are evidence of functional hormone secretion and risk of malignancy. Biochemical tests and cross-sectional imaging are thus essential for diagnosis and operative planning. Localized adrenocortical

carcinomas should be resected en bloc through an open approach. Laparoscopic adrenalectomy is appropriate for smaller noninvasive lesions and for metastatic adrenal tumors.

The Management of Pheochromocytoma

James C. Cusack, Jr., MD, and
Roy Phitayakorn, MD, MHPE (MEd)

OVERVIEW

Until recently, rare tumors arising from chromaffin cells of neural crest origin and located in sympathetic and parasympathetic paraganglia were called pheochromocytomas. In 2004, the World Health Organization more specifically classified these tumors based on their origin and designated the more common tumor that arises approximately 90% of the time in the adrenal medulla as pheochromocytoma. In contrast, the term paraganglioma is now used to describe the less common extraadrenal tumor that arises from the para-aortic sympathetic chain, the sympathetic and parasympathetic chain of the neck (including the carotid body) and posterior mediastinum, the organ of Zuckerkandl, or the urinary bladder. Most commonly, patients with pheochromocytoma/paraganglioma present with nonspecific symptoms of catecholamine excess, such as hypertension, headaches, palpitations, and sweating, although 10% of tumors are asymptomatic. Serious complications associated with catecholamine storm, including myocardial infarction, cardiac failure, aortic dissection, and takotsubo cardiomyopathy, may first occur during induction of general anesthesia or surgery. The incidence rate of pheochromocytoma and paraganglioma is two to eight per million persons per year and is equally distributed between males and females, most commonly in their third to fifth decade. Although rare, these tumors are present in up to 1% of patients with hypertension and up to 5% of patients with incidentally discovered adrenal masses. The historical "10% rule" no longer pertains to pheochromocytoma and paraganglioma. Although 10% of these tumors are extra-adrenal in location, 15% to 20% are now estimated to be malignant, defined by the presence of metastases not local invasion, and as many as 25% of these tumors occur in the setting of a hereditary syndrome such as multiple endocrine neoplasia types 2A and 2B, von Hippel-Lindau disease, neurofibromatosis type 1, and hereditary paraganglioma syndrome. These changes have implications in the workup, management, and surveillance of the patient newly diagnosed with pheochromocytoma or paraganglioma. For example, genetic testing should be considered for patients diagnosed with pheochromocytoma or paraganglioma, particularly those with bilateral or multifocal disease, sympathetic and malignant extra-adrenal disease, family history suggestive of a hereditary pheochromocytoma-paraganglioma syndrome, and age less than 50 years. Effective leadership by the well-informed surgeon, who coordinates the efforts of the multidisciplinary team that includes the endocrinologist, radiologist, anesthesiologist, surgeon, and genetics counselor, is requisite to the successful management of the patient with pheochromocytoma and paraganglioma.

CLINICAL PRESENTATION

With the current frequency of radiographic imaging, one of the most common presentations of a patient with pheochromocytoma is an incidentally found adrenal mass. Clinical signs or symptoms of functional pheochromocytomas include hypertension, blurred vision, headaches, sweating, dyspnea, chest pain, constipation, tachycardia/palpitations, nausea/vomiting, and psychiatric symptoms including anxiety, aggression, and a feeling of impending doom. However, approximately 20% of patients may have a pheochromocytoma that is biochemically inactive. Some patients may also present after hypertensive complications upon receiving general anesthesia for an unrelated operation.

DIAGNOSIS

All patients with a suspected pheochromocytoma or paraganglioma should undergo biochemical screening that typically includes 24-hour urinary catecholamines and metabolites (vanillylmandelic acid, total and fractionated metanephrines, epinephrine, norepinephrine, and dopamine). These results can be confirmed with measurements of plasma catecholamine and metabolite levels and chromogranin A. Figure 1 illustrates an example of a biochemical workup algorithm. Alternatively, some centers use plasma metanephrines to *exclude* a biochemically functional pheochromocytoma and then proceed with urinary catecholamine and metabolite measurements only for patients with plasma catecholamines that are three to four times the upper limits of normal. Table 1 lists various foods and medications that may lead to falsely elevated urinary or plasma catecholamine or metabolite levels.

Once the biochemical diagnosis of pheochromocytoma or paraganglioma is confirmed, localization studies include either adrenal-protocol computed tomographic (CT) imaging or magnetic resonance imaging (MRI). An adrenal-protocol CT scan includes 2-mm to 5-mm scanning slices with 3 phases of imaging (noncontrast, with contrast, and delayed washout). Pheochromocytomas and paragangliomas are typically dense on CT scan (Hounsfield units, >10) and retain contrast on delayed washout images. An MRI may be more useful in patients who cannot receive radiation (pregnancy, children) or have contrast allergies. Pheochromocytomas and paragangliomas are typically hyperintense on T2-weighted images and isointense to hypointense relative to liver on T1-weighted images. Radiographic signs associated with malignancy include large size, gross invasion of surrounding structures, and metastases.

If neither CT scan nor MRI is able to locate a pheochromocytoma or paraganglioma or metastatic disease is suspected in a patient with positive biochemical testing, an ^{123}I-metaiodobenzylguanidine (MIBG) image is often obtained next because of its excellent specificity for pheochromocytoma. Importantly, patients who undergo ^{123}I-MIBG imaging should receive a short course of either supersaturated potassium chloride (SSKI) or potassium perchlorate to prevent post-procedure thyroid complications. Similarly, [^{18}F] fluorodeoxyglucose (FDG) positron emission tomography (PET) may be useful to localize possible metastases in cases of malignant pheochromocytoma, but false-positive results from retroperitoneal brown fat are common.

PREOPERATIVE MANAGEMENT

Before adrenalectomy, patients with a pheochromocytoma should have a complete blood count, basic metabolic panel, and an electrocardiogram (EKG). The EKG frequently shows repolarization abnormalities, which are the result of the toxic effects of excessive catecholamines on the myocardium. A preoperative echocardiogram may be of value in patients with a significant cardiac history or a new cardiac murmur to aid in risk stratification.

General recommendations are that all patients with pheochromocytoma undergo alpha-adrenergic blockade, which should be started 1 to 2 weeks before surgery. An exception to alpha-adrenergic blockade may be patients with a pheochromocytoma that only secretes dopamine. The clinical goal of alpha-blockade is postural hypotension, but patients may experience other side effects, including fatigue, reflex tachycardia, loose stools, dizziness, somnolence, or

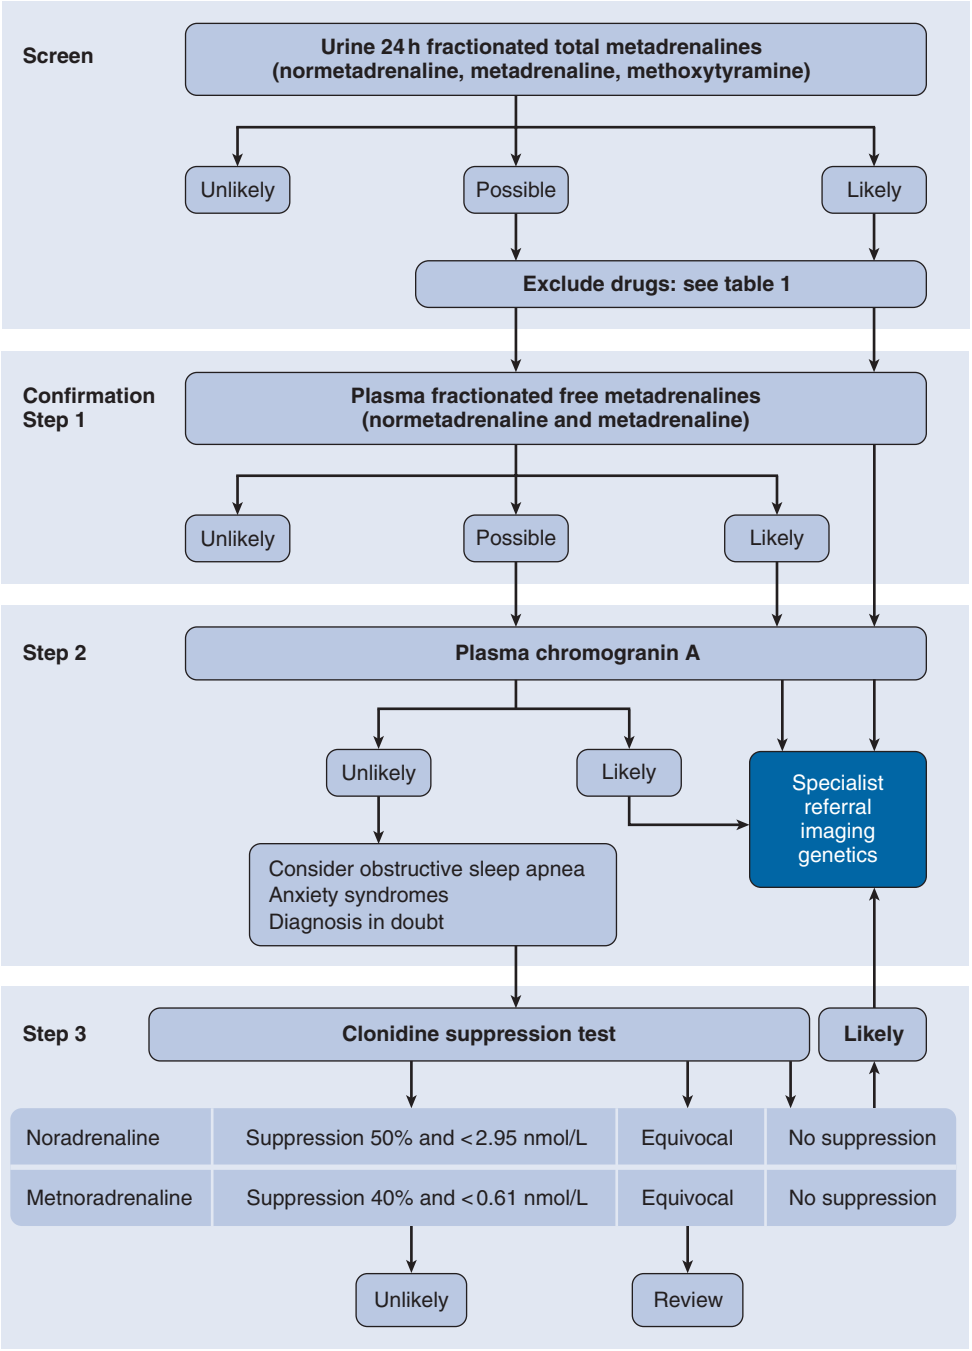

FIGURE 1 A sample biochemical workup algorithm for patients with a suspected functional pheochromocytoma or paraganglioma. *(Used with permission from Barron J: Phaeochromocytoma: diagnostic challenges for biochemical screening and diagnosis,* J Clin Pathol *63:669-674,* 2010.*)*

nasal congestion. Several alpha-blockers are commonly used in patients with pheochromocytoma. The authors most commonly use phenoxybenzamine (Dibenzyline), which is a long-acting, noncompetitive alpha-antagonist. Patients are started on a 10-mg dose twice a day, and the dose is gradually increased by 10 mg every other day until the patient becomes orthostatic. Most patients become orthostatic with a total dosage of 40 to 120 mg/d (1 mg/kg), but dosages up to 240 mg/d may be necessary. The authors typically titrate alpha-blockade on an outpatient basis, but some patients need inpatient admission to achieve successful blockade. Phenoxybenzamine can lead to tachycardia from increased norepinephrine release by cardiac sympathetic nerve endings. This side effect can be ameliorated with the concomitant usage of beta-blockers. Beta-blockers are typically started several days before surgery after alpha-adrenergic blockade and subsequently titrated to a goal heart rate of around 60 beats per minute. Beta-blockers should not be given before alpha-adrenergic blockade to avoid unopposed alpha-adrenergic receptor stimulation, which can cause hypertensive crisis.

Selective short-acting alpha-adrenergic blockers (doxazosin, prazosin, and terazosin) are competitive α_1-receptor antagonists and have a shorter duration of action, less associated reflex tachycardia, and a lower incidence of postoperative hypotension compared with phenoxybenzamine. However, incomplete alpha-adrenergic blockade may occur with prazosin or terazosin because they require more frequent dosing than doxazosin.

Dihydropyridine calcium-channel blockers, amlodipine, nifedipine, or nicardipine, may also be used as part of the preoperative preparation for patients with pheochromocytoma as an adjunct to alpha-adrenergic blockade or in patients who are intolerant to alpha-blockers. Preferential use of calcium channel blockers before surgery

Chocolate
Beers and wine
Cured or smoked meats
Aged cheeses (including yogurt and sour cream)
Fermented soy bean or fish products (tofu, soy sauce, fish sauce, shrimp paste)
Nuts (peanuts, coconuts, Brazil nuts)
Certain fruits (raspberries, red plums, pineapples, bananas, and figs)
Certain vegetables (avocados, eggplants, fava beans, snow peas, green beans, and sauerkraut)
Opioid analgesics (oxycodone, morphine, tramadol, heroin) and naloxone
Corticosteroids
Antidepressants such as tricyclic antidepressants (amitriptyline, nortriptyline, imipramine, clomipramine), norepinephrine reuptake inhibitors, type-A monoamine oxidase inhibitors (phenelzine and deprenyl), and selective serotonin reuptake inhibitors (fluoxetine, duloxetine, paroxetine)
Antibiotics such as linezolid
Antipsychotics such as droperidol, sulpiride, chlorpromazine
Antiemetics such metoclopramide and prochlorperazine
Nasal decongestants that contain pseudoephedrine or phenylpropanolamine
Weight-loss supplements that contain fenfluramine, amfepramone, phendimetrazine, phenylethylamine, or phentermine
Antinarcolepsy medications that contain dextroamphetamine
Attention-deficit hyperactivity disorder medications that contain amphetamine or methylphenidate
Anti-impotence supplements that contain yohimbe bark extract
Illegal recreational drugs such as ketamine and cocaine
Chewing tobacco

may be of more value in patients with normotensive conditions who have intermittent paroxysmal hypertensive episodes to avoid the side effects of orthostatic hypotension associated with the alpha-adrenergic blockers.

Metyrosine (alpha-methyl-para-tyrosine) is also used for preoperative preparation of patients with pheochromocytoma. Metyrosine depletes adrenal catecholamine stores by inhibiting tyrosine hydroxylase, the rate-limiting enzyme in catecholamine synthesis. However, metyrosine may also cause extrapyramidal side effects, sedation, depression, and galactorrhea. Because of its greater toxicity, including potential negative effect on cardiac function, the authors reserve metyrosine for patients who cannot tolerate alpha and beta blockade or who have hypertension that is refractory to alpha-adrenergic blockade.

Patients with pheochromocytoma require preoperative intravascular volume resuscitation with a balanced oral electrolyte solution after starting alpha-blockade. Some clinicians also advocate a high sodium diet (>5 g/d), and others admit patients with pheochromocytoma the day before surgery to supplement intravascular volume with isotonic intravenous fluids. Ideally, a patient should receive enough preoperative volume resuscitation to have a hematocrit value that has been reduced into the normal range before surgery. These measures likely help to minimize severe postoperative hypotension after resection of the pheochromocytoma, but no randomized controlled studies exist to confirm their efficacy.

INTRAOPERATIVE MANAGEMENT

Careful preparation for the potentially dramatic hemodynamic swings that may accompany resection of pheochromocytoma and paraganglioma is requisite to the safe intraoperative management of these patients. Before induction of general anesthesia, large-bore intravenous access is established to facilitate rapid volume resuscitation and an intraarterial catheter is placed for continuous blood pressure monitoring. Although a pulmonary artery catheter is reserved for patients with underlying systolic or diastolic cardiac dysfunction, a central venous catheter may be helpful in select patients. A urinary catheter is placed routinely. The management plan for intraoperative acute catecholamine excess before ligation of draining veins of the pheochromocytoma or paraganglioma, and intraoperative acute catecholamine deficiency after control or ligation of the draining veins, should be discussed by the anesthesiologist and surgeon as a component of the Universal Protocol. The pharmacologic agents to be used during the procedure are mixed in advance, and the lines are fed through pumps.

Short-acting antihypertensive agents are used for rapid control of hypertension. Sodium nitroprusside, a potent direct-acting vasodilator favored for this purpose because of its rapid onset of action (within seconds) and short duration of effect (3 to 4 minutes), may be titrated at doses of 0.5 to 8 μg/kg/min. Transient dose increases up to 8 μg/kg/min to control acute hypertension should never exceed 10 minutes because of potentially toxic accumulation of cyanide ion. Other agents such as esmolol, nicardipine, and nitroglycerine have less desirable properties of a somewhat slower onset of action or a longer duration of effect but may be used to supplement the antihypertensive effects of sodium nitroprusside. Fenoldopam mesylate, a benzazepine derivative and selective dopamine-1–receptor agonist is a more recently developed agent used to manage hypertensive crisis that has both an intermediate time to onset and duration of effect. Intravenous magnesium has recently been advocated as a safe and effective adjunct in the intraoperative management of pheochromocytomas and paragangliomas because it provides a catecholamine blockade and protection against life-threatening cardiac arrhythmias. Lidocaine bolus followed by continuous infusion may also be used to manage ventricular arrhythmias.

Hypotension that may accompany ligation of the adrenal vein or draining vessels of a paraganglioma results from a rapid drop in serum levels of vasoactive catecholamines. The likelihood of significant hypotension after ligation of the venous drainage from the tumor is associated with large tumor size and the presence of high circulating levels of catecholamines. Hemodynamic instability appears to be less dependent on surgical approach, the type of preoperative adrenergic blockade used, or the specific type of tumor syndrome. Resultant hypotension after ligation of the draining vessels typically responds to immediate cessation of all vasodilatory agents, titration of exogenous catecholamines (epinephrine, norepinephrine, or dopamine) or phenylephrine, and rapid volume resuscitation with crystalloids or blood as indicated.

Refractory hypotension as may occur in the setting of intraoperative hemorrhage or massive serum catecholamine levels may be rescued with transfusion or vasopressin therapy, respectively. Most importantly, minimization of manipulation of the adrenal gland or paraganglioma before ligation of the draining veins and close communication between surgeon and anesthesiologist at the critical step of ligation of the venous drainage minimize hemodynamic lability during surgery.

OPERATIVE TECHNIQUE

Selection of the surgical approach (transabdominal or retroperitoneal) and technique (open, minimally invasive laparoscopic, or single-port access) used to manage pheochromocytoma depends to

a large degree on whether the tumor is unilateral, bilateral, or multifocal and whether the patient has hereditary or sporadic pheochromocytoma. Factors that influence the choice of an open surgical approach include a suspicion of local invasion as determined by size greater than 6 cm or radiographic evidence of vascular invasion and the location of a paraganglioma in a region not easily accessed with minimally invasive techniques. Minimally invasive adrenalectomy is the preferred technique because it is associated with less postoperative pain, shorter hospital stays, and quicker return to work compared with open adrenalectomy.

Recent technical advances have led to changes in the specific approach used to treat pheochromocytoma, and posterior retroperitoneoscopic adrenalectomy is preferentially used in certain centers for the resection of sporadic pheochromocytoma less than 5 cm and unilateral hereditary pheochromocytoma in the presence of a normal contralateral adrenal. Although both approaches have proven to be safe and have comparable blood loss, the posterior retroperitoneoscopic approach offers early control of the adrenal vein and requires less manipulation of the adrenal and adjacent soft tissue structures and therefore requires less operative time. Patients with hereditary disease and evidence of bilateral adrenal involvement are generally treated with an open technique, comprised of a total adrenalectomy and a contralateral cortical-sparing adrenalectomy. Cortical-sparing adrenalectomy is also used in the setting of contralateral metachronous pheochromocytoma in patients who have undergone prior adrenalectomy.

Transabdominal Laparoscopic Adrenalectomy

The patient is administered intravenous antibiotics and sequential compression devices are placed for deep venous thrombosis (DVT) prophylaxis. The patient is administered general endotracheal anesthesia in the supine position and then placed in the lateral decubitus position with the bed flexed to increase the distance between the ribs and iliac crest. After a pneumoperitoneum is established, 3 10-mm trocars are placed with direct visualization 2 cm below and parallel to the costal margin and spaced equidistance from the midclavicular line medially to the midaxillary line laterally. A 30-degree laparoscope is placed through the middle trocar, and the peritoneal reflection of the kidney is dissected to facilitate placement of a fourth trocar at the costovertebral angle.

In the case of a left adrenalectomy, the splenic flexure is taken down medially to facilitate displacement of the colon away from the inferior aspect of the adrenal. The lienorenal ligament is incised 1 cm from the spleen, and the dissection continues up to the diaphragm, stopping at the short gastric vessels posterior to the stomach. The tail of the pancreas and spleen fall medially to expose the adrenal gland. The lateral and anterior portions are dissected free with careful grasping and retracting of the perirenal fat, with care to leave the adrenal capsule intact. The adrenal vein, which drains into the left renal vein, is clipped, as is the adrenal artery, and divided. The smaller branch vessels are divided with a Harmonic scalpel (Ethicon Endosurgery, Cincinnati, Ohio), EnSeal device (SurgRx, Inc, Redwood City, Calif), or LigaSure (Covidien, Boulder, Colo) vessel-sealing device. Once separated from the remainder of the retroperitoneal attachments, the adrenal is placed into an EndoCatch bag (Ethicon Endosurgery) and removed. All trocar sites are closed with absorbable suture.

For a right adrenalectomy, the lateral peritoneal attachments to the liver and the triangular ligament are taken down, and the liver is retracted with a fan retractor placed through the medial port. The adrenal gland, identified at the medial aspect of the superior pole of the kidney, is dissected circumferentially after incising Gerota's fascia. The right adrenal vein, which drains into the vena cava, is identified, clipped, and divided. The adrenal artery is similarly divided, and the smaller vessels are controlled with a vessel-sealing device. The right adrenal gland may then be removed as described for the resection of the left adrenal gland.

Posterior Retroperitoneoscopic Adrenalectomy

The principle advantage of posterior retroperitoneoscopic adrenalectomy (PRA) over anterior laparoscopic approaches is direct access to the adrenal glands without the need to enter the peritoneal cavity or displace adjacent organs. Another noteworthy advantage to this approach includes access for potential bilateral adrenalectomy. Furthermore, insufflation of the retroperitoneal space may be better tolerated from a cardiac and pulmonary perspective than insufflation of the peritoneal cavity used in the laparoscopic transabdominal approach. This approach is rapidly becoming the preferred approach for benign pheochromocytomas up to 6 cm in diameter. Disadvantages of this approach are difficulty controlling significant hemorrhage because of the small working space and a paucity of anatomic landmarks during the initial phases of the dissection. Contraindications to this approach include malignant pheochromocytoma and any evidence of invasion of the tumor into surrounding structures on preoperative imaging studies. Morbid obesity with a body mass index (BMI) of more than 45 is a relative contraindication. Single-access techniques with this approach are also in development.

The patient receives preoperative antibiotics and DVT prophylaxis as in the case of the laparoscopic approach. The patient is first positioned in the supine position for the administration of general endotracheal anesthesia. The patient is then repositioned in the prone jackknife position on a Cloward table (Cloward Surgical Saddle, Surgical Equipment International, Honolulu, Hawaii), which supports the anterior iliac crests laterally and allows the abdomen to hang anteriorly between the saddle to reduce pressure on the retroperitoneal space (Figure 2). Knees and hips are bent at a 90-degree angle, and the knee rest is lowered to minimize pressure on the knees. The face is padded, and the arms are flexed on arm boards with the elbows bent at a 90-degree angle.

Relative to careful patient positioning, port placement is equally important. A 1.5-cm incision is made immediately adjacent to the tip of the 12th rib, and the subcutaneous tissues are dissected to facilitate entry into the retroperitoneal space (see Figure 2). This site subsequently is used as the middle port site. A small space 5 cm medial and 5 cm lateral is developed in the retroperitoneal space with blunt dissection. The medial (10-mm) trocar is placed just lateral to the paraspinous muscles and 5 cm medial to the middle port site. The trocar is aimed at the adrenal gland and angled at 45 degrees cephalad. The lateral (5-mm) trocar is placed inferior to the 11th rib and 5 cm lateral to the middle trocar and aimed medially toward the adrenal. A 12-mm trocar with an inflatable balloon and adjustable sleeve is then placed into the middle trocar site. A pneumoperitoneum is created with CO_2 to a pressure of 20 to 24 mm Hg to minimize venous bleeding in the operative field. A 10-mm, 30-degree videoscope is placed into the middle trocar, and the retroperitoneal space below the diaphragm is dissected with sharp and blunt technique. The videoscope is placed through the medial trocar, and the surgeon works through the middle and later trocars to reveal Gerota's fascia. The fascia is then dissected to reveal the superior pole of the kidney. With further dissection, the paraspinous muscles are retracted to reveal the adrenal gland. On the right side, the inferior vena cava (IVC) is identified, and the liver may be visible through the peritoneum. On the left side, the posterior wall of the stomach and spleen may be appreciated through the peritoneum. A tear in the peritoneum during the course of dissection does not compromise the pneumoperitoneum and need not be repaired.

With the Harmonic scalpel or the EnSeal device, the adrenal gland is dissected first along its inferior aspect overlying the superior aspect of the kidney by gently retracting the adrenal gland in the cephalad direction and the kidney in the caudal direction. Dissection of the medial attachments then reveals the adrenal vein, which on the right side drains medially into the IVC (Figure 3) and on the left side drains inferiorly into the renal vein (Figure 4). The adrenal vein is clipped and divided. The dissection of the superior and medial aspects of the adrenal gland is then completed. The gland is placed

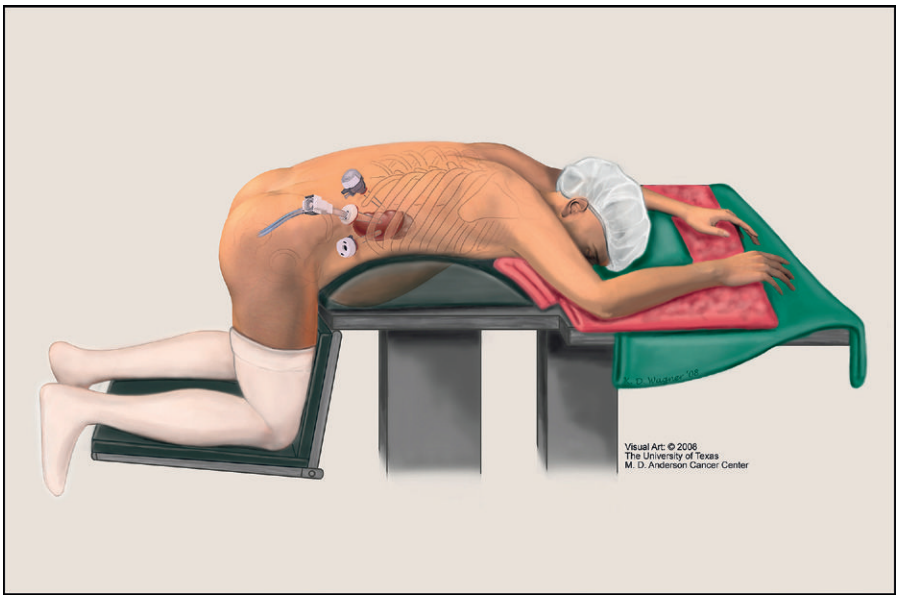

FIGURE 2 The Cloward table (Cloward Surgical Saddle, Surgical Equipment International, Honolulu, Hawaii) allows the patient's abdomen to hang anteriorly to decrease pressure on the retroperitoneal space. *(Used with permission from Callender GG, Kennamer DL, Grubbs EG, et al: Posterior retroperitoneoscopic adrenalectomy,* Adv Surg *43(1):147-157, 2009.)*

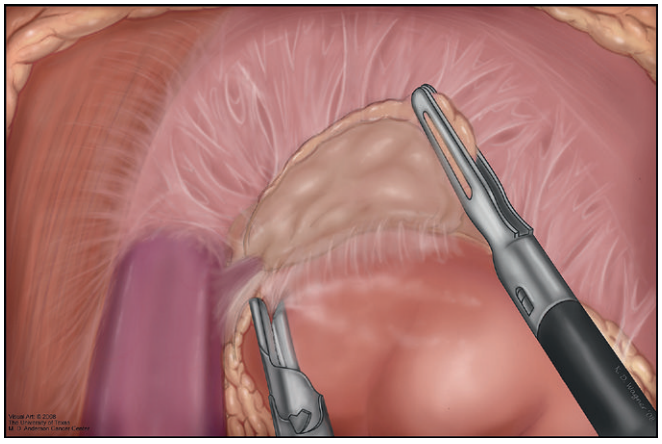

FIGURE 3 Right posterior retroperitoneoscopic adrenalectomy. After identification of the paraspinous muscles *(left),* the inferior vena cava, and the superior pole of the right kidney, the adrenal is dissected inferiorly off the kidney, leaving the superior and medial attachments intact. The adrenal vein is identified medially, then clipped and divided. The medial and superior dissection can then proceed. *(Used with permission from Callender GG, Kennamer DL, Grubbs EG, et al: Posterior retroperitoneoscopic adrenalectomy*, Adv Surg *43(1):147-157, 2009.)*

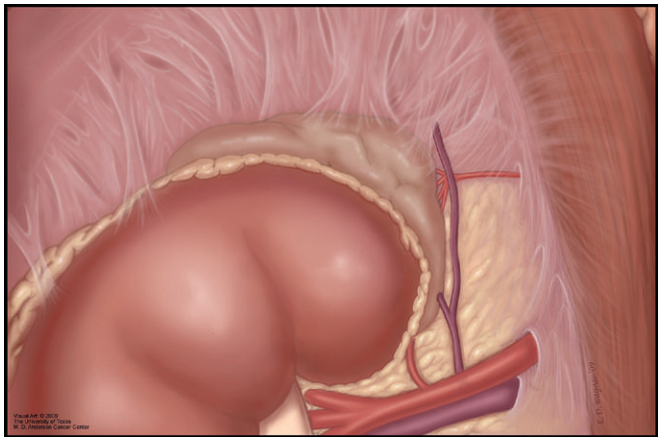

FIGURE 4 Left posterior retroperitoneoscopic adrenalectomy. After dissection of the inferior aspect of the adrenal gland from the left kidney, the adrenal gland can be gently retracted laterally by grasping the periadrenal fat to reveal the adrenal vein, which drains inferiorly into the renal vein. The adrenal vein is clipped and divided before dissecting the gland superiorly and medially. *(Used with permission from Callender GG, Kennamer DL, Grubbs EG, et al: Posterior retroperitoneoscopic adrenalectomy*, Adv Surg *43(1):147-157, 2009.)*

into an EndoCatch device passed through the middle trocar and removed. The retroperitoneal space is inspected for bleeding as the insufflation pressure is reduced to 10 mm Hg. Once hemostasis is obtained, the ports are removed and the sites are closed with absorbable sutures.

Open Adrenalectomy and Cortical-Sparing Adrenalectomy

When an open adrenalectomy is considered, a standard operative approach through either a long subcostal, bilateral subcostal, or upper midline incision is used. Although the classic thoracoabdominal incision, which extends from the abdomen up through the seventh or eighth intercostal space and through the diaphragm, provides excellent exposure to the retroperitoneum, it is associated with increased morbidity and is rarely used. Critical steps involved in a right adrenalectomy include superior and medial mobilization of the liver to expose the inferior vena cava and right hepatic vein. This facilitates complete visualization of the adrenal gland. Dissection is performed along the superior and inferior aspect to expose the adrenal vein at the superomedial aspect of the gland. Dissection of the retroperitoneal soft tissues along the IVC above the duodenum toward the tumor is performed, and small veins draining the caudate lobe into the IVC are ligated and divided. Gentle traction on the adrenal gland laterally and inferiorly combined with medial and

anterior traction of the IVC with a vein retractor expose the short, broad adrenal vein as it enters the posterior aspect of the IVC. The adrenal vein may be suture ligated or clipped and divided. The adrenal artery branch from the inferior phrenic artery may be identified at the superomedial aspect of the gland. This vessel should be ligated and divided, followed by division of the small arterial and venous branches located inferomedially, connected to the renal artery, aorta, and renal vein.

The open left adrenalectomy is approached through a long left subcostal or upper midline incision. The omentum is mobilized from the left transverse colon and splenic flexure. Adhesions from the posterior wall of the stomach to the pancreas are lysed, and the inferior border of the pancreas is dissected free from retroperitoneal soft tissues with careful blunt technique. The lateral peritoneal attachments to the spleen are divided, and the spleen and the body and tail of pancreas are reflected toward the right upper quadrant. The adrenal vein, located inferomedially, may be visualized early in the course of dissection, in which case it should be ligated and divided. Often a large tumor may obscure visualization of the adrenal vein, in which case the gland needs to be mobilized along the superior border. Similar to the right, the arterial branch from the left phrenic artery may be controlled. The left renal vein is dissected with care to protect a branch of the renal artery, which courses adjacent to the posterolateral aspect of the gland. The adrenal vein is then identified, ligated, or clipped and divided. The remaining branch vessels along the inferomedial aspect of the gland are then divided.

Planning for a cortex-sparing adrenalectomy requires accurate preoperative imaging of the vascular supply of the adrenal gland, particularly that portion to be preserved. Although the adrenal gland typically receives its blood supply from the renal artery, inferior phrenic artery, and aorta, it is the blood supply from the phrenic artery that must be preserved when in situ preservation of the adrenal cortex is considered. The open technique has been used traditionally for cortex-sparing adrenalectomy, but experience with minimally invasive approaches has recently been reported. Whether performed with an open approach or a minimally invasive approach, cortex-sparing adrenalectomy should result in the preservation of approximately one third of the cortex that is well perfused. With resection of the medullary portion of the adrenal gland, the retroperitoneal attachments to the superior portion of the gland must be left intact to avoid devascularization of the preserved cortex.

POSTOPERATIVE MANAGEMENT

The mortality rate for adrenalectomy in all patients with a pheochromocytoma should be less than 1% for an elective operation in a properly prepared patient. Potential postoperative complications after pheochromocytoma resection include life-threatening arrhythmias, splenic injury, prolonged intubation, renal dysfunction, hypoglycemia, and persistent hypotension. Interestingly, the rate of postoperative myocardial infarction or stroke is very low. Severe hypoglycemia after resection of pheochromocytoma is related to catecholamine-induced depletion of glycogen stores, overstimulation of insulin production by preoperative alpha-blockade, and hyperinsulinemia after loss of catecholamine inhibitory effect on the $beta_2$-receptors of the pancreatic islet cells. Cardiac beta-blockade and the residual effects of anesthesia may mask any clinical signs or symptoms of hypoglycemia, so patients may initially present with seizures. As a result, blood glucose levels should be monitored for at least 24 hours after surgery and intravenous fluids should include dextrose.

The average length of stay for laparoscopic adrenalectomy for pheochromocytoma is 1 to 2 days; the authors typically discharge patients on beta-blocker therapy and reduced levels of antihypertensive medications. These medications are carefully weaned on an outpatient basis. Repeat catecholamine levels are typically checked on the first postoperative visit to confirm curative resection.

PALLIATIVE THERAPY

The current World Health Organization classification defines malignancy of pheochromocytomas and paragangliomas as the presence of metastases to a site where paraganglionic tissue is not normally present, most commonly the liver, lung, bone, and retroperitoneal or mediastinal lymph nodes. Importantly, local invasion into surrounding soft tissues, despite its potential lethality, is a poor predictor of metastases, and conversely, the absence of invasion does not preclude development of metastases. The development of recurrence at the site of origin in 6.5% to 16.5% of patients with sporadic pheochromocytoma and paraganglioma up to 15 years after initial resection further defies a clear distinction between benign and malignant disease. Locally advanced pheochromocytoma that involves the kidney, liver, spleen, pancreas, diaphragm, or inferior vena cava should be managed with margin negative resection of surrounding soft tissues. Preservation of adjacent organ function should be considered when feasible with early control of tumor venous drainage.

Despite the lack of consensus on how to determine malignant potential based on the histologic and immunohistochemical characteristics of the primary tumor, 15% to 20% of these tumors are estimated to be malignant. In addition, 50% of patients with development of recurrent disease experience distant metastasis. The 5-year survival rate in the setting of metastatic disease identified at the time of initial diagnosis or diagnosed after surgery as recurrent disease is approximately 45%.

As in the case for primary tumors, surgical resection is the treatment of choice for recurrent, multifocal, and metastatic tumors if all identifiable disease can be resected. Palliative resection of large tumors in the setting of multifocal metastatic disease may be considered for symptom relief but does not improve survival. Alternative interventions such as arterial embolization, cryoablation, external-beam radiation therapy, and radiofrequency ablation may offer effective symptom relief with less potential morbidity in this scenario. For the 60% of patients with metastatic pheochromocytoma or paraganglioma sites that are MIBG-avid, treatment with ^{131}I-MIBG has improved 5-year survival rates to as high as 65%. Patients with unresectable or multifocal metastatic disease may also be considered for systemic therapies. Although systemic therapy has not been shown to improve survival in patients with metastatic disease, it may provide effective symptom relief. The most frequently used cytotoxic chemotherapy regimen with cyclophosphamide, vincristine, and dacarbazine offers a biochemical response rate of 72% and a median survival of 3.3 years. The more recently used targeted therapy with the tyrosine kinase inhibitor sunitinib also offers promising response rates.

The Management of Thyroid Nodules

Daniel W. Karakla, MD, and Matthew J. Bak, MD

The incidence of well-differentiated thyroid carcinoma (WDTC) is increasing, and estimates are that more than half of those of us over age 50 years have a thyroid nodule. The dilemma and challenge lie in determination of who truly has a malignancy. At times, malignant disease is obvious. For instance, a 70-year-old man with a rapidly enlarging right thyroid mass, progressive hoarseness, and dyspnea has anaplastic (undifferentiated) thyroid cancer until proven otherwise. At other times, disease is much less obvious. Take for instance a 36-year-old woman with an asymptomatic 2-cm left thyroid nodule and no family history of thyroid disease.

A thyroid nodule is a discrete lesion that with physical examination or radiography (ultrasound scan [US], computed tomographic [CT] scan, magnetic resonance imaging [MRI]) is distinct from its surrounding thyroid parenchyma. Palpable nodules are more common in women (5%) than in men (1%). More thyroid nodules are detected radiographically, and the incidence of WDTC is increasing, likely because of this. Fortunately, the mortality from WDTC has not really increased.

HISTORY

A pertinent history of thyroid nodules should always include duration, mode of discovery, associated pain, and voice changes. Many patients may describe intermittent hoarseness, which may be related to reflux or vocal abuse (prolonged voice strain or speaking). The voice change that persists and is progressive is more concerning for laryngeal or recurrent laryngeal nerve pathology.

Does the patient have symptoms of hyperthyroidism, such as anxiety, tremor, weight loss, muscle weakness, diarrhea, palpitations, or heat intolerance? Hypothyroid symptoms include fatigue, weight gain, cold intolerance, constipation, and dry or brittle skin and hair.

Compressive symptoms may be obvious, such as dyspnea or dysphagia. Patients can sometimes localize these symptoms to the location of the thyroid but, unfortunately, may not be able to accurately explain the symptom. The patient may describe a pressure sensation, choking feeling, difficulty finding a comfortable position to sleep, or a nagging cough, unrelated to reflux or respiratory infection. Another sometimes subtle but potentially worrisome report is aspiration.

Personal history of neck radiation should always be sought. Children exposed to radiation at lower doses are counterintuitively at increased risk for development of thyroid malignancy. Radiation for lymphoma treatment, occupational exposure, fallout from Chernobyl or other nuclear accidents, and even remote childhood radiation for acne or thymus enlargement done in years past are risk factors for thyroid malignancy.

Family history of thyroid disease especially should be elicited. Medullary thyroid carcinoma (MTC) may be familial or sporadic, associated with multiple endocrine neoplasia (MEN) 2a and MEN 2b. Papillary thyroid carcinoma (PTC) is usually isolated, but one should consider Cowden disease, familial adenomatous polyposis, and familial nonmedullary thyroid cancer.

PHYSICAL EXAMINATION

A thorough head and neck examination should be performed. Unfortunately, this is not always done. Without ever thinking about it, surgeons immediately assess for visual asymmetry or visible goiter or neck mass and listen for dysphonia or stridor. Although rare in the general thyroid nodule patient population, oral mucosal neuromas should prompt consideration of MEN 2b. Every patient evaluated for a thyroid nodule, especially before surgery, should have a laryngeal examination. This may be with mirror (indirect laryngoscopy) or fiberoptic nasopharyngolaryngoscopy to assess vocal cord mobility. Not every patient with vocal cord paresis or paralysis has a perceptible voice change, so a laryngeal examination only in patients with hoarseness may miss this important finding. Is there stridor, and is it inspiratory, expiratory, or biphasic? Inspiratory stridor tends to be associated with glottic or supraglottic obstruction. Expiratory stridor tends to be related to obstruction below the level of the glottis.

Obviously, palpation of the neck is the key element of the examination. A methodic examination sometimes elicits pathologic metastatic lymphadenopathy, but this is may be extremely difficult in the thick, obese, or muscular neck. Assessment should be made of the airway anatomy for deviation from the thyroid. The thyroid nodules should be assessed for mobility, firmness, tenderness, size, and location. If one cannot palpate the inferior extent of the mass, then significant substernal extension may exist, and imaging to investigate that is warranted.

LABORATORY ASSESSMENT

The single most useful test is a thyroid-stimulating hormone (TSH) level. If the TSH value is low or high, then a free T4 and free T3 should be assessed. Elevated TSH level may represent subclinical or clinical hypothyroidism, and further testing of thyroid antibodies and thyroid hormone replacement may be indicated. Suppressed TSH values may represent subclinical or clinical hyperthyroidism. Patients with hyperthyroidism may need medical treatment. Patients with toxic nodules, toxic multinodular goiter (MNG), and Graves' disease have an extremely low incidence of malignancy. Measurement of vitamin D and calcium levels is probably also reasonable in patients before surgery. Measurement of serum calcitonin in patients

with suspected or known MTC is certainly indicated, but not in every patient with a thyroid nodule.

RADIOLOGY ASSESSMENT

Ultrasound Scan

Thyroid or neck US is being done more commonly than ever before. US is done by surgeons and should be considered as an extension of your fingers or physical examination. US is done by endocrinologists and, of course, by radiologists as well.

Thyroid nodules can be examined with US to determine size, cystic versus solid nature, location, and concerning characteristics. Characteristics concerning for malignancy include ill-defined or irregular borders, microcalcifications, internal vascularity, absence of colloid halo sign, hypoechogenicity, and suspicious lymph nodes. The presence of two or more of these characteristics likely increases the risk for malignancy, but US characteristics alone are rarely pathognomonic. US-guided fine-needle aspiration (FNA) has been shown to yield more diagnostic specimens than free-hand nodule palpation FNA.

Nuclear Medicine

Thyroid scintigraphy used to be included in most algorithms describing the workup of thyroid nodules. It should really only be used for patients with hyperthyroidism and is an unnecessary expense for euthyroidism or hypothyroidism.

Computed Tomographic Scan

In the authors' opinion, CT scan of the neck with contrast is an extremely valuable imaging modality in the workup of patients with a larger thyroid mass, question of substernal extension, or malignancy, lymphadenopathy, or a difficult thyroid or neck examination. The authors have regretted *not* obtaining a neck CT scan at surgery but cannot ever recall regretting that a CT scan was obtained. One should consider that obtaining a CT scan with iodinated contrast may delay the administration of I_{131} after surgery. However, in practical use, I_{131} treatment has not been meaningfully delayed. Urinary iodine can be assessed usually within 2 to 3 months, and I_{131} administered after that. CT scan is rapid and cheaper than MRI, gives multiple reformatted views, and defines relevant relationships of the thyroid and nodes to the airway, alimentary tract, vessels, and mediastinum. It, in essence, provides an excellent road map in the more surgically challenging cases.

Magnetic Resonance Imaging

MRI is more costly than CT scan. It usually requires more time in the scanner for the patient, who may not be comfortable supine or may have claustrophobia, and some motion artifact may occur (Table 1).

MRI gives excellent anatomic and soft tissue information and multidimensional views without the concern for iodine treatment that may be considered with CT scan contrast.

Fine-Needle Aspiration

Fine-needle aspiration biopsy has become a mainstay in the workup of a patient with a thyroid nodule. Typically, a 25-gauge (or 23-gauge) needle is placed into the thyroid nodule without negative pressure to obtain a less bloody specimen. Several aspirations are taken, and the slides are air dried or immediately fixed for further cytopathologic staining and interpretation. As mentioned previously, US guidance has been shown to give a higher yield of diagnostic FNA specimens. The cytopathologist typically wishes to see at least six groups of cells in an adequate sampling.

A core needle biopsy may be indicated in the occasional patient with a thyroid mass. Patients suspected of having anaplastic thyroid carcinoma, thyroid lymphoma, metastatic disease to the thyroid, or unresectable primary thyroid carcinoma may be candidates for core needle biopsy and the further treatment planning, without the need for open incisional biopsy.

Thyroid FNA has been assigned a sensitivity ranging from 65% to 98% and a specificity from 72% to 100%. Its utility really lies in "ruling in" cancer, so that appropriate surgery can be planned and expedited, and in "ruling out" cancer, so that patients and surgeons can avoid unnecessary and potentially morbid surgery.

Unfortunately, although FNA has certainly helped with more appropriate decisions with and for patients, it is still imperfect. The various terminologies assigned to FNA cytopathologic interpretation have been inconsistent and difficult to interpret. The Bethesda System for Reporting Cytopathology has been promulgated in an attempt to facilitate uniformity, communication, and research (Box 1 and Table 2).

The atypia of undetermined significance (AUS) and follicular lesion of undetermined significance (FLUS) categories have been studied. These indeterminate specimens comprise a significant proportion of patients with thyroid nodule. A panel of molecular tests can be examined, such as BRAF, RET/PTC, PAX8/PPARG1, and Ras. The cytologic evaluation can be evaluated in conjunction with these molecular results, and it may increase the predictive power regarding cancer versus benign diagnosis. The hope is that this testing may allow some patients to avoid potentially unnecessary diagnostic surgery.

TABLE 1: Charges for imaging procedures (including professional fee)

US	$585
CT scan neck with contrast	$1906
MRI with contrast	$4358

CT, Computed tomographic; *MRI,* magnetic resonance imaging; *US,* ultrasound scan.

SURGICAL CONSIDERATIONS

Patients with a thyroid nodule considered for surgery include those with compressive symptoms, radiographic airway or esophageal compression, substernal extension, and malignant, suspicious, or indeterminate cytopathology. When the decision for surgery and appropriate preoperative counseling, consent, and clearance are obtained, one must give strong consideration to airway management (Figure 1).

Discussion with the anesthesia team is paramount before induction of anesthesia. Most patients can be induced, masked, and intubated in the standard way. However, a simple and somewhat predictive evaluation can be done in the preoperative area. Ask patients whether they can sleep supine at night. Do they have to wake up and sleep semi upright? Do they have choking episodes? Can they lie supine without difficulty in the preoperative area? Patients with large, compressive thyroid nodules, who cannot lie flat, with Mallampati III/IV airways, trismus, poor cervical extension, prior C-spine fixation, or

BOX 1: Recommended diagnostic categories for reporting thyroid cytopathology

I. Nondiagnostic or Unsatisfactory
- Cyst fluid only
- Virtually acellular specimen
- Other (obscuring blood, clotting artifact, etc.)

II. Benign
- Consistent with a benign follicular nodule (includes adenomatoid nodule, colloid nodule, etc.)
- Consistent with lymphocytic (Hashimoto's) thyroiditis in the proper clinical context
- Consistent with granulomatous (subacute) thyroiditis
- Other

III. Atypia of Undetermined Significance or Follicular Lesion of Undetermined Significance

IV. Follicular Neoplasm or Suspicious for a Follicular Neoplasm
- Specify whether Hürthle cell (oncocytic) type

V. Suspicious for Malignancy
- Suspicious for papillary carcinoma
- Suspicious for medullary carcinoma
- Suspicious for metastatic carcinoma
- Suspicious for lymphoma
- Other

VI. Malignant
- Papillary thyroid carcinoma
- Poorly differentiated carcinoma
- Medullary thyroid carcinoma
- Undifferentiated (anaplastic) carcinoma
- Squamous cell carcinoma
- Carcinoma with mixed features (specify)
- Metastatic carcinoma
- Non-Hodgkin's lymphoma
- Other

TABLE 2: The Bethesda System for Reporting Thyroid Cytopathology: implied risk of malignancy and recommended clinical management

Diagnostic category	Risk of malignancy (%)	Usual management*
Nondiagnostic or unsatisfactory	1-4	Repeat FNA with ultrasound scan guidance
Benign	0-3	Clinical follow-up
Atypia of undetermined significance or follicular lesion of undetermined significance	~5-15†	Repeat FNA
Follicular neoplasm or suspicious for a follicular neoplasm	15-30	Surgical lobectomy
Suspicious for malignancy	60-75	Near-total thyroidectomy or surgical lobectomy‡
Malignant	97-99	Near-total thyroidectomy‡

FNA, Fine-needle aspiration.
*Actual management may depend on other factors (e.g., clinical and sonographic) besides the FNA interpretation.
†Estimate extrapolated from histopathologic data from patients with "repeated atypicals."
‡In the case of "suspicious for metastatic tumor" or a "malignant" interpretation indicating metastatic tumor rather than a primary thyroid malignancy, surgery may not be indicated.
From Ali SZ, Cibas ES: The Bethesda System for Reporting Thyroid Cytopathology, *New York, 2009, Springer.*

challenging full or obstructive dentition, may require special airway management, such as fiberoptic intubation.

The choice of endotracheal tube should also be a joint decision, made by the surgeon and the anesthesia team. An oversized endotracheal tube can lead to laryngotracheal injury, even with a relatively short intubation duration. Electrophysiologic recurrent laryngeal nerve (RLN) monitoring tubes may help decrease the incidence of RLN injury during thyroid surgery. Guidelines for its use have been developed. However, RLN monitoring tubes at this time can be viewed as an adjunct to RLN visualization during thyroid (parathyroid) surgery and are not uniformly standard of care across various geographic institutions (Figure 2).

When should the surgeon consider an incisional biopsy? Incisional biopsy should be considered in situations where a core needle biopsy might be considered: that is, in patients suspected of having anaplastic thyroid carcinoma, thyroid lymphoma, metastatic disease to the thyroid, or unresectable primary thyroid carcinoma not diagnosed with FNA or core needle biopsy.

When should the surgeon consider a level 6 (central compartment) neck dissection? Ideally, the thyroid surgeon will foresee the need for a level 6 node dissection before starting the surgery. Warning or predictive indicators before surgery include medullary thyroid carcinoma diagnosis, US/CT scan/MRI findings of likely pathologic lymphadenopathy, physical examination finding of firm or fixed

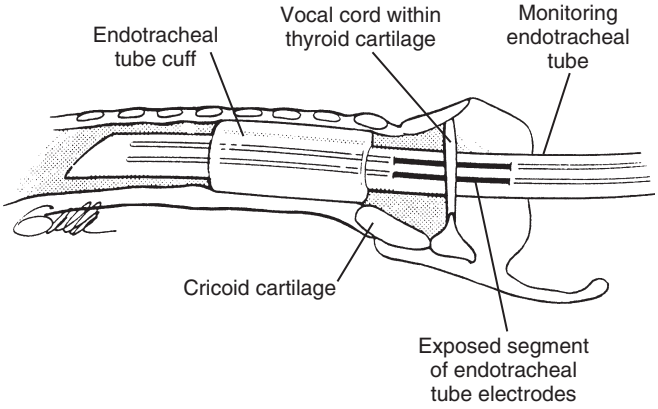

FIGURE 2 Monitoring endotracheal tube in place. The tube's cuff is in the subglottis; *black lines* on the side of the tube represent the exposed segment of electrodes that come into contact with the luminal surface of the vocal cord. *(From Randolph GW: Surgery of the thyroid and parathyroid glands, ed 2, Philadelphia, 2013, Saunders, p 327, Fig 33-15B.)*

thyroid mass, palpable pathologic lymphadenopathy, and RLN paresis or paralysis.

During surgery, the finding of pathologically enlarged level 6 lymphadenopathy, lateral neck (levels 2, 3, 4) lymphadenopathy, T3 or higher primary papillary carcinoma, or MTC should prompt the surgeon to perform a level 6 dissection. By definition, this dissection should include the soft tissues from hyoid bone to manubrium and carotid to carotid. Realistically, most of the concerning node-bearing tissue lies at an axial plane inferior to the typical superior parathyroid location, so that the superior parathyroids may be maintained in situ with their blood supply. The inferior parathyroid glands typically lie within the node-bearing soft tissues and should be identified, dissected, and reimplanted. A thorough level 6 dissection should also entail the superior mediastinum (level 7). The old adage "do it right the first time" here pays dividends, as reoperative surgery in the central neck puts the recurrent laryngeal nerves and parathyroid glands at significant risk.

There is rarely a role for subtotal thyroid lobectomy. Near total or total thyroid lobectomy is the appropriate surgery for a patient with a solitary thyroid nodule that meets indications for surgery. Meticulous dissection and preservation of the parathyroid glands and recurrent laryngeal nerves should be routine. Generally, the external branch of the superior laryngeal nerve is avoided by careful dissection directly on the thyroid superior pole.

The definition of minimally invasive thyroid surgery in unclear. The techniques of minimally invasive video assisted thyroidectomy (MIVAT), minimally invasive thyroid surgery, and robotic transaxillary and periauricular/retroauricular thyroidectomy are being promoted and marketed. Whatever technique is used, it should result in complete thyroid surgery, with an extremely low incidence of recurrent laryngeal nerve and parathyroid injury, acceptable scar, competitive cost, and rapid patient recovery.

INTRAOPERATIVE FROZEN SECTION

Frozen section should not be used when a diagnosis of malignancy papillary thyroid carcinoma (PTC) has already been made with FNA. It is not useful in diagnosis of follicular carcinoma and infrequently useful in diagnosing the follicular variant of PTC. It is useful in diagnosing PTC, medullary, anaplastic, lymphoma, and malignancies metastatic to the thyroid. The cost of intraoperative frozen section at the authors' institution is $200 for the initial block and $100 for each subsequent block, so cost should be factored into the decision-making algorithm.

An intraoperative diagnosis of PTC on frozen section may enable the surgeon, if indicated, to perform a total or near-total thyroidectomy at the initial surgery, instead of a lobectomy alone. The advantages here are a single anesthetic, less cost than two surgeries, not having to deal with healing changes or fibrosis from the first surgery, and, importantly, less emotional and psychologic distress for the patient. Surgeon-pathologist discussions, intraoperative touch prep for cytology, comparison with previous FNA slides, and an experienced thyroid pathologist help to maximize frozen section utility in intraoperative decision making.

Intraoperative parathyroid hormone (PTH) assessment may prove useful in predicting which patients may have clinically significant hypoparathyroidism or hypocalcemia. A baseline PTH is drawn before incision, and another rapid PTH is drawn approximately 15 minutes after either a total thyroidectomy or a completion thyroidectomy. If a greater than 70% drop in the PTH is seen, then these patients may be at increased risk and can be started on prophylactic supplemental oral calcium and vitamin D. Patients with a stable PTH can be released home sooner and safely. Other surgeons have found that placing all patients with completion or total thyroidectomy on a supplemental calcium and vitamin D regimen and releasing them home on the day of surgery, with detailed reinforced instructions has proven safe and cost effective.

SUMMARY

The management of thyroid nodules is truly a team effort, incorporating the knowledge and skills of the surgeon, endocrinologist, pathologist, and radiologist. Thoughtful treatment plans can be developed individually for each patient, incorporating newer technologies before and during surgery, as warranted.

Nontoxic Goiter

Gerard M. Doherty, MD, FACS

OVERVIEW

Goiter is a nonspecific term referring to any enlargement of the thyroid gland. However, in common use, it mainly denotes benign causes of thyroid enlargement, such as toxic multinodular goiter, diffuse toxic goiter (Graves' disease), or nontoxic multinodular goiter. Though malignant enlargement of the thyroid gland can technically be considered a goiter, it is usually referred to as a mass or nodule.

Nontoxic goiter is a benign condition. Though some thyroid glands resected because of nontoxic goiter may contain small cancers within them (up to 20% contain microcarcinomas), the predominant process and the decision making are based upon the benign enlargement. In some areas of the world, nontoxic goiters are endemic due to iodine deficiency, though public health efforts have reduced this somewhat.

PATHOGENESIS

A nontoxic multinodular goiter is defined as an enlargement of the thyroid gland containing follicles that are morphologically and functionally altered. The pathogenesis is multifactorial and can include iodine deficiency, goitrogens such as bamboo shoots, maize and sweet potatoes, genetic factors, and dyshormonogenesis. A family history of nontoxic goiter could indicate environmental, dietary, or dyshormonogenesis as causes. Aside from severe iodine deficiency, the cause in an individual is typically not evident, nor does it often influence management.

CLINICAL FEATURES

Nontoxic goiters may remain asymptomatic, or they may give rise to compressive features such as dyspnea, dysphagia, or venous congestion/discomfort with certain movements. A change in the voice can occur from direct pressure on the larynx or from stretching of the laryngeal nerve. Direct effects on the nerve causing paresis of the ipsilateral vocal fold are uncommon from benign goiter because nerve paresis is much more commonly associated with malignant infiltration of the nerve. Sudden changes in the goiter, as from hemorrhage into a nodule, can cause transient, intermittent, or permanent hoarseness. Thyroidectomy can often assuage voice changes due to direct pressure on the larynx, but the benefits for more uncommon changes due to effects on the nerve are less consistent.

On physical examination, the size of the gland, the features of diffuse enlargement or nodularity, tracheal deviation, extension of the gland below the sternum or clavicular heads, or high up into the neck near the angle of the mandible are all important for treatment planning. Associated lymphadenopathy should raise suspicion of malignancy (Figure 1).

EVALUATION

Thyroid stimulating hormone (TSH), free T4, and T3 levels should be checked to identify subclinical or overt thyrotoxicosis, hypothyroidism, or a euthyroid state. Fine-needle aspiration should be performed with ultrasound guidance for any suspicious thyroid nodule. Ultrasound features that raise the risk of malignancy include hypoechogenicity, microcalcifications, hypervascularity, and solid components of complex (cystic and solid) nodules.

Plain chest films can demonstrate tracheal deviation, retrotracheal and retrosternal extension, airway compression, and gross calcifications. However, cross-sectional imaging, such as computed tomographic (CT) scan or magnetic resonance imaging (MRI), is more informative for these findings. In particular, evaluating the extent of airway compression, the precise geometry of goiter position in the chest, and any associated lymphadenopathy that might indicate a clinically significant malignant component is much more effective with CT or MRI.

Radioiodine scans, pulmonary function tests, flow volume loops, and barium swallow studies may each be useful in specific situations, but they are not typically necessary in the era of accurate cross-sectional imaging.

Preoperative assessment of vocal cord movement should be considered for each patient. Deliberate voice assessment is mandatory, and fiberoptic laryngoscopy should be considered for patients with any voice alteration or any prior neck operation.

INDICATIONS FOR TREATMENT

Nontoxic goiter that causes local discomfort, such as tightness or a choking sensation, especially with certain movements, or that has caused mechanical partial obstruction of the upper aerodigestive tree should be considered for treatment. Substantial extension of the goiter into the chest, even in the absence of symptoms, should be considered a relative indication for treatment, because further enlargement of the thoracic component can lead to the need for a more disruptive operation to resect it in the future. Cosmesis alone is rarely an isolated concern or indication for therapy, as most patients with goiter of sufficient size to be bothersome also have other symptoms.

TREATMENT MODALITIES

TSH-suppression therapy with thyroxine has little role in the management of an established goiter. Prospective trials have failed to demonstrate a benefit for management of multinodular goiter. The side effects of TSH-suppression, including bone density loss and atrial arrhythmias, negate the theoretical value, particularly in the elderly patients for whom nonoperative therapy might be most attractive.

Radioiodine administration can cause goiter size reduction of 40% to 60% within 2 years, decreasing compressive symptoms. Complications include radiation thyroiditis and hypothyroidism, as well as a temporary enlargement of the gland that may be important in some clinical situations. Recent experience with the use of exogenous TSH administration to increase the efficiency of radioiodine administration in goiters with limited iodine uptake is promising, but follow-up to date is limited. These approaches may be useful for patients who have comorbidities that affect the safety of operative management, but those same comorbidities must be considered if the patient may become temporarily hyperthyroid from treatment or as the time course of correction of the local pressure symptoms of the goiter is extended.

Surgical management remains the mainstay of treatment for symptomatic, nontoxic goiter, and it is generally well tolerated, even in patients with limited physiologic reserve. The operation should typically be a bilateral procedure, removing all, or nearly all, of both thyroid lobes, in addition to any substernal extension. The operation is nearly always limited to a cervical incision, with median

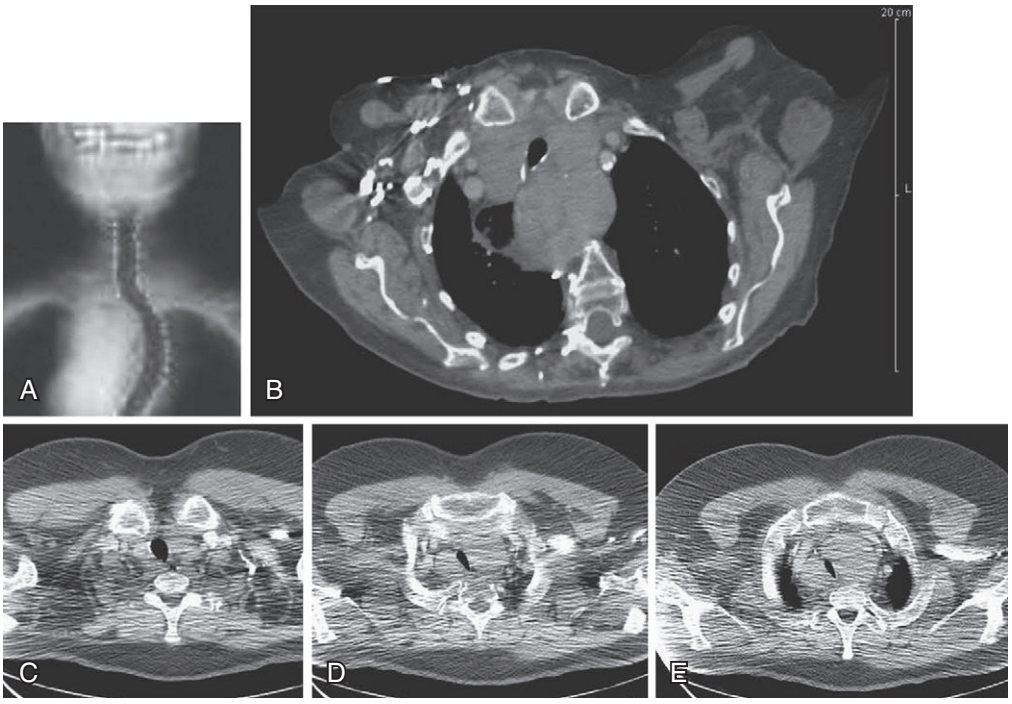

FIGURE 1 Images of goiters. **A,** Standard chest radiograph can demonstrate a goiter mainly by the displacement of the path of the trachea. In this image, a large substernal goiter displaces the trachea to the left. **B,** Posterior extension of the mediastinal goiter can make the resection more complicated. This patient has a large posterior extent from the left thyroid lobe, which must be managed carefully to avoid stretch injury to the left recurrent laryngeal nerve. The esophagus is also compressed distally and at the level of this image is displaced to the right, and contains both air and debris. **C, D,** and **E,** These images demonstrate that though the thyroid may be relatively normal in the neck on examination, ultrasound, and CT scan (**C**), the retrosternal portion (**D** and **E**) can be quite bulky. This patient presented with respiratory compromise of unclear etiology until the CT scan was obtained.

sternotomy or posterolateral thoracotomy being necessary only very rarely in previously unoperated patients. In experienced centers, complication rates are low (<2%) with techniques that include careful hemostasis and liberal parathyroid autotransplantation. For patients with significant airway compression or deviation, securing the airway can be the most critical part of the operation and may require conscious fiberoptic intubation under topical anesthesia to begin the procedure.

The thyroid gland should be exposed by a sufficient incision; though many thyroid operations can be done through very limited incisions, the geometry of the large multinodular goiter often requires long incisions in order to safely expose and remove the gland. Subplatysmal flaps improve the exposure of the limits of the gland, especially superiorly for glands with upper poles that extend high in the neck. The strap muscles can be separated in the midline or divided near the upper pole, as necessary, in order to expose the thyroid gland. The larger the cervical portion of the gland, especially the upper poles, the more likely it is that transverse division of the sternohyoid and sternothyroid muscles will be helpful.

The author typically starts the operation on the side of the larger lobe if the goiter is asymmetric. The upper pole of the gland is isolated by first separating the lateral aspect of the upper portion of the thyroid gland from the carotid sheath. If recurrent nerve monitoring is used, then the sheath is opened and the vagus nerve stimulated to establish baseline electromyography (EMG) function. The plane between the larynx and the upper pole of the thyroid gland is then opened, exposing the superior thyroid artery. The external branch of the superior laryngeal nerve (EBSLN) can be identified during some operations by direct inspection or by nerve monitor stimulation. However, in any case, the delicate fascia over the cricothyroid muscle should be kept intact because the nerve is deep to this. As the plane is followed superiorly, the nerve should stay medial and superior to the upper pole of the thyroid and its vessels. The upper pole vessels can then be divided safely using any number of hemostatic strategies, including ligatures, clips, and powered dissection tools. The branches of the superior thyroid artery should be individually controlled immediately adjacent to the thyroid parenchyma to minimize the risk to the EBSLN.

Once the upper pole is fully mobilized, the thyroid is partially rotated anteriorly to continue dissecting the lateral portion of the thyroid gland. The middle thyroid vein, if present, is divided and the thyroid separated from the carotid sheath along its entire extent. The dissection can then be carried posteriorly to the deep muscles of the neck. The ability to rotate the thyroid gland may be limited by a large substernal component. The decision of whether to proceed with the dissection of the tracheoesophageal groove, recurrent laryngeal nerve, and parathyroid glands next (the author's preference) or dissect the substernal portion of the goiter in order to create the necessary mobility is dictated by the geometry of the particular patient and goiter. Occasionally, dividing the isthmus of the thyroid gland immediately anterior to the trachea can provide a needed degree of freedom to rotate the gland sufficiently.

The tracheoesophageal groove is dissected to identify the recurrent laryngeal nerve (RLN). The author tries to identify the RLN as low in the neck as possible, because this is the area where the nerve is least tethered to surrounding structures and least likely to be stretched during dissection and identification. The nerve is identified by its appearance, by it location and course, and by stimulation if nerve monitoring is used; however, stimulation alone is not sufficient to identify the RLN. In particular, the absence of an EMG signal does

not demonstrate that a stimulated structure is not the RLN. Although intraoperative nerve monitoring is used by many experienced thyroid surgeons as an intraoperative adjunct, large trials have failed to show a benefit to patients as measured by RLN injury rates. The use of intraoperative nerve monitoring is a reasonable adjunct at the discretion of the surgeon, but it is not a standard of care.

Once the nerve is identified, it can be separated from the posterior aspect of the thyroid gland, and the intrathoracic portion can be safely delivered into the wound. The arterial supply to the thyroid goiter comes entirely from branches in the neck; there is no intrathoracic arterial supply to be concerned with. The only risk, then, is traction on the RLN as the substernal or paraesophageal intrathoracic portion of the goiter is delivered into the cervical wound by blunt dissection and gentle traction.

An important note of caution: in posteriorly displaced goiters with a component that extends inferiorly along the esophagus, especially on the right, the RLN may pass anterior to some portion of the goiter and may appear to be buried within the thyroid parenchyma because it has been trapped between nodules. This configuration makes the RLN especially vulnerable to stretch injury if this possibility is not recognized and anticipated early in the dissection.

Once the nerve is identified and the inferior portion of the thyroid gland mobilized, the RLN is traced up to its insertion into the larynx under the inferior border of the cricothyroid muscle. The small branches of the inferior thyroid artery are divided along the parenchymal surface of the gland, with the RLN always in view and protected. The parathyroid glands typically become evident during this portion of the dissection. Their blood supply from the inferior thyroid artery should be preserved if possible. If not, then the glands should be removed and grafted into the sternocleidomastoid muscle. As the dissection approaches the insertion of the RLN into the larynx, the RLN becomes progressively more fixed by surrounding tissues, including branches of the inferior thyroid artery, the fascial attachments of the thyroid gland to the trachea, and the insertion itself. Great care is necessary to safely dissect the thyroid gland away from the RLN without directly injuring or stretching the RLN. Once the RLN is fully separated from the thyroid gland, then the final attachments of the thyroid gland to the trachea can be divided. If intraoperative nerve monitoring was used, then the EMG signal with vagus nerve stimulation should be assessed at the completion of the dissection.

The process is then repeated on the opposite side. If there has been difficulty with the dissection on the initial side, then the contralateral procedure may be modified to reduce the risk of complications. For example, if the RLN lost function as documented by intraoperative nerve monitoring, then the contralateral RLN dissection may be modified to leave the RLN segment near the laryngeal insertion undisturbed by leaving a portion of the thyroid lobe in place at that position.

Devitalized parathyroid tissue should be cut into small (1- to 2-mm) pieces and grafted into small pockets in the sternocleidomastoid muscle. It is best to close each pocket with a suture to hold the graft in place while it develops a blood supply over the ensuing 6 to 12 weeks. It is not necessary to attempt to mark the site with permanent sutures or clips because subsequent reoperation to remove these remnants is extremely rare and best guided by ultrasound if necessary.

Meticulous hemostasis is important because bleeding in the confined space of the neck can compress the airway. The strap muscles are reapproximated in some fashion, depending on how they were opened or divided, but the closure should not be occlusive. The platysma muscle is reapproximated to align the skin edges and remove tension from the wound. The skin is closed according to the preference of the surgeon; the author's current preference is to approximate the skin edges with a running 3-0 polypropylene pull-out subcuticular suture, followed by skin glue. The suture is removed after the glue is dry (about 2 minutes). This provides a cosmetic closure that requires no further attention until after the glue peels away at about postoperative day 14.

POSTOPERATIVE CARE

In the author's practice, patients remain hospitalized overnight after removal of a nontoxic goiter in order to manage their limited pain and to monitor them for neck hematoma or hypocalcemia. All patients are managed with oral calcium supplements (calcium carbonate 1250 mg orally TID) beginning on the morning after surgery. If they are symptomatic with numbness or tingling, or if their calcium on the morning after surgery is below 8 mg/dL, then the dose is doubled (2500 mg TID). If their symptoms persist, either before or after discharge, or if there is special concern about the immediate parathyroid function—for example, if two or more parathyroid glands were grafted—then activated vitamin D is added to increase the gastrointestinal absorption of calcium (calcitriol 0.5 to 1.0 mcg daily in two divided doses).

Postoperative voice assessment is mandatory in all patients. Most patients have some immediate voice changes, but these nearly all resolve within 2 weeks of operation. Laryngoscopy to document vocal cord motion should be performed for all patients with significant voice changes that persist beyond 2 weeks and for all patients who have a change in their intraoperative nerve monitoring findings during the procedure if that adjunct has been used. While some have advocated for more broad use of laryngoscopy preoperatively and postoperatively, there is no evidence that this changes patient outcomes, so most experienced surgeons focus this effort in a more selective way.

The Management of Thyroiditis

Charles Parker, MD, and David Steward, MD

OVERVIEW

Thyroiditis refers to a diverse group of inflammatory disorders that affect the thyroid gland. Categorization of these conditions can be based on the presence or absence of pain, suspected etiology, or duration of disease (Table 1). Diagnosis can often be suspected on the basis of a thorough history and physical examination, although laboratory or radiologic workup may be necessary for confirmation. Management requires an understanding of the evolution of the ensuing disease process and thyroid pharmacology.

CHRONIC LYMPHOCYTIC THYROIDITIS

Overview

Chronic lymphocytic thyroiditis (Hashimoto's thyroiditis) is the most common inflammatory condition of the thyroid gland and the most common cause of hypothyroidism in the United States. The disease results from an autoimmune process characterized by lymphocytic infiltration and follicular destruction of the gland. Progression of thyroid destruction can lead to chronic thyroid failure and an atrophic gland in approximately 10% of patients. Up to 95% of chronic lymphocytic thyroiditis occurs in women, usually between the ages of 30 and 50 years. Presentation is typically asymptomatic, but symptoms of hypothyroidism can be present in approximately 20% of patients at the time of diagnosis. Even fewer (~5%) have thyrotoxicosis develop during the early phase of the disease. Patients with euthyroidism with Hashimoto's disease have development of hypothyroidism at a rate of approximately 5% per year. Physical examination generally reveals a firm, irregular, and nontender goiter. Some patients may report a feeling of tightness or fullness in the neck.

Diagnosis is suspected on the basis of clinical examination finding of a goiter and is confirmed with laboratory findings of hypothyroidism (elevated thyroid-stimulating hormone [TSH] and low free thyroxine [FT4] values) and elevated thyroid peroxidase antibody, which is present in 90% of patients with Hashimoto's thyroiditis. Thyroid ultrasound scan is obtained for suspicion of a dominant nodule on examination or family history of thyroid malignancy. Ultrasound scan shows an enlarged gland with a heterogenous or diffusely hypoechogenic pattern in most patients depending in part on the extent of lymphocytic infiltrate. The heterogenous hypoechogenicity may result in pseudonodularity, which may be difficult to distinguish from nodular disease. Infrathyroidal lymph nodes are frequently present, especially in younger patients, and may be mistaken for nodular disease.

Management

Management of Hashimoto's thyroiditis is primarily medical. Indications for thyroid hormone therapy include symptomatic or biochemical hypothyroidism. Levothyroxine therapy is initiated, with the dose determined by the patient's TSH level, age, and body mass; the dose can be up to approximately 1.6 μg/kg/d, with a goal for the TSH in the lower half of the reference range (1 to 3 mIU/L). TSH level should be rechecked 6 weeks after initiation of therapy and then every 6 to 12 months. If dose changes are needed, they should be made in increments of 12.5 μg to 25 μg or higher depending on the TSH level. A TSH test should be repeated in 6 weeks to ensure adequate replacement. Patients may not experience complete relief of hypothyroid symptoms until after 3 to 6 months of therapy. For patients with persistent hypothyroid symptoms despite TSH levels in the range of 1 to 3 mIU/L, FT3 levels may be checked; if levels are low, liothyronine (LT3) therapy should be considered. In patients with progressively enlarging goiter and compressive symptoms despite adequate replacement therapy or with suspected malignancy, surgical management is indicated. Total thyroidectomy is often performed for the compressive goiter, with more than 90% of patients experiencing symptomatic relief after surgery. Two-stage surgery with hemithyroidectomy and completion thyroidectomy may reduce the risk of bilateral recurrent laryngeal nerve injury or hypoparathyroidism and is a reasonable alternative. If thyroid malignancy is suspected because of suspicious findings on ultrasound scan, diagnostic evaluation should include an ultrasound scan–guided fine-needle biopsy. Coexistence of Hashimoto's thyroiditis does not significantly alter the management of thyroid nodules, which is determined by the results of fine-needle biopsy. Rarely, a rapidly enlarging goiter may represent primary lymphoma, which requires core or incisional biopsy for diagnosis.

SUBACUTE LYMPHOCYTIC THYROIDITIS

Overview

Subacute lymphocytic thyroiditis (subdivided into silent or postpartum thyroiditis) may represent a variant of Hashimoto's thyroiditis with a similar autoimmune etiology. Subacute lymphocytic thyroiditis should be suspected in the patient with goiter and self-limiting thyrotoxicosis. As a result of follicular destruction, patients may experience a transient period of thyrotoxicosis as a result of the release of stored hormone. This phase may last from 2 to 4 months. A period of hypothyroidism may follow from depletion of stored hormone and typically lasts up to 6 months before the patient returns to a euthyroid state. However, up to 20% of patients may experience chronic hypothyroidism and need life-long hormone therapy. Diagnosis is suspected based on a history of transient thyrotoxicosis and the laboratory findings of evolving thyroid function studies. Unlike subacute granulomatous thyroiditis, systemic symptoms such as fever, thyroid tenderness, and an elevated erythrocyte sedimentation rate are unusual in subacute lymphocytic thyroiditis. If Graves' disease is suspected, a radioiodine uptake study can differentiate between the two hyperthyroid states. Graves' disease is associated with elevated uptake from increased hormone synthesis, and subacute lymphocytic thyroiditis shows decreased uptake. Anti-TSH receptor antibodies in Graves' disease are not present in subacute lymphocytic thyroiditis. Anti-thyroid peroxidase (anti-TPO) and anti-Tg antibody testing is often positive in subacute lymphocytic thyroiditis (silent and postpartum), but on average, lower levels are seen then in Hashimoto's thyroiditis.

Postpartum thyroiditis is similar to silent thyroiditis but is defined as the development of thyroid dysfunction within 12 months after pregnancy in a previously euthyroid female. Postpartum thyroiditis can also develop after spontaneous or induced abortion. Approximately 20% to 40% of patients exhibit the characteristic triphasic course of an initial hyperthyroid phase, followed by subsequent

TABLE 1: Features of thyroiditis*

Form of thyroiditis	Duration of disease	Etiology	Presence of pain	Thyroid function	Management
Chronic lymphocytic thyroiditis (Hashimoto's)	Chronic, progressive	Autoimmune	Painless	Hypothyroid	Levothyroxine
Subacute lymphocytic thyroiditis (silent and postpartum)	Subacute, transient, or progressive	Autoimmune	Painless	Triphasic	Beta-blockers, levothyroxine
Subacute granulomatous thyroiditis (de Quervain's)	Subacute, transient	Viral	Painful	Triphasic	NSAIDs, beta-blockers, levothyroxine
Acute suppurative thyroiditis	Acute	Bacterial	Painful	Euthyroid	Antibiotics, surgical drainage
Invasive fibrosis thyroiditis (Reidel's)	Chronic, progressive	Idiopathic	Rarely painful	Euthyroid or hypothyroid	Steroids
Drug-induced	Acute/subacute, transient, or progressive	Pharmacologic	Painless	Hyperthyroid or hypothyroid	Thionamides, steroids, beta-blockers, levothyroxine, surgery

NSAIDs, Nonsteroidal antiinflammatory drugs.

hypothyroidism and then a return to the euthyroid state. Another 20% to 30% experience only hyperthyroidism, and 40% to 50% only hypothyroidism. Management is similar to that of silent thyroiditis.

Management

Management is towards alleviation of symptoms. Symptoms of thyrotoxicosis, such as palpitations, tachycardia, tremors, anxiety, and heat intolerance, are best controlled with beta-blocker therapy. Antithyroid medications are not helpful because the thyrotoxicosis is not the result of excess hormone production but of release of prestored hormone. Common therapeutic agents include propranolol 10 mg to 40 mg 3 to 4 times daily or atenolol 25 mg to 100 mg daily or twice daily. Symptomatic hypothyroidism can be managed with levothyroxine therapy. Thyroid function laboratory results should be monitored every 4 to 6 weeks to confirm resolution of thyrotoxicosis and detect onset and resolution of hypothyroidism.

SUBACUTE GRANULOMATOUS THYROIDITIS

Overview

Subacute granulomatous thyroiditis (de Quervain's thyroiditis) is the most common cause of a painful thyroid gland. It is most likely caused by a viral infection and is generally preceded by an upper respiratory tract infection. Numerous etiologic agents have been implicated, including mumps virus, echovirus, coxsackievirus, Epstein-Barr virus, influenza, and adenovirus. Women between the ages of 30 and 50 years are most likely to be affected. Typical presentation is that of acute thyroid pain and low-grade fevers. Pain may be exacerbated with turning of the head or swallowing and may radiate to the jaw, ear, or occiput. Similar to subacute lymphocytic thyroiditis, patients may experience a triphasic course in relation to thyroid function. About 50% of patients present with symptoms of thyroidotoxicosis from follicular disruption and release of stored thyroid hormone. This phase may last 4 to 6 weeks before thyroid stores are depleted and the patient experiences hypothyroidism. Symptoms of hypothyroidism may last up to 6 months. As follicles repair, normalization of thyroid studies and euthyroidism develops. About 5% to 15% have persistent hypothyroidism after 12 months. Laboratory evaluation reveals a mildly elevated erythrocyte sedimentation rate (ESR) early in the disease course, normal white blood cell count (WBC), and evolving thyroid function tests. Antithyroid antibodies are normal.

Management

Management is directed against symptom control similar to subacute lymphocytic thyroiditis. Pain is often managed with nonsteroidal antiinflammatory drugs (NSAIDs). Rarely, severe pain refractory to NSAIDs may be managed with steroids. Median time for resolution of pain is 5 weeks. Beta-blockers are used to control symptoms of thyrotoxicosis, and levothyroxine is used during the hypothyroid phase.

ACUTE SUPPURATIVE THYROIDITIS

Overview

Acute suppurative thyroiditis is a rare disorder most commonly caused by bacterial infection from *Staphylococcal* and *Streptococcal* species. In the patient with immunocompromise, fungal, mycobacterial, or parasitic sources should also be suspected. The disorder is rare because of the intrinsic resistance the thyroid has to infection as a result of its rich lymphovascular supply, fascial encapsulation, and high iodine content. Mechanisms for infection include lymphovascular spread, direct trauma, or more commonly, a persistent piriform

sinus fistula. In children with acute suppurative thyroiditis, a left piriform sinus fistula is the most common cause. In adults, the condition is more likely to occur in patients with preexisting thyroid disease, such as Hashimoto's thyroiditis, nodular goiter, or thyroid cancer. Presentation is that of acute neck swelling, pain, and high fevers. Some may present in acute airway distress from a compressive abscess requiring intubation and emergent drainage. Laboratory workup reveals an elevated WBC, elevated ESR, and normal thyroid function studies. Human immunodeficiency virus screening should be performed in patients because of its association with an immunocompromised state. Computed tomographic (CT) scan of the neck with contrast is often the first diagnostic test performed. CT imaging allows for identification of any fluid collection, its accessibility to needle aspiration, extrathyroidal extension, and the possibility of a piriform sinus fistula. Ultrasound scan with needle aspiration is performed next to obtain fluid for culture and antibiotic sensitivity testing.

Management

Management begins with broad-spectrum empiric antibiotics. Common agents include penicillinase-resistant penicillins and beta-lactamase inhibitors (piperacillin/tazobactam or ampicillin/sulbactam) or clindamycin for a penicillin allergy, plus vancomycin if methicillin resistant *Staphylococcus aureus* is suspected. Antibiotics are narrowed once sensitivity data are obtained. Duration of antibiotics is determined by clinical response; however, 14 days of therapy is reasonable in most patients. In the unstable airway, emergent transcutaneous incision or open-surgical drainage is needed. If the patient's condition is stable and CT imaging has identified the thyroid as the site of infection, then ultrasound scan with needle aspiration may be more appropriate. If fluid accumulation recurs or clinically the patient's condition fails to improve, the decision needs to be made to determine the success of repeat needle aspiration versus surgical drainage and possible partial or total thyroidectomy. Thyroid resection may be necessary in patients with persistent disease or when multiple poorly defined abscesses are present. Management of a piriform sinus fistula often requires direct endoscopy for identification and complete fistula tract excision with hemithyroidectomy after resolution of the acute illness.

INVASIVE FIBROUS THYROIDITIS

Overview

Invasive fibrous thyroiditis (Reidel's thyroiditis) is a rare idiopathic disorder characterized by progressive fibrosis and inflammation of the thyroid gland and adjacent cervical structures. The mean age at presentation is 50 years, and 80% of all cases occur in females. A hard fixed mass involving the thyroid with compressive symptoms or neck pain is common. Extension into adjacent structures may cause dyspnea, hoarseness, dysphagia, and restricted neck movement. Association with systemic fibrosis is seen in up to one third of patients, with common sites being the retroperitoneum and mediastinum. Evaluation requires thyroid function studies and ultrasound scan. Ultrasound scan shows a diffuse, hypoechoic, hypovascular appearance from the extensive fibrosis. Unique to the patient with Reidel's thyroiditis is the finding of carotid artery encasement, which is not typically seen in other benign goiter diseases. Hypothyroidism is present in 80% of patients during the course of disease. Ultrasound scan–guided fine-needle aspiration is often nondiagnostic but may reveal inflammation and fragments of fibrous tissues. Definitive diagnosis with open biopsy to rule out possible thyroid malignancies is often needed.

Management

Management is often with both surgical and medical therapy. Surgery to relieve compressive symptoms may initially be performed at the time of open biopsy. Total thyroidectomy is difficult because of the extrathyroidal extension of disease and loss of fascial planes. Debulking surgery, limited to an isthmectomy, is often performed to prevent surgical complications from a more aggressive dissection and to reduce airway constriction. Prednisone is the first step in medical therapy and has been shown to have a more dramatic effect in reducing the size of the mass and compressive symptoms when initiated early in the disease course. Doses may range from 15 mg to 100 mg daily and may be required for years, with tapering and withdrawal based on clinical response. In cases refractory to prednisone, the addition of tamoxifen has been reported to be successful. A recent report describes the use of mycophenolate mofetil in combination with prednisone to successfully reduce the size of a mass.

DRUG-INDUCED THYROIDITIS

Overview

Several drugs are known to cause thyroid inflammation, including amiodarone, interferon-alfa, interleukin-2, and lithium. A thorough history often reveals the suspected agent. Patients may present with either symptoms of hypothyroidism or hyperthyroidism depending on the pharmacologic agent and length of use. Baseline thyroid function tests are needed before the start of any of the previous medications and should be monitored every 6 months with continued therapy. Amiodarone is associated with both hypothyroidism and hyperthyroidism. In iodine-deficient areas, amiodarone-associated hyperthyroidism is more common; however, in iodine-sufficient areas, amiodarone-associated hypothyroidism is more common. Thyroid dysfunction may occur acutely after initiation of amiodarone therapy or may develop after several years of therapy. There are two types of amiodarone-induced thyrotoxicosis. Type 1 is from the increased thyroid hormone production, often from the iodine load exacerbating underlying thyroid disease, and type 2 is from follicular destruction and release of stored hormone. Differentiating between the two types can be difficult because of the similarity in presentation. Characteristics of type 1 amiodarone-induced thyrotoxicosis are a detectable radioactive iodine uptake level, hypervascularity on color flow Doppler scan, and a multinodular or diffuse goiter seen on ultrasound scan. Characteristics of type 2 amiodarone thyrotoxicosis are a nondetectable radioactive iodine uptake level, absent vascularity on color flow Doppler scan, and no goiter or small goiter on ultrasound scan. Lithium is more commonly associated with hypothyroidism from chronic use; however, several reports have described thyrotoxicosis from chronic lithium use. Both interferon-alfa and interleukin-2 can be associated with hypothyroidism and thyrotoxicosis.

Management

Often these medications can be continued, and the patient is treated for thyroid symptoms with either levothyroxine or beta-blockers. In type 1 amiodarone-induced thyrotoxicosis, hyperthyroidism is the result of increased thyroid synthesis. Effective management requires thionamides, methimazole 30 mg to 40 mg daily, along with potassium percholorate at 1 g daily, to prevent further hormone production. Type 2 amiodarone-induced thyrotoxicosis is best treated with several months of glucocorticoids. In both types, if thyrotoxicosis persists despite medical therapy and amiodarone cannot be discontinued, then total thyroidectomy may be necessary.

Hyperthyroidism

William S. Duke, MD, and David J. Terris, MD

INTRODUCTION

Hyperthyroidism refers to thyrotoxicosis specifically caused by hyperactivity of the thyroid gland. This state of metabolic excess is the result of elevated levels of the thyroid hormones, tetraiodothyronine (thyroxine, T4) and the metabolically active triiodothyronine (T3). Signs and symptoms of this condition reflect the underlying hypermetabolic state, which if left untreated may progress to heart failure and arrhythmia, significant neurologic derangements, thyroid storm, and even death (Table 1). The incidence rate of hyperthyroidism in the United States is approximately 0.5 to 1 per 1000, with women affected 10 times more often than men.

Graves' disease is the most common cause of hyperthyroidism, accounting for more than 50% of all cases. This autoimmune condition is caused by antibodies directed against the thyroid-stimulating hormone (TSH) receptor, resulting in thyroid enlargement, an increase in thyroid vascularity, and increased production and secretion of thyroid hormone.

Hyperthyroidism may also be caused by a toxic multinodular goiter, which usually arises within the background of a longstanding nontoxic multinodular goiter, or by a solitary toxic nodule, which is the result of a hyperfunctioning adenoma. Less commonly, hyperthyroidism may be associated with excess iodine intake, as in the case of amiodarone-induced hyperthyroidism and the Jod-Basedow effect, or may be the result of high levels of human chorionic gonadotropin (gestational thyrotoxicosis), which is structurally similar to TSH. Hyperthyroidism may also be present during the early phase of Hashimoto's thyroiditis, another type of autoimmune thyroiditis.

Regardless of etiology, the goal of management of hyperthyroidism is to decrease the hyperfunctioning state of the thyroid gland, mitigate the immediate and long-term sequelae of exposure to excess thyroid hormone, and return the patient to a euthyroid state. This can be achieved through the use of medications, radiation therapy, or surgery.

TABLE 1: Clinical manifestations

Symptoms	Signs
Palpitations	Tachycardia
Heat intolerance	Arrhythmia
Diaphoresis	Valve disease
Anxiety/nervousness	Congestive heart failure
Restlessness	Dyspnea
Emotional lability	Hyperreflexia
Psychosis	Hyperkinesis
Increased appetite	Weight loss
Diarrhea	Stare, lid lag
Hair loss	Proptosis
Fatigue	Dermopathy
Muscle weakness	Bone demineralization
Insomnia	
Pathologic fracture	
Reproductive impairments	

ASSESSMENT AND DIAGNOSIS

The thyroid gland secretes T4 and T3 in response to TSH stimulation in a feedback cycle. As T4 and T3 levels increase, the anterior pituitary gland decreases the amount of TSH produced. Primary hyperthyroidism occurs when the thyroid gland no longer responds appropriately to falling levels of TSH by decreasing the synthesis and release of T4 and T3.

Patients with symptoms concerning for hyperthyroidism should have serum TSH and free thyroxine (T4) tests obtained, and if indicated, free T3. Primary hyperthyroidism is associated with a TSH level generally below 0.1 mU/L with an elevated T4. Subclinical hyperthyroidism is present when the TSH is suppressed but the thyroid hormone levels are normal. Measurement of serum TSH receptor antibodies may be useful in the management of patients with Graves' disease.

Imaging studies are often beneficial in evaluation of patients with thyroid disease. Radioactive iodine uptake scans, performed with either ^{123}I or ^{131}I, may help elucidate the etiology of thyrotoxicosis. In Graves' disease, diffuse homogeneous uptake is seen throughout the gland, whereas toxic nodular disease shows intense uptake in the pathologic nodules. Hashimoto's thyroiditis and conditions of exogenous excess thyroid hormone intake result in decreased uptake on radioactive thyroid scans. Most patients should undergo a thyroid ultrasound scan to evaluate for the presence of nodules, which may suggest toxic nodular disease or lesions concerning for concurrent malignancy.

NONSURGICAL TREATMENT

The treatment of hyperthyroidism is separated into three principal modalities: medications to suppress thyroid function, radioactive iodine (RAI) ablation of the thyroid gland, and surgery. The choice of therapy depends on many factors, including the natural history of the disease and the wishes of the patient. Antithyroid medications and RAI are more common in the United States, with surgery generally reserved for failures or complications of other modalities, concern for a coexisting thyroid malignancy, an obstructive or cosmetically significant goiter, or patient preference.

The thionamides, methimazole and propylthiouracil (PTU), are the primary agents for the medical control and preoperative management of hyperthyroidism. They impair thyroid hormone production.

PTU also functions to inhibit the peripheral conversion of T4 to T3, which makes it particularly useful in patients with life-threatening thyrotoxicosis. The effects of thionamide therapy may become apparent after several weeks, although maximal efficacy may take 2 months or more to achieve. Both agents cross the placenta, and methimazole has been associated with certain birth defects. Severe reactions such as agranulocytosis may occur with either agent. PTU carries an additional risk of severe hepatotoxicity, and in 2009, the U.S. Food and Drug Administration (FDA) recommended reserving PTU for patients in the first trimester of pregnancy or who are allergic to or intolerant of methimazole.

Beta-blockers are frequently used to control the catecholamine-mediated symptoms of hyperthyroidism. Propranolol is especially useful because it assists in blocking the peripheral conversion of T4 to T3. Beta-blockers should not be administered in isolation without other medications to suppress thyroid function and should not be used in patients who have concurrent congestive heart failure, unless tachycardia caused by the hyperthyroidism is the cause of the heart failure.

Radioactive iodine treatment with ^{131}I achieves a hypothyroid state in approximately 80% of patients. This effect may take several months to achieve, during which time patients should be continued on the pretreatment medical regimen to control the hyperthyroidism. RAI is contraindicated during pregnancy and lactation and may exacerbate the ophthalmologic manifestations of Graves' disease.

SURGICAL INDICATIONS AND CONTRAINDICATIONS

Surgical management of hyperthyroidism may be appropriate in several circumstances. The decision to proceed with surgery over other forms of therapy should be based on several factors, including response to and tolerance of medical therapy, the patient's candidacy for RAI, comorbid disease, and patient preference.

Medical treatment of hyperthyroidism with thionamides may be complicated by allergy or severe side effects that preclude their continued use. Some patients do not have the disease adequately controlled with medical therapy, and approximately 50% of patients treated with thionamides have relapse once therapy is discontinued.

Surgery may be favored in those patients who continue to manifest symptoms of hyperthyroidism despite prior treatment with thionamides and RAI. Although no studies have shown a consistent significant risk of secondary malignancy with RAI, some patients are reluctant to have any form of radiation therapy and favor surgery over long-term medical treatment. RAI is used with caution in young children with hyperthyroidism.

Several other factors may favor surgery over medical therapy. Patients with thyroid nodules that are concerning for or proven to be malignant should undergo surgical treatment. Surgery may be the preferred treatment option for patients desiring to become pregnant soon after treatment or in patients who are already pregnant but who are either resistant to thionamide treatment or whose symptoms are so severe that they cannot wait several weeks for the medications to reach efficacy. Surgery may also be appropriate for young children, patients with compressive goiters, and patients who are deemed poor candidates for long-term follow-up.

SURGICAL PREPARATION

Thyroid storm is a severe, life-threatening exacerbation of thyrotoxicosis that may be triggered by surgery. This hypermetabolic state may be manifested by fever, tachycardia and other arrhythmias, cardiovascular collapse, gastrointestinal disturbances, mental status changes including coma, and death. Every effort should be made to control hyperthyroidism and convert the patient to a euthyroid state before surgery. Coordination of preoperative medical management of the patient's hyperthyroidism with an endocrinologist who can assist in medication selection and dosing is essential (Table 2).

Thionamide treatment should begin several weeks before surgery, although achieving a euthyroid state may require several months in some patients. Elective surgery should be postponed until a euthyroid state is reached to avoid precipitating thyroid storm.

Methimazole may be started at 20 to 40 mg once daily or twice daily in divided doses. No parenteral form is available. PTU may be started at 300 to 600 mg/d, divided every 8 hours. PTU may be given rectally in patients with severe thyrotoxicosis who are unable to take medications orally. Higher doses may be needed for acute thyroid storm, and both agents may be decreased to lower maintenance doses as the hyperthyroidism resolves.

Iodine-containing agents are useful adjuncts in achieving a euthyroid state before surgery and for controlling acute thyrotoxicosis. Lugol's solution (8 mg of iodide per drop) and saturated solution of potassium iodide (SSKI; 50 mg iodide per drop) work by transiently inhibiting thyroid hormone production and release. An initial response may be present within 24 hours, with peak efficacy reached

TABLE 2: Medications for treatment of hyperthyroidism

Class	Mechanism of action	Medication	Starting dose
Thionamide	Impair thyroid hormone production	Methimazole	20-40 mg PO daily or divided twice daily
		Propythiouracil	300-600 mg PO divided every 8 h
Beta-blocker	Block catecholamine-mediated hyperthyroid symptoms	Propranolol	20-40 mg PO every 6 to 8 h
Iodine preparation	Inhibit thyroid hormone synthesis and release	Lugol's solution	2-5 drops PO 1 to 3 times daily
		Saturated solution of potassium iodide (SSKI)	1-2 drops PO 1 to 3 times daily
Steroid	Support metabolic function in critical illness	Hydrocortisone	50-100 mg IV every 8 h
		Dexamethasone	2 mg IV every 8 h

IV, Intravenously; *PO,* orally.

within 2 weeks. These medications should be administered concurrently with a thionamide to decrease the risk of accelerated release of stored thyroid hormone and rebound hyperthyroidism once the iodine solution has been withdrawn. SSKI is started at 1 to 2 drops by mouth (PO) 1 to 3 times daily, and Lugol's solution is started at 2 to 5 drops PO 1 to 3 times daily. These agents cross the placenta, and their use in pregnancy may result in fetal harm.

Beta-blockers are used perioperatively to control the catecholamine-mediated cardiovascular symptoms of hyperthyroidism. As mentioned previously, propranolol (20 to 40 mg PO every 6 to 8 hours) is especially useful because it also assists in blocking the peripheral conversion of T4 to T3.

Treatment with steroids may also be necessary, as patients in thyroid storm have both increased cortisol metabolism and inadequate cortisol secretion to meet metabolic demands. When given with iodine-containing agents and thionamides, steroids may also help decrease thyroid hormone synthesis and peripheral conversion of T4. Hydrocortisone (50 to 100 mg intravenously [IV] every 8 hours) or dexamethasone (2 mg IV every 8 hours) may be given to meet the steroid requirement in these critically ill patients.

SURGICAL OPTIONS

The appropriate surgical intervention for patients with hyperthyroidism depends on the underlying cause of the disease. Patients with Graves' disease, toxic multinodular goiter, and other processes that affect the entire gland should undergo total thyroidectomy. Total thyroidectomy removes all identifiable thyroid tissue, resulting in a hypothyroid state and the need for thyroid hormone replacement.

Subtotal thyroidectomy is mentioned only so that it may be condemned. It is a procedure done historically for logical reasons but has little role in a modern thyroid practice. It purports to preserve 3 to 6 g of thyroid tissue superiorly near the insertion of the recurrent laryngeal nerve (RLN), with the thought of protecting the RLN and endeavoring to avoid permanent hypothyroidism. After several decades of this surgery, a high risk of recurrent hyperthyroidism has been recognized; now, wide consensus exists that the RLN should be identified in all cases to avoid inadvertent injury.

Patients with a toxic nodule may be eligible for a unilateral thyroid lobectomy to remove the pathologic adenoma (if the contralateral lobe is normal), which is nearly always permanently curative. Attempts to extirpate just the nodule from the surrounding normal tissue are discouraged.

SURGICAL ANATOMY

The thyroid is a bilobed gland that resides in the anterior neck. The lobes are connected by a central isthmus, which crosses the trachea approximately at the level of the third tracheal ring. Occasionally, a pyramidal lobe, a remnant of the thyroglossal duct, may extend superiorly from the isthmus. The gland is posterior to the sternothyroid and sternohyoid muscles and medial to the carotid sheath. Each lobe is about 4 cm in height, 2 cm wide, and 2 cm deep; the total gland typically weighs approximately 20 g. Glands affected by Graves' disease, large nodules, or diffuse goiter can be significantly larger and extend into the chest or posterior to the esophagus. The gland is held tightly adherent to the trachea by a suspensory ligament, Berry's ligament.

Blood supply to the gland is provided by the superior thyroid artery, which arises from the external carotid artery, and the inferior thyroid artery, which branches off the thyrocervical trunk. These vessels contribute to the superior and inferior vascular pedicles, respectively.

The superior laryngeal nerve (SLN) exits the vagus nerve and gives off an external branch that supplies the cricothyroid muscle. Although significant variation can be found in the course of this nerve, it typically crosses posterior to the external carotid artery and travels to the cricothyroid muscle in close proximity to the superior thyroid artery and along the inferior constrictor muscle. This nerve is not routinely exposed during thyroidectomy, and transecting the superior vascular pedicle near its insertion into the thyroid gland decreases the risk of nerve injury.

The RLN, also a branch of the vagus, provides some laryngeal sensation and supplies motor innervation to all of the intrinsic laryngeal muscles except the cricothyroid. This nerve must be protected during dissection to avoid postoperative hoarseness or, in the case of bilateral injury, acute respiratory distress. The left RLN recurs around the aortic arch and ascends the neck in the tracheoesophageal groove (Figure 1). The right RLN recurs around the subclavian artery and approaches the larynx from a more lateral location, making its location more variable. The nerve is usually deep to the inferior thyroid artery. Identification of the nerve in the soft tissue near the inferior pole of the gland can be difficult. The nerve may be more consistently identified near its insertion under the inferior constrictor muscle near the cricothyroid joint.

Preservation of parathyroid integrity is of paramount importance in thyroid surgery. There are usually two superior and two inferior parathyroid glands, although some patients may have supernumerary glands. The exact location of the parathyroid glands varies,

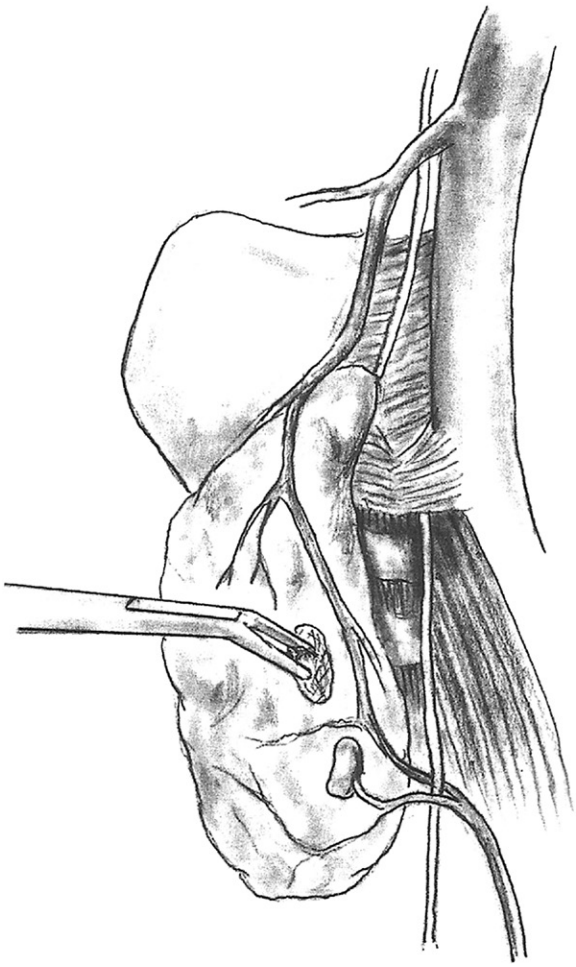

FIGURE 1 The left superior laryngeal nerve is identified posterior to the superior thyroid artery along the inferior constrictor. The left recurrent laryngeal nerve is located in the tracheoesophageal groove deep to the inferior thyroid artery. *(Reprinted with permission from Terris DJ, Gourin CG:* Thyroid and parathyroid diseases: medical and surgical management, *New York, 2009, Thieme Medical Publishers, Inc.)*

but they are closely associated with the superior and inferior poles of the thyroid gland. The superior parathyroid gland is found approximately 1 cm superior to the junction of the RLN and the inferior thyroid artery, tightly adherent to the posterior aspect of the gland. The location of the inferior parathyroid glands is more variable, usually adjacent to the inferior pole of the thyroid gland. The parathyroid glands tend to be oval, flat, or bean-shaped and have a reddish brown or rust-colored appearance. Both the superior and inferior glands receive their vascular supply from the inferior thyroid artery, which should be preserved during dissection.

SURGICAL TECHNIQUE

Conventional Thyroidectomy

The traditional approach to thyroidectomy has evolved considerably over the past 10 years. It involves placing the intubated patient supine on the operating room table without extension. A horizontal incision, rarely longer than 6 cm long, is centered on the midline and marked previously with the patient upright in the holding area. Once the skin and subcutaneous tissues have been divided, the platysma is identified and divided horizontally. Subplatysmal flaps are no longer raised (as was classically taught). Instead, the midline raphe between the strap muscles is simply divided vertically, with exposure of the underlying thyroid gland. The strap muscles are elevated off the anterior face of the thyroid lobes and retracted laterally. The superior extent of each thyroid lobe is identified, and the vessels of the superior vascular pedicle are ligated and transected as a single bundle with an advanced energy device such as Harmonic shears (Ethicon Endosurgery, Cincinnati, Ohio) or the LigaSure (Covidien, Boulder, Colo; Figure 2). Care should be taken during this portion of the dissection to avoid injuring the external branch of the SLN or the superior parathyroid gland.

Once the superior vascular pedicle has been divided, the lobe is retracted medially and the posterior and lateral surface aspect of the gland is dissected. The superior parathyroid gland should be identified along the mid to upper third of the gland, dorsal to the RLN, and reflected posterolaterally.

The middle thyroid vein is ligated and transected, and the inferior parathyroid is dissected away from the thyroid. Once the inferior pole is fully mobilized, the RLN can be readily identified distal along its course, just deep to the tubercle of Zuckerkandl. The easiest method is to find the nerve dissecting perpendicular to its course with blunt elevators (Terris Blunt Elevators, Medtronic, Minneapolis, Minn).

Once the RLN has been identified, the ligament of Berry can be divided and all remaining attachment to the trachea released.

The isthmus is ligated and divided if only a lobectomy is necessary. If a total thyroidectomy is necessary, the ipsilateral lobe may be removed or the isthmus left intact, and the procedure is repeated on the opposite side. The pyramidal lobe, if present, is removed in continuity. Once the gland is resected, hemostasis is ensured and the integrity of the RLNs and parathyroid glands are verified. Parathyroid glands that have become devascularized are reimplanted by mincing the affected gland into 1-mm pieces, then placing the pieces into a small pocket created in the anterior aspect of the sternohyoid muscle. The pocket is closed and its location marked with either a surgical staple or a nonabsorbable suture.

The strap muscles are reapproximated in the midline with a single 3-0 vicryl figure-8 suture (Ethicon, Inc, Somerville, NJ; Figure 3). The subcutaneous tissues are closed with buried interrupted 4-0 vicryl sutures, and the skin edges are sealed with tissue adhesive and horizontal ¼-inch Steri-Strips (3M Corporation, St Paul, Minn).

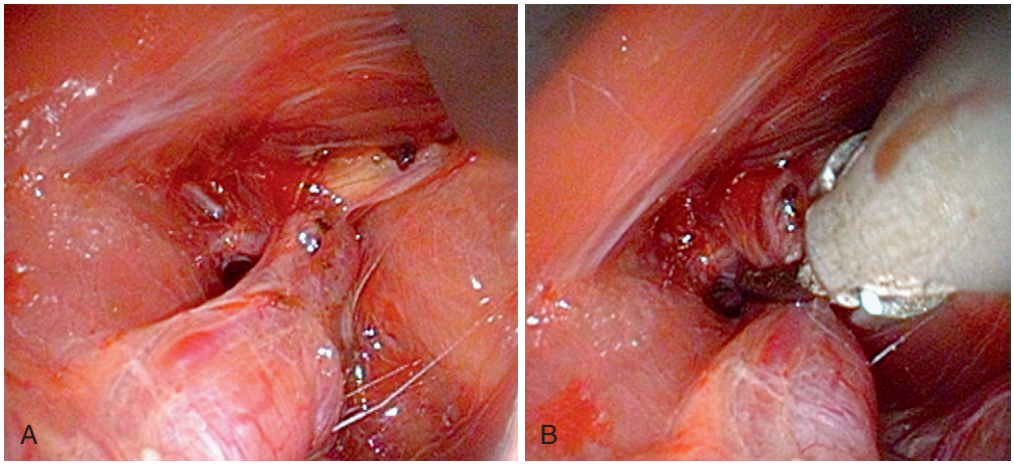

FIGURE 2 **A,** The superior vascular pedicle is isolated. **B,** The vessels are simultaneously ligated and divided immediately adjacent to the superior border of the gland with a Harmonic-ACE 23E (Ethicon Endosurgery, Cincinnati, Ohio). *(Reprinted with permission from Terris DJ: Novel surgical maneuvers in modern thyroid surgery,* Operative Techniques Otolaryngol *20(1):23-28, 2009.)*

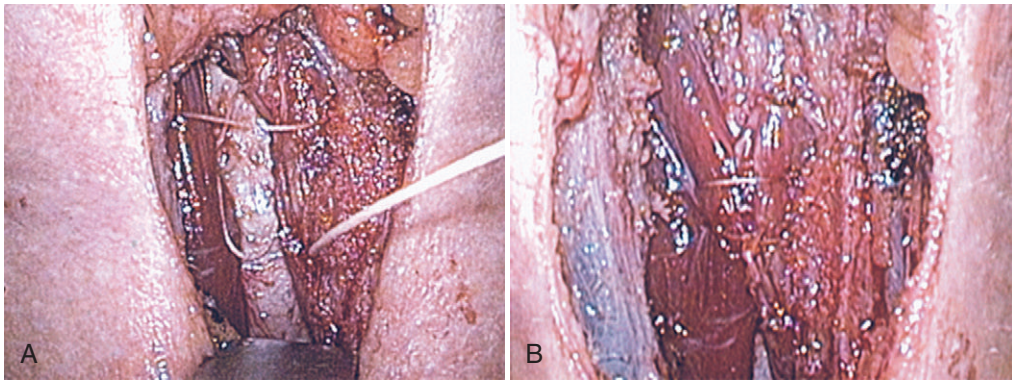

FIGURE 3 **A,** The midpoint of the strap muscles is identified. **B,** The muscles are closed with a single figure-8 3-0 vicryl suture (Ethicon, Inc, Somerville, NJ). *(Reprinted with permission from Terris DJ: Novel surgical maneuvers in modern thyroid surgery,* Operative Techniques Otolaryngol *20(1):23-28, 2009.)*

The conventional approach to thyroidectomy offers the surgeon wide exposure of the operative field. However, this procedure results in a long scar and the extent of dissection frequently necessitates drain placement and overnight hospitalization. Most patients heal well, and with proper placement, the scar fades over time and may be nearly imperceptible. Despite the acceptable long-term healing outcomes, many patients are reluctant to consent to a longer incision and are uncomfortable and inconvenienced with a drain after surgery. As technology has evolved, new techniques and approaches have emerged to mitigate the cosmetic impact and extent of dissection frequently associated with the conventional thyroidectomy technique.

Minimally Invasive Nonendoscopic Technique

The minimally invasive nonendoscopic procedure uses a smaller incision than the conventional technique and eliminates elevation of the subplatysmal flaps. A 3-cm to 5-cm incision is marked in a low cervical skin crease while the patient is awake and upright (usually in the holding area). Anesthesia is established, and the neck is maintained in a neutral position without use of a shoulder roll. An incision is made in the previously marked skin crease and carried down through the platysma, with exposure of the sternohyoid and sternothyroid muscles. The muscles are separated in the midline and retracted laterally, with liberal lateral and posterior mobilization of the thyroid gland.

The superior pole is isolated and the upper pedicle ligated as a single bundle. Care is taken to avoid injury to the superior laryngeal nerve. The superior lobe is mobilized and the superior parathyroid gland identified. The middle thyroid vein is ligated. The inferior lobe is mobilized sufficiently to identify the inferior parathyroid gland and the recurrent laryngeal nerve. The inferior pole vessels are then ligated where they enter into the capsule of the thyroid gland. The remainder of the gland is dissected off of the trachea, with the recurrent laryngeal nerve kept under direct vision. Vessel ligation and hemostasis are accomplished with the ultrasonic shears (Harmonic ACE-23P or Focus; Ethicon Endosurgery).

For unilateral lobectomy, the isthmus is divided adjacent to the contralateral lobe. When total thyroidectomy is performed, the contralateral lobe is dissected as mentioned previously. The strap muscles are approximated with a single figure-8 suture of 3-0 vicryl (Ethicon, Inc). The subcutaneous tissues and platysma muscle are closed with interrupted 4-0 vicryl sutures. The skin is closed with skin adhesive. No drain is used.

Minimally Invasive Video-Assisted Thyroidectomy

The minimally invasive video-assisted thyroidectomy (MIVAT) is similar to the nonendoscopic minimally invasive approach except that an endoscope is necessary to achieve the magnification needed to reduce the incision to below 3 cm.

A 15-mm to 20-mm low horizontal cervical incision is used. The procedure begins much like the nonendoscopic approach until the superior pole is addressed. The room lights are darkened, and a 5-mm 30-degree laparoscope is introduced into the wound to visualize the superior pole of the thyroid gland with the scope angled upward. Harmonic-ACE shears (ACE23P; Ethicon Endosurgery) are used to coagulate and divide the superior pole vessels close to the thyroid capsule.

After the middle thyroid vein is ligated and the inferior pole mobilized, the endoscope is angled downward to facilitate identification of the recurrent laryngeal nerve, which is traced for a length of approximately 20 or 30 mm. The inferior parathyroid gland is identified and dissected away from the thyroid.

The lobe is then exteriorized with liberal use of hemostat clamps placed directly on the gland itself. The recurrent laryngeal nerve is then traced to its entrance under the inferior constrictor muscle as with open surgery. The Harmonic-ACE shears are used to ligate vessels and divide tissue during this dissection. The isthmus is then divided with electrocautery or the harmonic shears.

The contralateral lobe is removed in similar fashion if indicated by clinical circumstances. Closure is the same as for minimally invasive nonendoscopic surgery, and the procedure is accomplished on an outpatient basis.

Remote Access/Robotic Thyroidectomy

Advances in robotic surgical technology now allow access to the thyroid gland through incisions placed remotely, with cosmetically conspicuous anterior cervical scars avoided. This remote access, robotically assisted surgery was originally described in South Korea with an axillary point of entry. This concept has been further refined, and now the procedure can be accomplished via a postauricular incision, similar to the facelift incisions with which most head and neck surgeons are familiar. This robotic facelift thyroidectomy (RFT) is most appropriate for patients with nodules smaller than 4 cm who have unilateral disease and are not morbidly obese.

The patient is marked sitting upright in the holding area. A proposed cervical incision is outlined in the unlikely event that conversion to open surgery is necessary. The postauricular hair is trimmed. A facelift incision is then outlined, hidden by the postauricular crease. The incision crosses over to the occipital hairline at a level that will be obscured by the ear. The incision is continued inferiorly approximately 1 cm within the occipital hairline so that it will be completely concealed once the hair grows back. The patient is placed supine on the operating table. After induction and intubation with an electromyographic endotracheal tube (for laryngeal nerve monitoring), the head is turned 30 degrees away from the anticipated side of lobectomy and supported with a soft cushion to prevent excessive neck rotation. The operating table is placed in reverse Trendelenburg's position and tilted away from the surgeon to facilitate the open dissection.

Development of an ample surgical pocket during the open dissection facilitates the robotic portion of the procedure. The open dissection involves the sequential identification of a series of structures, starting with the sternocleidomastoid muscle (SCM) and including the great auricular nerve, then the external jugular vein, then the omohyoid muscle. The omohyoid and strap muscles are retracted ventrally while all other structures remain dorsal (Figure 4). The triangle bounded by the anterior surface of the SCM, the posterior sternohyoid muscle, and the superior border of the omohyoid muscle is widely opened, providing superb access to the superior pole of the thyroid gland. A series of progressively deeper retractors is used to achieve this dissection. Once the anteromedial surface of the SCM is dissected to the clavicle, a customized retractor blade, which is compatible with the modified Chung fixed retractor system (Marina Medical, Sunrise, Fla), is introduced and placed underneath the omohyoid and the other strap muscles to maintain the operative pocket.

With the retractor fixed in position, the daVinci surgical robotic system (Intuitive Surgical Inc., Sunnyvale, Calif) is deployed. The robotic pedestal is angled approximately 30 degrees to the operating table, with its long axis parallel to the retractor system. Fine positioning adjustments are more easily made by moving the operating table rather than the robot. Three arms are used. The camera arm is positioned first, holding a 30-degree down endoscope parallel to the retractor system, or angled slightly upward. A Maryland grasper is placed in the nondominant arm, and a Harmonic device (Ethicon Endosurgery) is placed in the dominant arm. These instruments are positioned on either side of the endoscope.

The robotic phase of dissection is characterized by a step-by-step series of landmark identification. This begins with ligation of the superior vascular pedicle with the Harmonic device. The superior

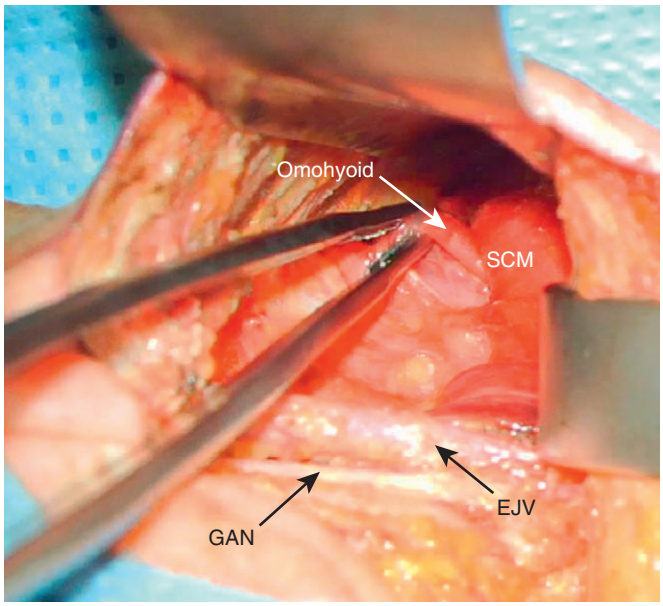

FIGURE 4 Surgical approach for robotic facelift thyroidectomy procedure. The vector of approach is superficial to the great auricular nerve *(GAN)* and external jugular vein *(EJV)*. The superior pole of the right lobe is medial to the sternocleidomastoid muscle *(SCM)* and deep to the omohyoid. *(Reprinted with permission from Terris DJ, Singer MC, Seybt MW: Robotic facelift thyroidectomy: II: clinical feasibility and safety,* Laryngoscope *121(8):1636-1641, 2011.)*

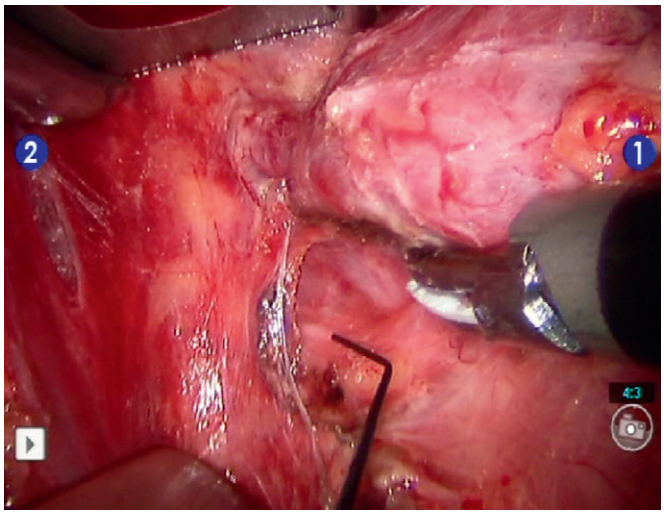

FIGURE 5 The recurrent laryngeal nerve, seen by the tip of the lower forceps, is identified under the inferior constrictor near its insertion into the larynx as the superior pole of the gland is retracted inferiorly. *(Reprinted with permission from Terris DJ, Singer MC, Seybt MW: Robotic facelift thyroidectomy: patient selection and technical considerations,* Surg Laparosc Endosc Percutaneous Techniques *21(4):237-242, 2011.)*

pole is reflected inferiorly and ventrally, and the inferior constrictor muscle is traced until the lower border is encountered. The external branch of the superior laryngeal nerve can usually be seen running along the inferior constrictor muscle. The superior parathyroid gland is visualized on the posterior surface of the thyroid and is dissected posterior-superiorly. The recurrent laryngeal nerve is seen laterally passing underneath the inferior constrictor muscle (Figure 5). After the nerve is dissected for a small distance inferiorly, the ligament of Berry may be safely divided with the Harmonic device, and the isthmus is transected at the midline. The middle thyroid vein is ligated with the Harmonic device, and then the inferior pole is fully mobilized. The inferior parathyroid gland is dissected inferiorly, and the inferior pole vessels are divided. The remaining attachments to the trachea are divided, and the thyroid lobe is retrieved.

After thorough irrigation and inspection of the thyroid bed and pocket, Surgicel (Ethicon, Inc) is placed in the thyroid compartment. The subcutaneous tissues are closed with interrupted sutures of 4-0 vicryl (Ethicon, Inc). Dermaflex skin adhesive (Chemence Medical Products, Inc, Alpharetta, Ga) is placed to seal the wound. The Quarter-inch Steri-Strips (3M Corporation) are placed horizontally along the incision.

POSTOPERATIVE MANAGEMENT

A great diversity exists in the postoperative management of patients for thyroidectomy, particularly in regards to drain utilization, calcium supplementation, the timing of postoperative discharge, and thyroid hormone replacement. Emerging evidence-based trends may help guide care during the postoperative period.

The use of drains after thyroidectomy is a long-held practice of conventional thyroid surgery. Meticulous attention to hemostasis and vessel ligation is more important for the prevention of hemorrhage, and the presence of a drain has no impact on hematoma formation. Nevertheless, some surgeons still advocate the use of drains (especially in patients with large goiters or substernal extension). Motivated patients may be instructed in outpatient drain care, eliminating their need for a protracted hospital stay. Patients may undergo follow-up in the office for drain removal.

Hypocalcemia is one of the most common complications of thyroid surgery. Transient hypocalcemia lasting less than 6 months may be seen in up to 36% of patients. Hypocalcemia may be related to excessive manipulation, devascularization or removal of the parathyroid glands, renal disease, or inadequate calcium or vitamin D intake. Patients undergoing surgery for hyperthyroidism are at increased risk for postoperative hypocalcemia. This may result from increased renal excretion of calcium and phosphorous and direct stimulation of osteoclasts by T3.

The two principal options for addressing this potential complication include: routine supplementation with calcium and vitamin D (typical dosing is a 3-week taper of calcium carbonate starting at 1 g three times a day [tid]) and serial calcium level acquisition to inform intervention.

Parathyroid hormone (PTH) levels may also be used to guide management. Patients with a postoperative PTH level greater than 30 pg/mL are at a low risk for requiring supplementation and may be observed. Patients should be counseled about the early symptoms of hypocalcemia, including perioral and distal extremity numbness and tingling. Patients experiencing these symptoms should be counseled to self medicate with calcium and to seek medical attention if they fail to resolve. In rare cases, addition of calcitrol (0.25 to 0.5 mg twice daily [bid]) may be necessary.

Although thyroid surgery has traditionally been performed on an inpatient basis, it is now clear that the vast majority of patients can be managed as outpatients. The Surgical Affairs Committee of the American Thyroid Association recently drafted a position paper providing guidance on this issue.

Finally, patients who undergo total thyroidectomy require thyroid hormone replacement. A number of considerations for arriving at an optimal starting dose exist, but the authors have found it easier to simply prescribe 100 mcg per day for most patients and allow the endocrinologist or primary care provider to titrate the level.

COMPLICATIONS

Modern thyroid surgery is generally regarded as a safe procedure; however, even experienced surgeons encounter a range of potential postoperative complications from poor wound healing and keloid formation to postoperative infections and mortality. Fortunately, most of these complications are rare. Some risks that are inherent to thyroid surgery warrant specific discussion.

Hematoma is one of the most feared complications of thyroidectomy. Although the risk is low (less than 2%), the consequences can be disastrous. Because of the relationship of the thyroid bed to the larynx, blood that is trapped beneath the strap muscles causes venous and lymphatic outflow obstruction, then supraglottic edema, then airway obstruction, then death. The best way to avoid airway compression is to close the strap muscles loosely (single point of fixation) so the blood can escape the thyroid compartment.

The most critical aspect of postthyroidectomy hematoma is early recognition. Patients may report increasing pain or dysphagia, and dyspnea and frank respiratory distress with visible neck swelling often occur later. Hematomas typically present within 24 hours of surgery, but the presentation may be delayed for even several days in some cases. The first step in management of compressive/expanding hematomas is expeditious opening of the wound to achieve decompression. The airway should be evaluated; if it is compromised, it should be secured by either intubation or temporary tracheostomy. The patient can then be returned to the operating room for exploration of the surgical field and definitive control of bleeding.

Hypocalcemia is the most common complication of thyroid surgery, with transient hypocalcemia occurring in up to 40% of patients and permanent hypocalcemia reported in as many as 15% of patients in some series. Early signs include numbness and paresthesias of the fingers and perioral region. Patients may demonstrate Chvostek's sign (facial nerve spasm when lightly tapping the cheek) or Trousseau's sign (carpal spasm when the upper arm is compressed with a blood pressure cuff). Later findings include worsening tetany, respiratory distress, mental status changes and neurologic impairments, and cardiac arrhythmias. Treatment involves rapid replacement of calcium (either orally or intravenously) and vitamin D and magnesium as indicated.

Nerve injury is an important potential complication of thyroid surgery. Injury to the SLN impairs contraction of the cricothyroid muscle, reducing the patient's dynamic pitch range. This injury rarely affects the conversational voice, and patients may be unaware of any changes until they attempt to sing. Patients with symptomatic SLN injury may benefit from speech therapy.

Recurrent laryngeal nerve injury is a more noticeable condition than SLN injury. Transient RLN injury may occur in up to 15% to 20% of patients, and permanent injury occurs in 1% to 3% of cases in expert case series. The risk of nerve transection is higher in patients with thyroid malignancy, large substernal goiters, and thyroiditis. The clinical manifestations of unilateral nerve injury depend on the extent of the damage and the ability of the patient to compensate for the injury. Injury patterns vary from asymptomatic mild paresis to complete paralysis with severe dysphonia, impaired speech fluency, and dyspnea from excess air escape. Because some patients with unilateral vocal cord paresis may be asymptomatic, consideration should be given to preoperative laryngoscopy to evaluate vocal cord mobility, especially in cases of revision or completion surgery.

Patients with unilateral paresis may be observed, treated with voice therapy, or referred for a temporary medialization procedure to improve glottic closure. An observation period of 6 to 12 months is recommended before definitive treatment. When the nerve is observed to be transected, repair should be performed. Although neurorraphy results in synkinesis and fails to produce meaningful movement of the vocal cord, it helps to maintain the bulk and tone of the cord, which helps to maintain the voice.

Bilateral RLN injury is a much more serious condition. The RLN provides innervation to the posterior cricoarytenoid muscles, which are the sole abductors of the vocal cords. Injury to both RLNs may result in acute airway obstruction. The patient may need immediate reintubation or urgent tracheostomy until a more definitive procedure to open the airway can be performed by an otolaryngologist.

Recurrent hyperthyroidism may occur in patients who undergo less than total thyroidectomy for surgical treatment of disease. Although very rare in the case of a solitary toxic adenoma, up to 2% of patients undergoing subtotal thyroidectomy for Graves' disease or toxic multinodular goiter may have recurrence of hyperthyroidism. The incidence rate of this complication should be close to zero for patients who undergo total thyroidectomy.

CONCLUSION

Medical treatment with antithyroid drugs and RAI therapy are the primary treatment modalities for treatment of hyperthyroidism in the United States. Surgery may be an appropriate option and provides a more durable cure in selected patients. Care should be taken to achieve a euthyroid state before surgery whenever possible. Complications are low when the surgery is performed by experienced surgeons with meticulous adherence to surgical principles. Surgical techniques continue to evolve, particularly with the advent of new technologies, and may make surgery easier, faster, or safer. Nevertheless, careful vigilance for complications and early intervention is mandatory. Recent advances continue to advance this surgical discipline, making it safer and more cosmetically acceptable to a growing number of patients.

Surgical Approach to Thyroid Cancer

Tammy M. Holm, MD, PhD, Diana Caragacianu, MD, and Gregory W. Randolph, MD

BACKGROUND

Goiter has been described since ancient times, with the first surgical resection recounted by Paulus in 500 AD. Initially a bloody, disordered procedure with significant morbidity and mortality, the surgery has since evolved in large part through the seminal work of Theodor Kocher, the father of modern thyroid surgery. Today, thyroidectomy is a precise, elegant operation with low operative morbidity and virtually nonexistent mortality.

Although nodular thyroid disease is relatively common, existing in approximately 4% to 7% of the general population with palpation criteria and up to 50% of elderly adults with ultrasound scan criteria, only 5% of these nodules are ultimately found to be malignant. Thyroid malignancies are thus relatively rare and constitute only 2% of all cancers. The incidence of thyroid cancer has been increasing at a higher rate than any other cancer in the United States. Study of the Surveillance, Epidemiology and End Results (SEER) database has revealed a 2.4-fold increase in thyroid cancer between 1973 and 2002. The National Cancer Institute (NCI) estimates 56,460 new cases of thyroid cancer in 2012 alone.

Thyroid cancers are generally classified into follicular cell-derived and nonfollicular cell-derived variants based on their cell type of origin (Table 1). Papillary thyroid cancer (PTC), follicular cancer (FC), Hürthle cell cancer (HCC), and anaplastic cancer (AC) are considered to be follicular cell-derived, whereas medullary thyroid cancer (MTC) and lymphoma are nonfollicular cell-derived. A detailed discussion of the characteristics of these different thyroid cancers is beyond the scope of this surgically oriented text, and the reader is referred to the Suggested Readings section for further details. However, the authors stress the importance of a basic understanding of the epidemiology, histopathology, clinical behavior, and prognosis of these thyroid cancers in evaluating, managing, and counseling affected patients (see Table 1).

PTC is far and away the most common thyroid cancer, comprising approximately 80% of all thyroid cancers. PTC may be associated with several hereditary diseases or syndromes, such as familial adenomatous polyposis (FAP), Gardner's syndrome, Cowden disease, Werner's syndrome, and Carney's complex, all of which should raise the index of suspicion for PTC in any patient presenting with a thyroid mass. PTC, FC, and HCC are also classified as well-differentiated thyroid cancers (WDTCs), which like other histologically well-differentiated cancers, generally have a relatively indolent course, with rather high 10-year survival rates. WDTC arises from the follicular cells of the thyroid gland and shares ionizing radiation as a common risk factor, an important piece of history to ascertain during the initial workup. As a whole, these slow-growing nonaggressive WDTCs account for approximately 95% of all thyroid malignancies. Staging for WDTC as described by the American Joint Committee on Cancer Staging (AJCCS) is unique in that age is a factor in determination of stage. Stage II is the highest possible stage in patients under the age of 45 years old. Tumor size, extrathyroidal spread, lymph node involvement, and metastatic disease allow for further classification in older patients. Notably, tumor node metastasis (TNM) staging is intended to provide information regarding survival and does not reliably predict disease recurrence, which, given the relatively indolent nature of WDTC, is the more clinically relevant endpoint as compared with mortality.

MTC, AC, and lymphoma are, in contrast, more aggressive malignancies with poorer prognoses. MTC is notable for its association with the multiple endocrine neoplasia (MEN), types 2A and 2B. Familial medullary thyroid carcinoma (FMTC) is now considered a variant form of MEN 2A. A diagnosis of medullary thyroid cancer should therefore be entertained in patients with a thyroid mass and family history of MTC. Moreover, MTC or the potential for MTC should be considered in any patient with stigmata of MEN 2A and 2B, such as pheochromocytoma, hyperparathyroidism, or mucosal neuromas.

The treatment of all thyroid cancers with the intention of cure is based on the foundation of complete surgical excision vis-à-vis total thyroidectomy. The plan and extent of surgery, however, depends on the type of thyroid cancer, locoregional spread, and the presence of distant metastatic disease.

DIAGNOSIS AND SURGICAL MANAGEMENT

Patients with thyroid cancer typically present with a palpable thyroid nodule. Surgical management of thyroid cancer is determined in large part by histologic data obtained from fine-needle aspiration biopsy (FNAB) of the thyroid nodule. The six distinct categories of thyroid fine-needle aspiration (FNA) cytology on which surgical management may be based are: (1) benign; (2) nondiagnostic; (3) suspicious for follicular/Hürthle neoplasm; (4) atypia of undetermined significance/follicular lesion of undetermined significance; (5) suspicious for malignancy; and (6) malignant.

With clearly benign cytology, surgery is usually deferred and serial ultrasound scan surveillance is appropriate. In some cases (i.e., when the nodule is particularly large [>4 cm] or the patient desires removal), lobectomy may be considered. For nondiagnostic results, repeat aspiration with ultrasound scan–guidance is warranted because half of all repeated aspirates are diagnostic. If multiple attempts at biopsy are nondiagnostic, core needle biopsy or diagnostic lobectomy should be considered. Patients should be counseled that approximately 10% of such nodules are malignant.

FNAB results that are suspicious for follicular or Hürthle cell cancer require resection of the nodule with hemithyroidectomy. Intraoperative frozen section is generally unreliable for confirmation of FC or HCC and is not recommended for a real-time confirmation of the cancer diagnosis because the issue of vascular invasion cannot be definitively settled with limited section and analysis available during frozen section. Approximately 20% of patients need second stage completion thyroidectomy for final histopathologic diagnosis of FC or HCC. In cases of significant contralateral lobe nodularity, history of head and neck radiation, or substantial perceived risk with a second anesthesia, total thyroidectomy can be recommended at the first operation.

Atypical or follicular lesions of undetermined significance have a 5% to 10% risk of malignancy. If repeat biopsy fails to clarify the diagnosis, lobectomy with or without intraoperative frozen section is warranted. In follicular lesions that are described as microfollicular with reduced colloid but no nuclear abnormalities, diagnostic lobectomy without frozen section is justified. In such lesions, if substantial nuclear abnormalities are noted, the potential for PTC exists. In these cases, frozen section analysis during lobectomy may be warranted because papillary cancers can be diagnosed in some of these cases on touch prep during frozen section analysis.

In addition to preoperative FNA, thyroid function blood testing studies are mandatory. The authors believe that all patients undergoing thyroid surgery must undergo preoperative laryngeal

TABLE 1: Thyroid cancer overview

	Cell of origin	FNA or histologic characteristics	Mean age at presentation (y)	Female:Male ratio	10-Y survival rate	Metastases	Response to RAI	Risk factors
Papillary (80%)	Follicular cell	Orphan Annie Eye nuclear changes, psammoma bodies*	40-50	3:1	>90%	Bone, lung (only 5% at time of presentation)	Yes	Ionizing radiation
Follicular (11%)	Follicular cell	Microfollicular pattern with reduced colloid cytologically with capsular invasion†	50-60	3:1	85%-92%	Lung, bone, brain (approximately 15% at time of presentation)	Yes	Iodine deficiency, ionizing radiation
Hürthle (3%-4%)	Follicular cell	>75% Hürthle cells‡ with capsular invasion†	50-60	2:1	75%	Lung, bone, CNS	Variable	Ionizing radiation
Medullary (5%-10%)	Parafollicular C cells	Uniform polygonal cells with fine, granular eosinophilic cytoplasm staining for calcitonin	30-40, 10 for MEN2B	1:1	70%-90%	Lung, liver, bone, brain	No	Family history, RET mutation
Anaplastic (1%-2%)	Follicular; dedifferentiated thyroid cancer	Spindle, giant, and squamoid cells	70-80	2-3:1	5%-10%§ at 5 y	Lungs, bone, brain	No	May arise from preexisting goiter or cancer
Lymphoma (1%-5%)	B/T cells	Multiple subtypes	60-80	3-4:1	50%-70%	–	No	Hashimoto's thyroiditis

§Survival at 5 years.

examination to determine vocal cord functional status. This is especially true in cases of past thyroid, parathyroid, or other surgery that may have jeopardized the recurrent or vagus nerves. It is also important in all cases of thyroid malignancy given the potential for invasive disease. One must note that not all vocal cord paralysis is symptomatic, and so only routine laryngeal examination identifies all cases of preoperative vocal cord dysfunction. This information is of dramatic importance in the conduct of the subsequent surgery and in an operative plan that avoids bilateral vocal cord paralysis as an outcome. Preoperative workup must also include evaluation of cervical spine pathology (arthritis, degenerative joint disease, atlantoaxial subluxation, etc.) to allow for appropriate positioning for resection. Preoperative radiographic evaluation with ultrasound scan of the neck for assessment of not only the thyroid gland but also pathologically enlarged lymph nodes suspicious for metastasis should be performed. In the case of WDTC, only evidence of lymph node macrometastases serves as an indication for compartmental neck dissection (i.e., central neck dissection or ipsilateral lateral neck dissection).

Approximately 60% to 80% of aspirates read as suspicious for PTC are positive. Lobectomy for removal of the thyroid nodule followed by total thyroidectomy as a single-stage procedure when frozen section findings are consistent with malignancy is recommended. Total or near total thyroidectomy is currently recommended by the American Thyroid Association (ATA) for management of PTC of more than 1 cm in the absence of surgical contraindications. The National Comprehensive Cancer Network (NCCN) recommends total thyroidectomy for all patients with biopsy-proven PTC and any one of the following criteria: (1) age less than 15 years or greater than 45 years; (2) radiation history; (3) known distant metastases; (4) bilateral nodularity; (5) extrathyroidal extension; (6) tumor with greater than 4 cm diameter; (7) cervical lymph node metastases; or (8) aggressive histologic variant.

Total thyroidectomy coupled with remnant radioactive iodine ablation allows for easier detection of nodal or metastatic recurrent disease. The rationale for and primary goal of total thyroidectomy in the setting of malignancy is to remove the gross primary tumor in its entirety along with any associated locoregional macroscopic nodal disease. Approximately 35% of patients presenting with PTC have macroscopic nodal disease at presentation. Ultrasound scan and, in some centers, axial computed tomographic (CT) scanning are tools to preoperatively map out nodal disease in both central and lateral compartments so that a rational surgical nodal plan can be developed. Microscopic nodal disease may be present in up to 80% of patients with PTC. Most believe such microscopic disease is of little significance and does not require prophylactic compartmental surgery.

Biopsy results read as suspicious for or diagnostic of MTC, AC, or lymphoma require further workup for appropriate management. All patients with suspected or confirmed MTC should undergo preoperative evaluation to exclude associated genetic disease (i.e., MEN 2A/B). Approximately one quarter of all MTC cases are hereditary; the remainders are sporadic. Sporadic disease tends to be more unilateral (68%), and familial disease tends to be bilateral or multifocal (94%) and usually presents at an earlier age.

Workup of MTC includes screening for pheochromocytoma and hyperparathyroidism and serum calcitonin, carcinoembryonic antigen (CEA), RET protooncogene analysis, and neck ultrasound scan with lymph node mapping. Patients with palpable lymph nodes or serum calcitonin greater than 150 to 400 pg/mL should undergo further imaging (CT scan of neck, chest, abdomen) to evaluate for distant metastatic disease.

Total thyroidectomy with compartment-oriented nodal dissection is the mainstay of therapy for MTC. Prophylactic thyroidectomy is recommended within the first year of life for children with MEN 2B and between 3 and 5 years of age in children with MEN 2A and familial MTC. The exact timing of prophylactic thyroidectomy relates to the risk of malignant transformation within C cell clones and the likelihood of the development of nodal disease. The ATA has made recommendations as to the timing of prophylactic thyroidectomy based on the risk for these events as it relates to the specific codon mutation. Pheochromocytoma must be evaluated for and, if present, must be addressed before thyroid resection.

In the case of FNAB suspicious for anaplastic thyroid cancer, early recognition and intervention is vital. Because of extensive necrosis, isthmectomy may be required to provide a tissue diagnosis and should not be delayed. Isthmectomy may need to be combined with tracheostomy depending on airway status, which can quickly deteriorate. Although palliative tracheostomy was once standard of care for all patients with unresectable disease, more recent data suggest that tracheostomy does not improve survival or quality of life in all patients. Today, the authors recommend palliative tracheostomy selectively in patients whose respiratory compromise is imminent and unresponsive to steroids.

The role for surgery is limited in anaplastic thyroid cancer (ATC) because of advanced disease at presentation. A large burden of distant metastases is a contraindication to surgery, although neoadjuvant radiation may transition inoperable disease to resectable disease. In the best case scenario, a full resection may be performed, followed by a full course of radiation therapy (XRT) 2 to 4 weeks after surgery. Positron emission tomography (PET)/CT scan should be performed on completion of XRT, with subsequent initiation of chemotherapy with paclitaxel or another taxane. Monthly restaging should be continued during chemotherapy and then every other month if the patient remains disease free for 6 months. After 2 years without recurrence, attention may be returned to underlying remnant PTC/FC and remnant radioactive iodine ablation (RRA) may begin.

Given the rapidly fatal progression of unrecognized ATC and the similarities in presentation between ATC and lymphoma, distinguishing the two processes is paramount for appropriate management. Definitive diagnosis is made with flow cytometry and occasional core needle biopsy. Open biopsy with isthmectomy is usually necessary for determination of the specific cell type of lymphoma. Surgery is otherwise not indicated for management of lymphoma, which is a medically managed entity. Thyroid lymphoma is generally sensitive to chemoradiation (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone [R-CHOP], 40 to 60 Gy). Typically, patients undergo one cycle of R-CHOP followed by radiation and five additional cycles of R-CHOP.

Although results of FNAB largely drive the surgical management of thyroid cancers, these results must also be considered in the context of the patient's clinical picture as a whole for appropriate surgical decision making. Additional clinical parameters regarding the extent of thyroidectomy include: (1) age of the patient, given increased risk of malignancy in patients over 60 years and under 20 years; (2) gender of the patient, with males generally having increased risk of malignancy; (3) family history of thyroid malignancy; (4) personal history of exposure to ionizing radiation; and (5) rapidly growing thyroid mass. Qualities such as size, firmness, and fixation of the thyroid mass, nodal disease, and vocal cord paralysis are also important indicators of malignant potential.

SURGICAL APROACH

The goals of effective operative therapy are constant between all types of thyroid cancer: (1) effective treatment of the disease; (2) minimized long-term side effects and complications; and (3) minimization of postoperative discomfort. The overriding principle is to encompass all gross disease and neck nodes at first resection, understanding that microscopic disease in the contralateral lobe and nodes likely has little significance towards overall survival. The extent of thyroidectomy is tailored to the patient's risk group (as detailed previously), intraoperative findings, and the progress of the surgery itself, particularly in cases where the contralateral lobe is not involved by cancer. Resection should always begin on the side of the nodule or the side with the most disease burden. Because injury to the

recurrent laryngeal nerve (RLN) on one side may be an indication for aborting a total thyroidectomy, initiation of the thyroidectomy on the affected side ensures that most, if not all, gross disease can be resected regardless of RLN injury.

For appropriate identification and preservation of the recurrent laryngeal nerves, nerve monitoring is recommended. Good communication between the anesthesiologist and surgeon is vital to ensuring a smooth case and postoperative recovery. The patient should be positioned supine with arms tucked and padded. The neck should be extended with the assistance of inflatable balloon or shoulder roll (Figure 1). The patient should then be placed in reverse Trendelenburg's position to reduce venous pressure. After positioning, the surgeon should assess the monitor for appropriate impedance value (<5 kΩ) and event threshold (100 μV) with the stimulator probe set at 1 to 2 mA. No paralytics should be used after induction to allow for appropriate nerve monitoring during surgery. This last point should be specifically vocalized and stressed to the anesthesia team. Once the team is satisfied that the patient is appropriately positioned and the nerve monitor is suitably situated and functional, the skin should be prepared from chin to sternum and bilateral neck to lateral clavicles in standard sterile fashion. The field should be draped to include the chin, bilateral neck, and suprasternal notch.

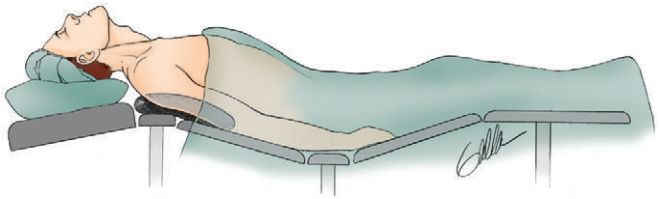

FIGURE 1 The neck is extended with a shoulder roll but adequately supported with a sponge donut. Twenty degrees of reverse Trendelenburg's position is maintained to avoid venous engorgement in the neck. *(From Randolph GW:* Surgery of the thyroid and parathyroid glands, *Philadelphia, 2002, WB Saunders.)*

The authors find it helpful to consider thyroidectomy as a logical sequence of steps progressing through the neck from anterior/ventral to posterior/dorsal. A small, 4-cm to 5-cm horizontal incision should be placed within a natural skin fold of the neck approximately 1 fingerbreadth below the cricoid cartilage's anterior arch. The platysma is then incised, reflecting a flap superiorly, with care taken to preserve the anterior jugular veins. The strap muscles are then encountered and divided along the midline raphe. Special attention is paid to the ease with which the strap muscles are dissected from the ventral aspect of the gland, with consideration of malignant infiltration in cases of difficulty. In cases where better exposure is required, the authors recommend dividing the strap muscles superiorly to prevent denervation. Continuing laterally, the middle thyroid vein is divided, which, together with lateral retraction of the strap muscles and sternocleidomastoid muscle (SCM), exposes the lateral thyroid region (Figure 2).

With use of a dry sponge to prevent slippage, the thyroid and larynx are retracted medially, with the thyroid rotated slightly up and over the trachea, to expose the parathyroid and RLN (Figure 3). The dissection is then continued inferiorly, with the inferior thyroid veins ligated to allow for visualization of the inferior parathyroid gland,

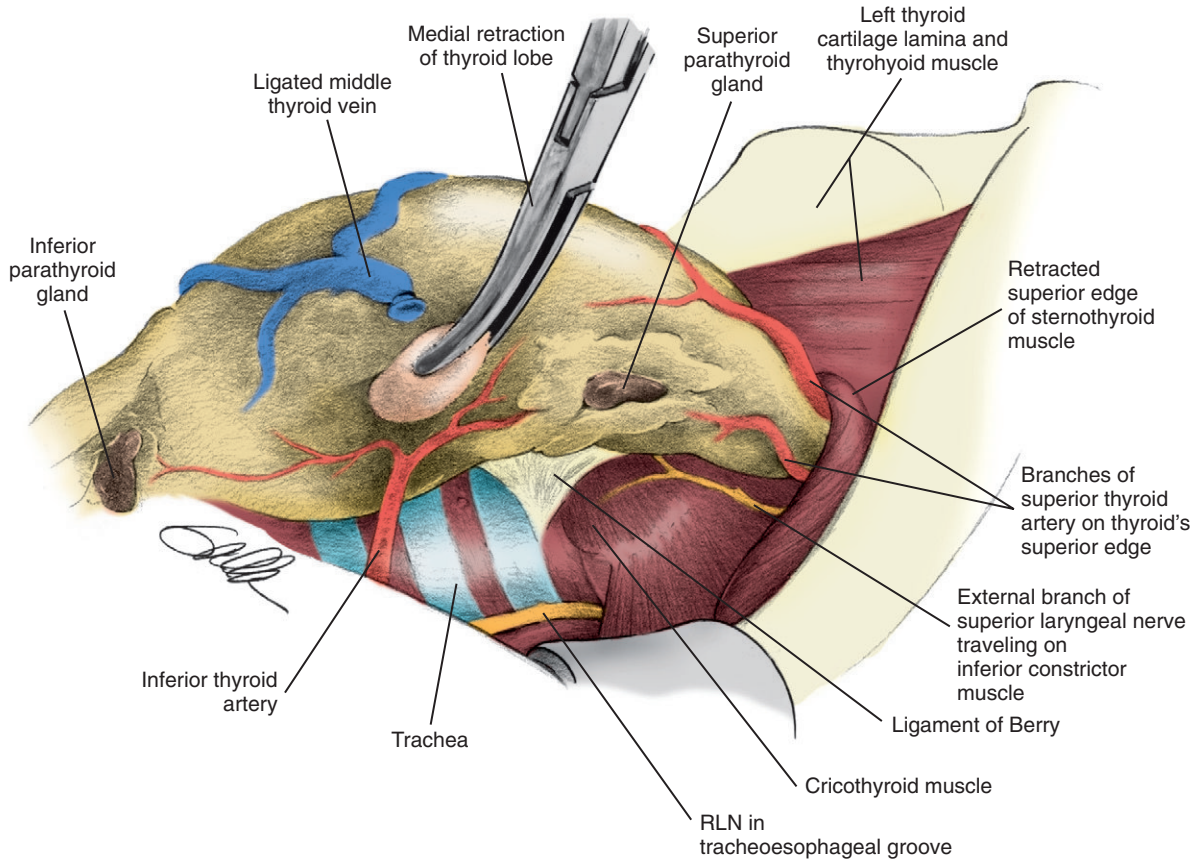

FIGURE 2 Left lateral view of lateral thyroid region shows exposure. Exposure of the region is facilitated by ligation of the middle thyroid vein and lateral retraction of strap musculature. Once this is performed, the thyroid lobe is retracted medially. As this is done, deeper anatomy, including the inferior thyroid artery, parathyroid glands, and recurrent laryngeal nerve *(RLN),* becomes apparent. *SLN,* superior laryngeal nerve. *(From Randolph GW:* Surgery of the thyroid and parathyroid glands, *Philadelphia, 2002, WB Saunders.)*

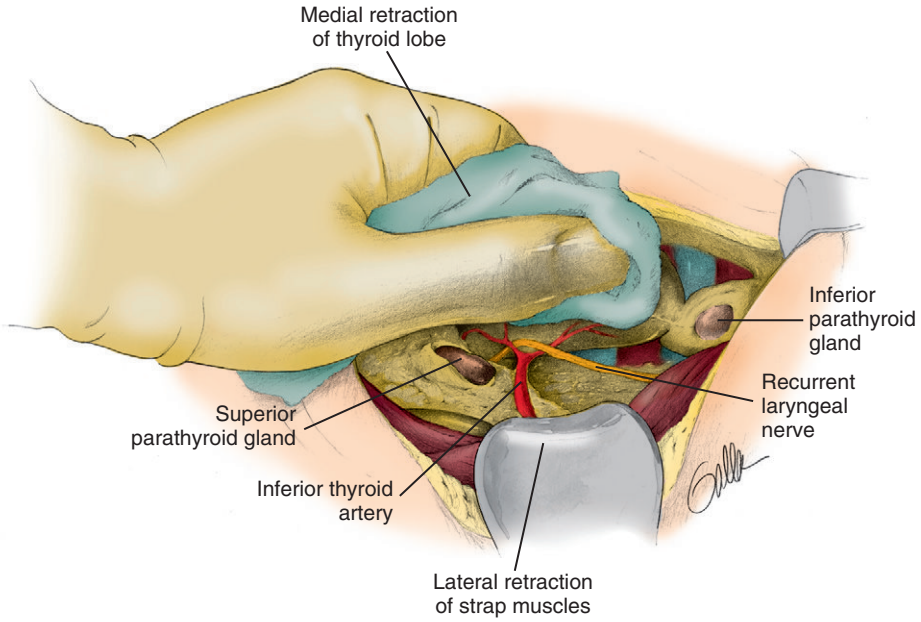

FIGURE 3 Appropriate traction on the thyroid gland in an anteromedial direction places the inferior thyroid artery under tension and facilitates exposure of the recurrent laryngeal nerve. The inferior parathyroid is usually located anterior to the nerve and approximately 1 cm inferior to the point at which the inferior thyroid artery crosses the nerve. The superior parathyroid gland is usually located superior to the inferior thyroid artery and posterior to the nerve, where it passes deep to the inferior constrictor muscle. *(From Randolph GW:* Surgery of the thyroid and parathyroid glands, *Philadelphia, 2002, WB Saunders.)*

which is usually situated anterior/ventral to the RLN just below the point at which the inferior thyroid artery crosses over the RLN. Visual identification of the RLN is confirmed with the nerve stimulator, and then the inferior thyroid artery is divided, with care taken to preserve the blood supply to the inferior parathyroid. With the inferior lobe freed before dissection of the superior pole, better lobe mobilization is facilitated and greater visualization is allowed of the superior pole region and the external branch of the superior laryngeal nerve (EBSLN), which supplies motor function to the cricothyroid muscle.

With dissection of the RLN superiorly, the ligament of Berry is encountered; this anchors the thyroid to the inferior aspect of the cricoid cartilage. Great care must be taken to avoid RLN injury at this point in the dissection because varying degrees of thyroid tissue may infiltrate the ligament, bringing thyroid tissue directly adjacent to the nerve, which lies deep to the ligament. Remember the less than 1% risk of a nonrecurrent right-sided nerve that is at risk for injury in this location. The superior pole vessels are divided individually, low on the thyroid to avoid damage to the EBSLN (Figure 4). After ligation of the superior pole vessels, the superior parathyroid should be seen at the ligament of Berry and tubercle of Zuckerkandl. Meticulous hemostasis is achieved with gentle pressure; clamping should be avoided until the RLN has been identified and confirmed. Pledgets soaked in diluted epinephrine or fine-tipped bipolar cautery may also be used.

Once the superior and inferior aspect of the thyroid lobe is freed, the thyroid lobe can be sharply dissected from trachea. The thyroid may be removed with or without isthmus division. In hemithyroidectomy, the isthmus and pyramidal lobe are taken as part of the final specimen. Special care must be taken with dissection of the ligament of Berry, pyramidal lobe, and the superior pole because these are the sites where thyroid remnants most frequently occur.

Once the specimen has been removed, the authors examine the neck for nodal disease visually and with palpation and reassess parathyroid viability. If the parathyroids appear marginal, they should be biopsied for confirmation and then reimplanted in the SCM. By invoking the mantra, "Every parathyroid is the only parathyroid," we continually remind ourselves of the importance of meticulous dissection and preservation, thereby reducing our risk for injury.

Once the thyroid has been removed, hemostasis is assessed for through irrigation and intermittent sustained Valsalva's maneuver to at least 30 mm Hg. Any sites of bleeding may be controlled with bipolar cautery, once again with care taken to avoid RLN injury. The

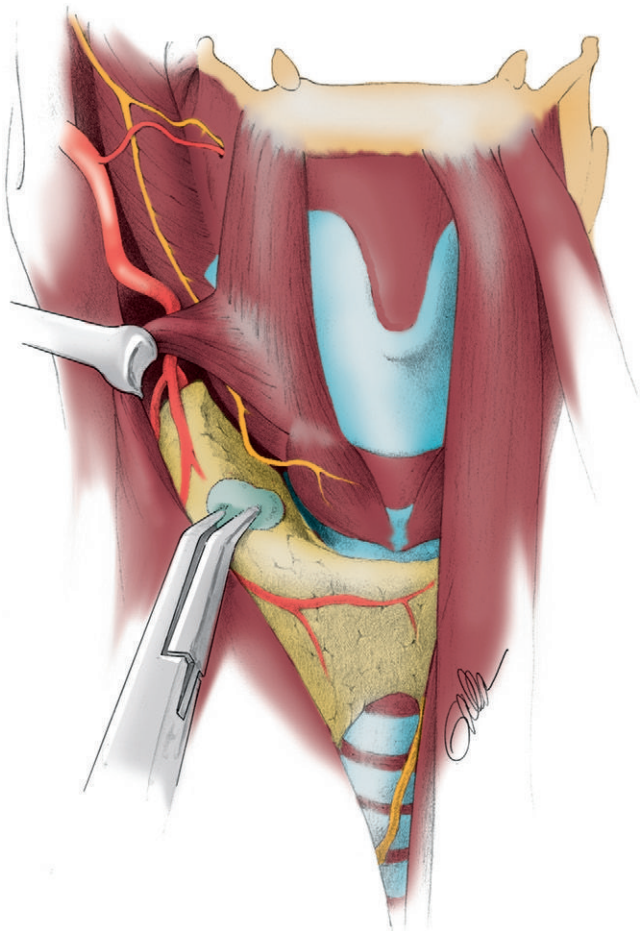

FIGURE 4 The external branch of the superior laryngeal nerve must be protected during dissection of the superior pole and ligation and division of superior pole vessels. The superior pole vessels are ligated and divided directly on the thyroid capsule of the superior pole to avoid inadvertent injury to the external laryngeal nerve. *(From Randolph GW:* Surgery of the thyroid and parathyroid glands, *Philadelphia, 2002, WB Saunders.)*

strap muscles are then reapproximated, with an open space kept inferiorly to allow for drainage in the rare case of hematoma. The platysma is then closed, followed by the skin. Drains are generally not indicated.

RECURRENT LARYNGEAL NERVE MONITORING

Recurrent laryngeal nerve trauma is one of the most serious complications of thyroid and parathyroid surgery. Unilateral vocal cord paralysis can result in vocal changes severe enough to necessitate change in vocation, significant dysphagia, and pulmonary complications. Bilateral vocal cord paralysis is a surgical emergency because of loss of airway. Rates of injury to the RLN are generally reported at 2% to 5%, although a systematic review of more than 25,000 patients showed an average of immediate postoperative vocal cord paralysis of 10%. Surgical exposure and visualization of the RLN is the gold standard of injury prevention and has been shown to lower the incidence rate of nerve injury to less than 1% in benign thyroid disease. Intraoperative nerve monitoring (IONM) is a valuable adjunct to visual nerve identification, serving as an aid to dissection and mapping of the RLN and as a tool to prognosticate the function of the nerve at the end of surgery.

The potential for unrecognized RLN injury, even in the setting of visual identification, is particularly high in cases of malignancy, substernal goiter, and revision surgery. Neural stimulation is superior to visual inspection in determination of intraoperative injury. Hence, intraoperative monitoring to establish functional status of the nerve remains an important tool for timely identification of injuries, especially in the context of bilateral surgery. Although the positive predictive value (PPV) varies in the literature from 10% to 90%, with an average of 45%, the PPV increases as a result of routine application of neural monitoring. In addition, aggressive endotracheal tube placement and troubleshooting algorithms can increase the PPV to 75% or higher.

Various intraoperative methods of monitoring the RLN exist, including continuous electromyography (EMG) monitoring, stimulation-evoked EMG monitoring, surface endotracheal tube–based EMG monitoring, and hook wire electrodes. The authors found the noninvasive surface electrode system with intermittent stimulation-evoked EMG monitoring ideal, accurate, and simple to use. On the basis of normative parameters of EMG amplitude and threshold, intraoperative EMG criteria can be formulated, which, when present, imply normal vocal cord function after surgery. These criteria are divided into: (1) initial/setup criteria, which inform the surgeon that the nerve has been appropriately identified and that the monitoring system is working; and (2) final/prognostic EMG parameters, which if satisfied, correlate with normal vocal cord function after surgery (Box 1).

IONM is a safe and reliable technique that can be predictive of and may lessen the risk of RLN morbidity by guiding intraoperative surgical decision making. Recognition of intraoperative EMG signal change can allow reexploration of the nerve to identify any site of potential injury and staging of the second side to avoid potential bilateral cord paralysis and airway compromise.

BOX 1: Recurrent laryngeal nerve (RLN) monitoring: prognostic function

Electrophysiologic Findings That Predict Normal Postoperative Vocal Cord Function

A. Initial Setup Criteria
 Average initial stimulation at 1 mA, 900 μV (range, 144 to 2050 μV)

B. Final Prognostic Criteria
 Final average stimulation at 1 mA, 1200 μV (range, 247 to 3607 μV)
 Final average threshold at 0.37 mA (range, 0.15 to 0.80 mA)

If A and B are met, expect normal postoperative vocal cord function; contralateral surgery can be considered.

If A and B are not met, consider neural injury, especially if there is a gradient of evoked waveform around possible injured segment with less than 100 μV for evoked EMG proximal to injury.

If RLN injury is considered via stretch in upper mediastinum with substernal goiter, then test ipsilateral vagus to ensure that entire ipsilateral circuit is intact.

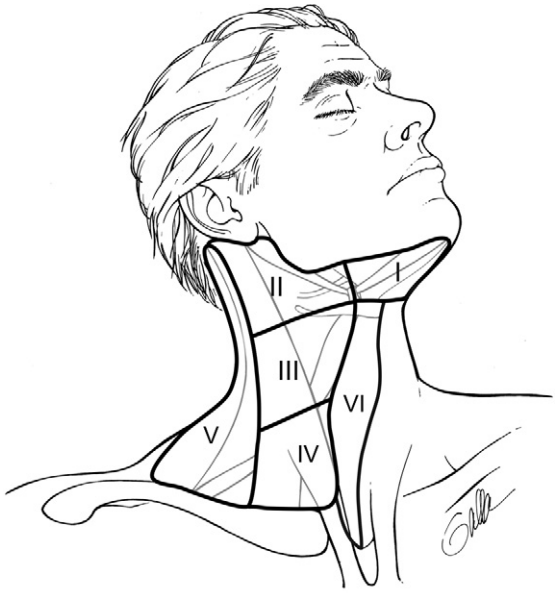

FIGURE 5 The level system for describing location of lymph nodes in the neck. *Level I,* Submental and submandibular group; *level II,* upper jugular group; *level III,* middle jugular group; *level IV;* lower jugular group; *level V,* posterior triangle group; *level VI,* anterior compartment group. *(With permission from Janfaza P, Nadol JB, Galla RJ, et al, editors:* Surgical anatomy of the head and neck, *Philadelphia, 2001, Lippincott Williams & Wilkins.)*

LYMPH NODE DISSECTION

The lymph nodes of the neck are divided into six levels (Figure 5). In thyroid cancer, the pertinent levels are the central (level VI) and lateral (levels II to IV) neck. Nodal malignancy is most frequently found within the central compartment. The central neck includes the prelaryngeal, pretracheal, and paratracheal nodes extending from the hyoid bone superiorly to the suprasternal notch inferiorly and the carotid arteries laterally. The anterior border of the lateral neck is comprised of the lateral edge of the carotid sheath, and the posterior border is the posterior border of the SCM. The superior border is the skull base, and the inferior border is the clavicle. The level V nodes make up the posterior triangle between the posterior border of the SCM and the anterior border of the trapezius muscle. The apex of these muscles forms the superior border; the clavicle lies inferiorly.

Central neck dissection involves removal of all nodes and fibrous fatty tissue within level VI. Modified lateral neck dissection involves removal of all nodes and fibrous fatty tissue within levels II to V, with preservation of the spinal accessory nerve, the internal jugular vein,

and the sternocleidomastoid muscle in the absence of malignant invasion. Nodal thyroid metastases in the lateral compartment do not frequently invade these structures; therefore, avoidance of their removal remains oncologically sound.

Therapeutic resection of clinically positive nodal metastases, identified either with ultrasound scan, CT scan, or palpation, by compartment-oriented resection has been shown to decrease subsequent nodal recurrence. "Berry picking" selected lymph nodes is associated with higher rates of regional node recurrence and is no longer recommended.

Although clear evidence exists for therapeutic lymph node dissection, prophylactic dissection for WDTCs, which commonly metastasize to the central and lateral neck (i.e., PTC and HCC), remains controversial. Both the ATA and NCCN recommend consideration of prophylactic resection in patients at high risk as defined by age older than 45 years old, male gender, increased invasiveness or extent of disease, and size larger than 4 cm. Proponents for prophylactic resection argue that preoperative ultrasound scan fails to identify up to 50% of malignant lymph nodes and that their identification may alter postoperative management, including the implementation of RRA. Opponents for prophylactic resection argue that the risk for recurrent nerve injury and hypoparathyroidism outweigh an unclear benefit given the low rate of development of clinical disease in the neck despite high rates of micrometastatic disease. Moreover, should clinically significant disease develop subsequent to thyroidectomy without lymph node dissection, the risk of injury to the recurrent nerve or parathyroid glands is no different between primary and reoperative central neck dissection in skilled hands.

OPERATIVE OUTCOMES

Complications of thyroid surgery include nerve injury (RLN, EBSLN), hypoparathyroidism, and bleeding or hematoma. In general, morbidity from thyroidectomy remains low with even further reduction of complications when performed by experienced thyroid surgeons. Hypoparathyroidism, as defined by calcium levels less than 8 mg/dL within 6 months of thyroidectomy, occurs in 1% to 6.5% of patients. Experienced centers report hematoma rates at less than 1%.

POSTOPERATIVE MANAGEMENT

Postoperative RRA destroys residual microscopic disease and removes remnant thyroid tissue to facilitate thyroglobulin monitoring as a proxy for recurrent disease. Although the recurrence and mortality benefit in patients at low risk is unclear, consistent benefit has been shown in patients with high-risk WDTC. As such, RRA is recommended in select patients with incomplete resection, aggressive histology, and extrathyroidal, nodal, or distant metastases.

Thyroid-stimulating hormone (TSH) stimulates follicular cell growth, invasion, and angiogenesis. Thyroid hormone replacement both suppresses TSH production and prevents the development of hypothyroidism. Standard dosing begins at 2 μg/kg/d and is titrated according to TSH level. The recommended level of TSH suppression is determined by primary tumor stage.

Well-differentiated thyroid cancer recurs in approximately 10% to 30% of patients after initial treatment, with the majority recurring within the first 2 years. Surveillance includes physical examination, ultrasound scan, and measurement of thyroglobulin and TSH levels every 6 months for 2 years and then annually if the patient remains disease free. Most patients have recurrent disease develop in the neck alone, and 20% have recurrence develop with distant metastases, typically the lung or bone. Approximately half of patients who undergo a second operation are rendered disease free.

In contrast to WDTC, postoperative RRA, external beam radiation, hormone suppression therapy, and chemotherapy are not effective in MTC. More than half of the patients with MTC and palpable tumor have nodal metastases at presentation, most frequently to the central neck. Serum calcitonin is a sensitive and specific tumor marker for disease and is also useful for follow-up surveillance. A direct correlation is found with calcitonin level and tumor mass.

Surveillance of MTC includes monitoring of calcitonin and CEA levels after surgery and then semiannually. If calcitonin is high, a metastatic workup should be initiated and can include CT scan of the neck, chest, abdomen, and pelvis.

In patients with advanced local disease and extensive distant metastases, palliation is the goal with preservation of the airway and speech and swallowing capabilities. Current clinical trials are exploring the benefit of external beam radiation (EBRT) for bone metastases and hepatic embolization in the case of liver metastases. Targeted molecular therapies are also being explored for systemic management of disease. Tyrosine kinase inhibitors (TKIs) make up the majority of current immunotherapy-based treatments and include sorafenib, which selectively targets RET, and vandetanib, which targets vascular endothelial growth factor receptor and epidermal growth factor receptor and RET.

Unfortunately, ATC remains a rapidly fatal disease, with median survival ranging between 3 and 5 months. The 5-year survival rate is approximately 5% to 10%, with "cure" being defined as survival longer than 2 years. Emerging therapies for ATC include small-molecule tyrosine kinase inhibitors and vascular disrupting agents. All patients should be referred to the physician data query (PDQ) database for appropriate clinical trials: http://cancernet.nci.nih.gov/search/searchclinical trialsadvanced.aspc.

Primary Hyperparathyroidism

Nishant D. Patel, MD, and Martha A. Zeiger, MD

BACKGROUND AND EPIDEMIOLOGY

Primary hyperparathyroidism is the most common cause of hypercalcemia. Parathyroid surgery has evolved from the identification of the first parathyroid gland in 1849 by Sir Richard Owen in an Indian rhinoceros to a variety of safe and effective surgical procedures for the management of primary hyperparathyroidism. The first parathyroidectomy was performed by Felix Mandel in 1925, and to this day, surgery remains the definitive treatment for primary hyperparathyroidism. Primary hyperparathyroidism is present in approximately 1% of adults in the United States, and the incidence increases to 2% after the age of 55. Women are two to three times more likely to have primary hyperparathyroidism than men.

PATHOPHYSIOLOGY, PRESENTATION, AND DIAGNOSIS

Primary hyperparathyroidism is characterized by hypercalcemia resulting from excessive parathyroid hormone production by one or more parathyroid glands. It is caused by a single adenoma in approximately 80% to 85% of patients, multigland hyperplasia in 10%, double adenoma in 4%, and parathyroid carcinoma in 1%. It is present in nearly all patients with multiple endocrine neoplasia type I and in 25% of patients with multiple endocrine neoplasia type 2A.

The clinical presentation of primary hyperparathyroidism results from the effects of excess parathyroid hormone, which in turn causes bone resorption of calcium and phosphorous, increased intestinal absorption of calcium, renal reabsorption of calcium, and hypercalciuria. Although most patients are asymptomatic, common signs and symptoms can include bone pain, osteopenia/osteoporosis, bone fractures, joint pain, kidney stones, urinary frequency/incontinence, fatigue, proximal muscle weakness, poor concentration, depression, nausea, and vomiting. Severe complications include renal dysfunction, hypertension, and severe neurologic dysfunction such as delirium or coma. The risk of developing symptoms or complications from primary hyperparathyroidism in patients who are asymptomatic at the time of initial diagnosis ranges from 23% to 62% by 10 years. Untreated disease may also lead to premature death from cardiovascular disease. The underlying physiologic basis is still under investigation but may involve decreased glucose tolerance, changes in vasomotor tone, hypertension, abnormal lipid metabolism, and obesity. The risk of premature death also increases with worsening hypercalcemia.

The diagnosis is most often made in the outpatient setting on routine laboratory evaluation. It is then confirmed by documenting the presence of high or high-normal calcium and concomitant elevated or high normal (nonsuppressed) parathyroid hormone levels. Associated laboratory abnormalities include decreased serum phosphate and increased or high-normal serum chloride levels. In addition, a 24-hour urinary calcium and creatinine should be collected to rule out familial hypercalcemic hypocalciuria (FHH), a disorder resulting from an autosomal dominant loss of function of the calcium-sensing receptor gene. A 24-hour urinary calcium to creatinine ratio of less than 0.01 distinguishes FHH from primary hyperparathyroidism. A family history of members younger than 10 years of age with hypercalcemia is also suggestive of FHH. Urinary calcium level is elevated in primary hyperparathyroidism (unlike FHH, which is <100 mg/24 hours); excretion that exceeds 400 mg in 24 hours is predictive of complications from primary hyperparathyroidism.

INDICATIONS FOR SURGERY

Currently, surgical management is the only curative therapy for patients with primary hyperparathyroidism, and patients who are symptomatic should undergo parathyroidectomy. With regard to asymptomatic patients, the most recent guidelines published in 2009 recommend parathyroidectomy for asymptomatic patients younger than 50 years of age, with serum calcium levels over 1 mg/dL above the upper limit of normal, creatinine clearance less than 60 mL/min, bone mineral density T score of 2.5 or lower at any site, or previous bone fracture fragility (Table 1). It is important to recognize that the symptoms of hyperparathyroidism are often subjective and subtle. Therefore, some patients who are considered "asymptomatic" and do not meet the criteria for surgical intervention may still benefit from parathyroidectomy.

LOCALIZATION

Most cases of primary hyperparathyroidism are due to a single parathyroid adenoma. Once the biochemical diagnosis of primary hyperparathyroidism is made, all patients should undergo localization studies to identify the abnormally functioning parathyroid gland(s) in preparation for minimally invasive parathyroidectomy. The two best preoperative localizations studies include the technetium-99m sestamibi scan (Figure 1) with single photon emission computed tomography (SPECT) and a neck ultrasound. A neck ultrasound will also identify any suspicious thyroid nodules.

Sestamibi with SPECT has a reported sensitivity of 80% to 90% in identifying a single adenoma (Figure 2). The sensitivity decreases with double adenomas and multigland hyperplasia. We routinely perform ultrasonography to localize parathyroid glands preoperatively. When findings are concordant with sestamibi scintigraphy, the sensitivity of preoperative localization improves to 94% to 99%. Although tumor biology influences the false-negative rate of sestamibi scans, the experience of the institution is also a critical factor. Successful visualization of a parathyroid adenoma can be as low as 50% to 60% in some centers. We recently reported on the subtleties or "shadows" discovered on sestamibi scans that had been initially read as negative or indeterminate. These subtleties include asymmetry of the thyroid gland, subtle posterior extension on a lateral view, or prominence of a thyroid lobe on early or delayed imaging. In our study "shadows" were found in 41% of cases with negative sestamibi and 76% of cases with indeterminate sestamibi scans. We showed that identification of these subtleties on sestamibi scan resulted in a successful minimally invasive approach in 91% of patients and a cure rate of 98%.

MINIMALLY INVASIVE PARATHYROIDECTOMY WITH INTRAOPERATIVE PARATHYROID HORMONE MONITORING

With a positive preoperative localization study (either sestamibi, ultrasound, or both), a unilateral or minimally invasive parathyroidectomy can be performed. A large-bore intravenous catheter is placed

TABLE 1: Indications for parathyroidectomy

Age	<50 years
Serum calcium	1.0 mg/dL above upper limit of normal
24-hour urinary calcium	Not indicated
Creatinine clearance	<60 mL/min
Bone mineral density	T score <–2.5 at any site, or previous bone fracture fragility

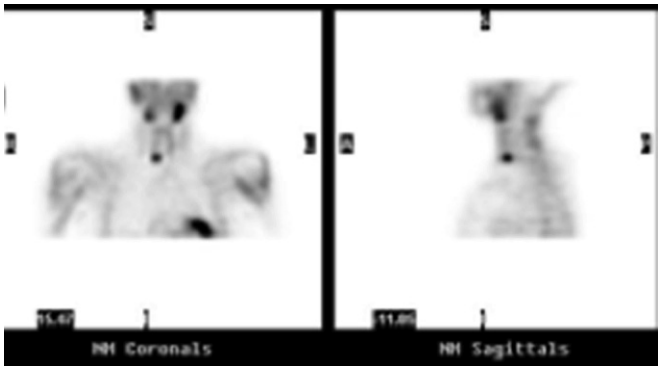

FIGURE 1 Anterior-posterior and lateral view of technetium-99m sestamibi scan with single photon emission computed tomograph (SPECT) showing parathyroid adenoma in the right inferior position.

FIGURE 2 Excised parathyroid adenoma weighing 256 mg.

preoperatively to allow for blood sampling, and a baseline parathyroid hormone level is measured. Under general anesthesia, a lateral or midline 2-cm to 4-cm transverse incision within a skin crease is made on the same side as the localized hyperfunctioning parathyroid adenoma. The platysma is divided and subplatysmal flaps are raised. The strap muscles are separated vertically and dissected off the thyroid gland. The thyroid gland is gently rotated medially. The parathyroid adenoma is identified, and its vascular pedicle is divided. Upon excision of the parathyroid gland, intact parathyroid hormone levels are measured at baseline and 5- and 10-minute intervals thereafter. Based on the Miami criteria, a drop of 50% or more in the intact parathyroid hormone level from the baseline or time 0 is considered successful. The strap muscle is closed with 2-0 running suture, the platysma reapproximated with 3-0 interrupted suture, and the skin closed with running 4-0 monofilament suture.

BILATERAL NECK EXPLORATION

Failure to achieve the 50% drop in the intact parathyroid hormone level suggests multigland disease and necessitates further operative exploration. If unilateral exploration fails or preoperative imaging does not localize, one should proceed with conventional bilateral neck exploration. Bilateral neck exploration is also the procedure of choice for multiple endocrine neoplasia. A slightly longer 3- to 5-cm transverse incision is made within a skin crease. All four parathyroid glands are identified, and a 3.5-gland parathyroidectomy (subtotal parathyroidectomy) or 4-gland excision with autotransplantation in the nondominant brachioradialis muscle is performed. Ectopic parathyroid adenomas can be located in the trachea-esophageal groove, the thymus, within the thyroid, or, finally, in the carotid sheath. Failure to achieve biochemical cure once these areas have been explored should lead to termination of the operation. Reexploration is then planned for a later date following further imaging studies (sestamibi-SPECT, computed tomographic scan, magnetic resonance imaging).

OUTCOMES AND FOLLOW-UP

The benefits of surgical management of primary hyperparathyroidism are well documented and include improvement in renal function, bone density, quality of life, survival, and a reduction in cardiovascular events. For bilateral neck exploration, the complication rate, including the risk of recurrent laryngeal nerve injury, remains low (4%), with success rates of 95% or better. Minimally invasive parathyroidectomy has comparable results with success rates of 98% and complication rates between 1% and 3%. The minimally invasive approach provides the additional advantages of smaller incision, improved cosmetic outcome, decreased pain, shorter operating time, same-day discharge, lower risk of nerve injury, and lower risk of postoperative hypocalcemia. Documentation of biochemical cure consists of eucalcemia 6 months postoperatively.

CONCLUSION

Parathyroidectomy remains the gold standard treatment for primary hyperparathyroidism. Minimally invasive parathyroidectomy has supplanted the traditional bilateral approach. Bilateral exploration is used, however, in patients with multigland disease, multiple endocrine neoplasia, and in the event that intraoperative parathyroid hormone levels do not drop appropriately or preoperative imaging fails to localize an adenoma. The majority of patients will be cured with minimal operative morbidity and will experience resolution of symptoms and excellent long-term health benefits.

PERSISTENT AND RECURRENT HYPERPARATHYROIDISM

Michael J. Campbell, MD, and Quan-Yang Duh, MD

INTRODUCTION

Most patients with primary hyperparathyroidism (HPT) are cured with parathyroidectomy. About 5% of patients, however, have persistent or recurrent disease. The risk of a failed parathyroidectomy is higher when performed by low-volume surgeons and at low-volume centers. Reoperations for persistent or recurrent hyperparathyroidism present a challenge to the endocrine surgeon; the diseased glands are harder to find, and the complication rates are higher because of scarring from the prior operation. A systematic approach to evaluation and treatment of these patients is therefore crucial. The approach, sequentially, should include confirmation of the diagnosis, reassessment of the indication for parathyroidectomy, localization of the diseased glands, and planning for a safe and successful reoperation.

DIAGNOSIS OF PERSISTENT OR RECURRENT HYPERPARATHYROIDISM

Persistent hyperparathyroidism is defined as hyperparathyroidism that did not resolve after the initial parathyroidectomy or that recurred within 6 months of the initial operation. Recurrent hyperparathyroidism is defined as the return of disease after an apparent cure more than 6 months subsequent to the initial parathyroidectomy. Although some overlap exists, the designation of persistent and recurrent hyperparathyroidism separates two relatively distinct groups of patients. Persistent disease accounts for 80% of reoperations and is the result of inadequate resection. This can be caused by failure to find a parathyroid adenoma, failure to identify a second adenoma or inadequate resection of an adenoma (partial resection of a "dumbbell" adenoma), or hyperplastic parathyroid tissue (insufficient subtotal parathyroidectomy). Recurrent disease accounts for 20% of reoperations and is usually the result of an abnormality that is intrinsic to all the parathyroid tissue. Recurrent hyperparathyroidism commonly occurs in patients with familial HPT (with or without multiple endocrine neoplasia [MEN] type 1) and in those with multigland disease (MGD) at the initial operation (double adenomas or hyperplasia). Development of a second adenoma (in a gland observed as healthy during the initial operation) is rare but has been reported in patients with a history of neck irradiation. Other rare causes of recurrent disease are parathyroid carcinoma or parathyromatosis from a ruptured capsule and regrowth of parathyroid tissue in the operative field.

In evaluation of patients for persistent or recurrent HPT, reconfirmation of the diagnosis of hyperparathyroidism, with documentation of concurrent hypercalcemia with an inappropriately elevated serum parathyroid hormone (PTH) value, is important. Five percent to 10% of patients who are cured with a parathyroidectomy have persistently elevated serum levels of PTH with normocalcemia. This results from secondary hyperparathyroidism that may be caused by bone hunger, vitamin D deficiency, inadequate calcium intake or absorption, reduced peripheral sensitivity to PTH, underlying chronic kidney disease, or a renal leak of calcium. Isolated high serum PTH value alone without concurrent hypercalcemia is not diagnostic of persistent or recurrent hyperparathyroidism.

Because 2% to 10% of failed parathyroidectomies result from an incorrect diagnosis, it is imperative to revisit the initial diagnostic workup and reconfirm the diagnosis of primary hyperparathyroidism by documenting concurrently elevated serum calcium and PTH levels. Patients with a diagnosis of normocalcemic hyperparathyroidism deserve closer scrutiny. Ionized calcium and 25-hydroxyvitamin D (25OHD) levels also need to be measured. Ionized calcium is not affected by hypoalbuminemia and is a more accurate measurement of physiologically active free serum calcium. Most patients with normocalcemic hyperparathyroidism have a normal plasma level of total calcium but an elevated ionized calcium value. Because 1,25-dihydroxyvitamin D is the most potent suppressor of PTH secretion, patients with vitamin D deficiency commonly present with a normal serum calcium value but an elevated PTH level. Vitamin D replacement resolves the secondary hyperparathyroidism in such patients and may obviate the need for parathyroidectomy.

Because of the high prevalence of vitamin D deficiency in patients with HPT, the Third International Workshop on Asymptomatic Primary Hyperparathyroidism recommended measurement of 25OHD in all patients with HPT and repletion of levels less than 20 ng/mL before any surgical decision is made. These patients may have a varying degree of primary and secondary hyperparathyroidism that may become more obvious after vitamin D replacement. Vitamin D replacement in patients with hypercalcemia hyperparathyroidism may worsen hypercalcemia or hypercalciuria, so it needs to be carefully monitored. Finally, patients should have a 24-hour urinary calcium and creatinine measurement to rule out benign familial hypocalciuria hypercalcemia (FHH), which is caused by a heterozygous germline mutation of the calcium sensor gene. Parathyroidectomy is not indicated in patients with FHH. FHH is suspected in patients with a family history of failed parathyroidectomy, if the 24-hour urine calcium excretion is less than 100 mg/24 hours or if the urinary calcium : creatinine clearance ratio is less than 1%.

INDICATIONS FOR REOPERATIVE PARATHYROIDECTOMY

In general, the indications for reoperation in patients with persistent or recurrent HPT are the same as those for initial parathyroidectomy. However, one needs to rebalance the potential benefits of a successful reoperation with the potential increased risks associated with a reoperation. Reoperative parathyroidectomy is associated with a higher

risk for a failed operation (10% vs 5%), permanent recurrent nerve injury (5% vs 1%), and hypoparathyroidism (5% to 10% vs 1%) when compared with initial parathyroidectomy.

Nephrolithiasis, fractures from osteoporosis/osteopenia, severe hypercalcemia or hypercalcemia-related pancreatitis, and peptic ulcer disease are strong indications for parathyroidectomy. Indications for parathyroidectomy in asymptomatic patients with milder disease are more controversial. The recommendations from the Third International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism in 2009 for parathyroidectomy are summarized in Box 1. More subtle indications for parathyroidectomy include the nonspecific symptoms of muscle aches, weakness, nocturia, and neurocognitive derangements such as depression, emotional labiality, and impaired cognition.

In patients with borderline indications, although the initial operation may have been indicated, a reoperation may not be. The surgeon and the patient should weigh the increased risks of a reoperative parathyroidectomy against the potential benefits when deciding on a reoperation.

PREOPERATIVE CONSIDERATIONS

Persistent HPT is most commonly caused by an inadequate initial operation. Most missed parathyroid adenomas are in the neck, and many are in their normal anatomic positions. The usual causes of persistent HPT are, therefore, inadequate exploration or failure to recognize the adenoma during the initial operation. Ectopic glands account for half of reoperative parathyroidectomies, and 80% of patients need resection of a single parathyroid adenoma. The most common ectopic locations are listed in Table 1 and shown in Figure 1. Some common ectopic locations, such as the cervical thymus for the lower glands and tracheoesophageal groove for the upper glands, are more likely to have already been explored by an experienced surgeon during the initial exploration. Incomplete resection of multiple abnormal glands accounts for about one third of patients with persistent HPT.

Recurrent HPT is most commonly associated with parathyroid hyperplasia in which all glands are abnormal or potentially abnormal. Many are caused by familial diseases such as MEN type 1 or familial HPT. In these patients, a "cure" for hyperparathyroidism depends on how much parathyroid tissue remains after the initial operation and how fast the remnants grow. During the initial operation and subsequent reoperation, the surgeon needs to balance the risk of recurrence from remnant parathyroid tissues versus the risk of hypoparathyroidism. When hyperplasia was recognized at the initial parathyroidectomy, the patients may have undergone a subtotal parathyroidectomy or a total parathyroidectomy and autotransplantation of parathyroid tissue to the forearm, thus determining where the recurrent disease is located.

BOX 1: Indications for surgical treatment in asymptomatic hyperparathyroidism

1. Total serum calcium greater than 1.0 mg/dL above the upper limit of normal
2. Creatinine clearance less than 60 mL/min
3. Bone mineral density T score ≤ 2.5 at any site
4. Age <50 years
5. Inability or unwillingness to undergo biannual biochemical surveillance

Modified from Bilezikian JP, Khan AA, Potts JT, et al: Guidelines for the management of asymptomatic primary hyperparathyroidism, J Clin Endocrinol Metab *94(2):333-334, 2009.*

Less than 1% of patients with primary HPT have parathyroid cancer, but more than half have recurrence. Persistent or recurrent disease from parathyroid carcinoma tends to occur at or near the primary tumor site, including the regional lymph nodes. Parathyromatosis is usually caused by capsular rupture and spillage of parathyroid cells during initial parathyroidectomy. Both parathyroid cancer and parathyromatosis have a high risk of re-recurrence and may require multiple reoperations.

PREOPERATIVE EVALUATION

After confirmation of the diagnosis of persistent or recurrent HPT and the indications for reoperation, attention is turned toward localization of the parathyroid tumor. Previous operative and pathology reports provide insights as to which glands have already been identified, biopsied, or removed. Review of the pathology slides shows whether the parathyroid tissue previously removed is hypercellular (adenoma or hyperplasia), normal, or parathyroid cancer. It is useful to correlate previous localization studies with the finding during the initial operation and pathology report. Discrepancies among them may provide clues as to the location of a missed gland or the likelihood of MGD. The history and physical examination should focus on the indications for parathyroidectomy and personal or family history of endocrinopathy that may suggest MGD.

Because reoperative parathyroidectomy is associated with a fivefold increased risk of injury to the recurrent laryngeal nerve, laryngoscopic evaluation of vocal cord function is mandatory. Approximately 7% of patients undergoing reoperative parathyroidectomy already have vocal cord palsy before the reoperation; some of these patients may not be hoarse or otherwise symptomatic. Because of the increased risk of bilateral vocal cord paralysis, bilateral reexploration should be avoided if possible.

PREOPERATIVE LOCALIZATION STUDIES

Bilateral four-gland exploration is a time-tested approach for initial parathyroidectomy, with a high success rate and a low complication rate. Reoperative parathyroidectomy, on the other hand, is best performed with a precise, targeted approach with minimal blind exploration. Scarring from the prior operation not only makes the parathyroid tumors harder to find but also increases the risk of injury to the recurrent laryngeal nerve and the healthy parathyroid glands. Thus, reoperative parathyroidectomy requires as precise as possible preoperative localization of the diseased gland.

TABLE 1: Location of ectopic glands identified during reoperation

Location	%
Paraesophageal	28
Mediastinal	26
Intrathymic	24
Intrathyroidal	11
Carotid sheath	9
High cervical/undescended	2

Data from Shen W, Duren M, Morita E, et al: Reoperation for persistent or recurrent primary hyperparathyroidism, Arch Surg *1996;131:861-869.*

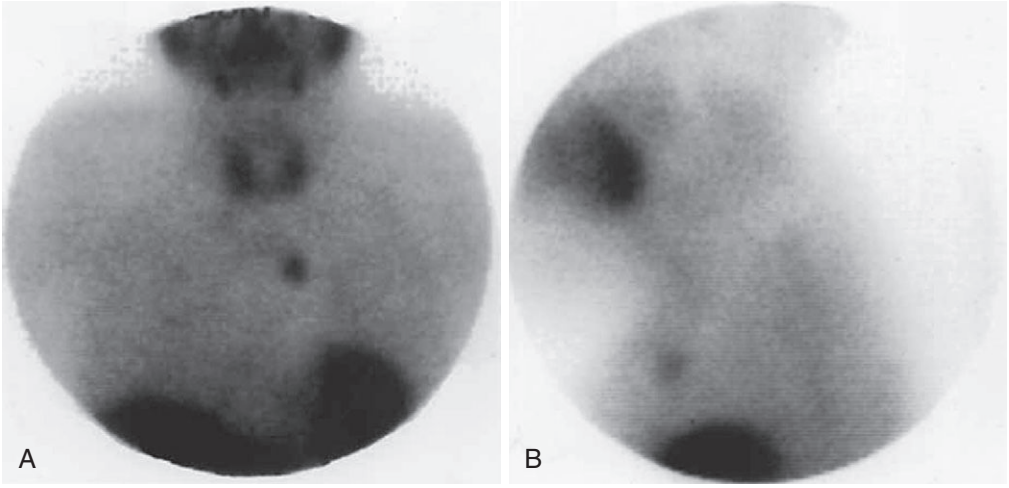

FIGURE 1 Technitium 99m sestamibi scan shows a mediastinal parathyroid adenoma. **A,** Frontal view. **B,** Lateral view of the same patient shows a parathyroid adenoma in the anterior mediastinum. *(From Arici, C, Cheah, WK, Ituarte, PHG et al: Can localization studies by used to direct focused parathyroid operations?* Surgery *129(6):720-729, 2001.)*

With good preoperative localization, the success rate of reoperation can be similar to that of initial parathyroidectomy. Because of potential false-positive and false-negative results, the authors recommend obtaining two concordant localization studies before proceeding with reoperative parathyroidectomy. The two most commonly used localization studies are ultrasound scan and sestamibi scan (MIBI). Computed tomographic (CT) scan and magnetic resonance imaging (MRI) may also be used. Selective venous sampling (SVS) for PTH is more invasive and is only used on rare occasions.

Ultrasound scan is widely available, well tolerated, inexpensive, and excellent for identification of parathyroid tumors in the neck. Ultrasound scan, however, is operator dependent and cannot penetrate air and bones to detect ectopic glands located deep in the neck or in the mediastinum. The reported sensitivity for detection of parathyroid tumors in patients with persistent or recurrent HPT is 57% to 74%, with a positive predictive value (PPV) of 52% to 92%. Ultrasound scan has an added advantage: to guide fine-needle aspiration (FNA) of suspected lesions. Because of occasional difficulty in distinguishing follicular thyroid tumors from parathyroid tissue with cytology, the needle aspirate should to be sent for both cytology and PTH tests. An elevated PTH level in the aspirate (in the range of hundreds or thousands) is nearly 100% specific for parathyroid tissue. In addition, ultrasound scan can be used during surgery to confirm preoperative findings and to guide exploration.

MIBI is more successful than ultrasound scan for localization of ectopic parathyroid glands (Figure 2) but is more expensive and requires use of radionucleotide. Sensitivity for MIBI in recurrent or persistent HPT is 79% to 85%, with a PPV of 89% to 96%. The addition of single photon emission computed tomography (SPECT-MIBI) increases the sensitivity and specificity of sestamibi scanning.

When ultrasound scan and MIBI suggest the same site (concordant), the accuracy of localization of a parathyroid tumor approaches 95%. When ultrasound scan and MIBI results are negative, inconclusive, or discordant, then additional localization studies, such as MRI and CT, are necessary.

MRI identifies parathyroid adenomas with its intermediate to low signal intensity on T1-weighted imaging and high intensity on T2-weighted imaging. Unfortunately, cervical lymph nodes have similar imaging characteristics and may cause false-positive findings. MRI has the advantage of not requiring contrast or exposing the patient to ionizing radiation, but it is expensive. Use of gadolinium (Gd) increases the accuracy of localization. MRI has a sensitivity of 47% to 82% and a PPV of 80% to 89% in patients with persistent or recurrent HPT.

CT scan detects parathyroid adenomas based on their relative enhancement over surrounding structures. Standard CT scan has a

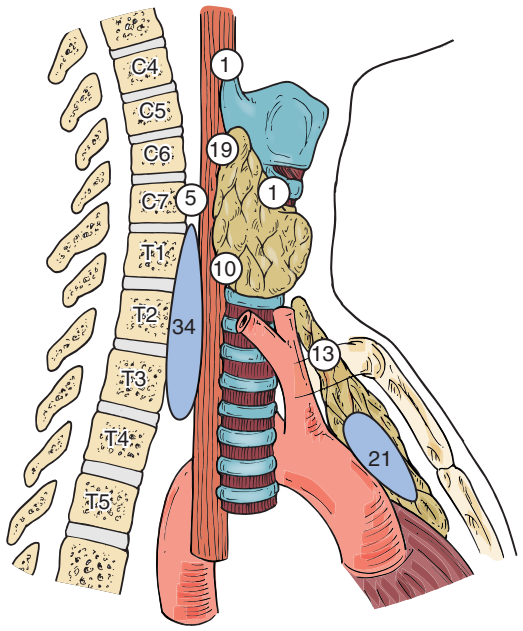

FIGURE 2 Anatomic locations of ectopic parathyroid glands with the number in each location given (n = 104). *(From Wang CA: Surgical management of primary hyperparathyroidism,* Curr Prob Surg *22(11):37, 1985.)*

sensitivity of 40% to 86% for detection of parathyroid adenomas. Recently, four-dimensional computed tomographic (4D-CT) scan has been shown to accurately localize hyperfunctioning parathyroid glands that have otherwise been difficult to localize. The fourth dimension of the 4D-CT scan is a timed study of contrast perfusion. Parathyroid tumors have a more rapid uptake and washout of contrast compared with healthy parathyroid glands. 4D-CT scan has 88% sensitivity for localizing hyperfunctioning glands in patients undergoing reoperative parathyroidectomy. 4D-CT scan is quick and produces excellent anatomic details of the adenoma and surrounding structures, but it exposes the patient to ionizing radiation and is limited by metal clips, which cause scattering artifacts. The choice of MRI versus CT scan for patients with persistent or recurrent HPT is usually institution dependent.

If the noninvasive localization studies are inconclusive or conflicting, then SVS for PTH may be helpful. SVS does not precisely localize

the parathyroid tumor but instead uses the gradient of PTH drainage to predict the side (lateralize) of the adenoma. Venous drainage with a twofold gradient in PTH levels is considered positive. SVS is 77% sensitive for lateralizing a hyperfunctioning parathyroid gland. Previous dissection can disturb normal venous drainage pathways and cause inaccuracy. Table 2 summarizes the sensitivities, benefits, and disadvantages of various localization studies.

OPERATIVE TECHNIQUE

After a review of the patient's history, previous operative and pathology reports, and localization studies, the surgeon can usually determine whether the patient has a solitary adenoma or multigland disease and the most likely location of the tumor(s). A missing upper gland must be distinguished from a lower gland because it may dictate the surgical approach (see subsequent discussion). More than two thirds of patients undergoing reoperation for hyperparathyroidism have a single adenoma. In these patients, with two concordant localization studies, a focused approach with intraoperative parathyroid hormone monitoring (ioPTH) can produce cure rates comparable with those of the primary (not reoperative) parathyroidectomy. A focused approach to reoperative parathyroidectomy, which minimizes unnecessary exploration, is less likely to injure the recurrent laryngeal nerve and the healthy parathyroid glands.

Most reoperative parathyroidectomies (85%) can be performed through the same cervical incision as the initial operation. Parathyroid glands in the neck can be explored via a central approach, between the strap muscles, or a lateral approach, between the strap muscles and the ipsilateral sternocleidomastoid muscle. Depending on the approach of the initial parathyroid exploration, the alternate approach can be used to minimize the need to dissect through scar tissue.

Most of the time, the neck has been previously explored through a central approach. In such cases, a lateral approach, with the previous cervical skin incision, usually works well and avoids previously violated surgical planes (Figure 3). In the lateral approach between the sternocleidomastoid muscle and the strap muscles, the carotid is retracted laterally, exposing the posterior border of the thyroid where most upper glands are found. The lateral approach also allows for a more direct approach to the tracheoesophageal groove and paraesophageal or retroesophageal area where many ectopic upper parathyroid glands are found. Because the upper glands are usually located behind the recurrent laryngeal nerve, the lateral approach is ideal, allowing for direct access and avoiding the nerve anteriorly. The inferior glands are located anterior to the recurrent laryngeal nerve and are usually easier to reach through a central approach with the same incision.

Normal-appearing parathyroid glands should be protected. They can be marked with a clip and biopsied. Because uncertainty always exists about the number and location of remaining healthy parathyroid glands, reoperative excision of even a single adenoma may risk permanent hypoparathyroidism. If available, a sufficient amount of the excised parathyroid tissue should be cryopreserved for potential

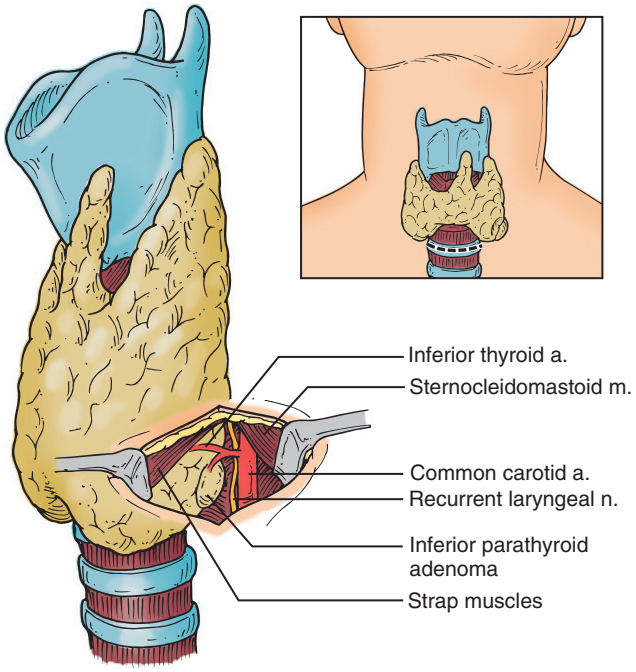

FIGURE 3 A lateral approach to identification of a posteriorly located parathyroid adenoma. *(From Wang TS, Udelsman R: Remedial surgery for primary hyperparathyroidism,* Adv Surg *41:1-15, 2007, Fig 5.)*

TABLE 2: Summary of the sensitivities, benefits, and drawbacks to localization tests in patients with persistent or recurrent hyperparathyroidism

Test	Sensitivity (%)	Benefit	Drawbacks
Ultrasound scan	57-74	No radiation, inexpensive	Unable to locate mediastinal glands, user dependent
^{99m}Tc Sestamibi scan with or without SPECT	79-85	Able to locate ectopic glands	Radiation exposure, time-consuming
MRI	47-82	No radiation exposure	Expensive
CT scan	40-86	Readily available, inexpensive	Radiation exposure, artifact from previous clips
4D-CT scan	88	More specific than standard CT scan	Less available, radiation exposure
Selected venous sampling for PTH	77-93	Good sensitivity in the face of otherwise negative localization	Invasive, expensive

future autotransplantation. If cryopreservation is not available and the anticipated risk for hypoparathyroidism is high, then immediate autotransplantation can be considered. Abnormal parathyroid tissue should be autotransplanted to an area that is easily accessible, in case of need for reexcision if disease recurs, usually in the nondominant brachioradialis muscle. Immediate autotransplantation has a 90% success rate, whereas autotransplantation of cryopreserved parathyroid tissue is 60% successful.

Occasionally, because of MGD or inconclusive localizing studies, a more extensive exploration is necessary. In such situations, a systematic approach to searching for missing parathyroid glands is pursued based on which glands have been identified, biopsied, or removed during previous operations. The normal anatomic locations should be considered first. The upper glands are often found cephalad to the inferior thyroid artery, posterolateral to the recurrent laryngeal nerve at the level of the cricoid cartilage. The lower parathyroid glands have a more variable location, but they are most often found caudal to the inferior thyroid artery and anteromedial to the recurrent laryngeal nerve. If a missing upper parathyroid gland is not found in its usual location, then one can search for an ectopic gland along its path of descent from its forth pharyngeal pouch origin. The most common locations for ectopic upper glands are in the tracheoesophageal groove, paraesophageal or retroesophageal space, carotid sheath, or high cervical position. The most common locations for ectopic inferior glands are in the thymus, anterior mediastinum, or intrathyroidal. Figure 4 shows the authors' algorithm for workup and management of these patients.

For patients with parathyroid hyperplasia found at the initial operation, subtotal parathyroidectomy is usually preferred, with approximately 50 mg of tissue left from the most normal-appearing gland. For reoperations, however, where the number and location of remaining glands are likely to be uncertain, complete resection of the abnormal glands with cryopreservation is preferred. If intraoperative PTH shows that the patient is likely to have hypoparathyroidism (<10 pg/mL), then immediate autotransplantation to the forearm is considered.

POSTOPERATIVE MANAGEMENT

The results of reoperative parathyroidectomy are usually worse than for initial operation, both because of patient selection (more likely to have ectopic glands and MGD) and scarring that necessitates more limited exploration. Large series from tertiary referral centers have

success rates of approximately 90%. Historically, the risk of permanent recurrent laryngeal nerve injury was estimated to be 3% to 10%, and the risk of permanent hypoparathyroidism 10% to 20%. With the newer localization studies, intraoperative PTH monitoring, and intraoperative recurrent laryngeal nerve monitoring, more modern series have 1% risk of recurrent laryngeal nerve injury and 2% risk of permanent hypoparathyroidism. Transient hypoparathyroidism is common after reoperative parathyroidectomy, and many patients need at least temporary oral calcium and vitamin D replacement. Even after an apparently successful reoperation, these patients need close follow-up for HPT because they are at higher risk of having, again, persistent or recurrent disease.

CONCLUSION

Reoperation for persistent or recurrent hyperparathyroidism is challenging. Before the operation, the diagnosis and indication for operation need to be confirmed. Review of prior operative and pathology reports and results of localization studies usually allows for a focused exploration. Preoperative laryngoscopy, intraoperative monitoring of the recurrent nerves and PTH levels, and cryopreservation of parathyroid tissue all need be considered to mitigate the expected higher risks of operative complications.

Secondary and Tertiary Hyperparathyroidism

Jason D. Prescott, MD, PhD, and Antonia Stephen, MD

OVERVIEW

Primary hyperparathyroidism is the overproduction of parathyroid hormone (PTH) by abnormal parathyroid glands, and secondary hyperparathyroidism (2°HPT) refers to the excess secretion of serum PTH by normal parathyroid glands in response to perturbations in calcium homeostasis. The most common pathologic process that affects normal calcium metabolism, and thus stimulates increased parathyroid gland function, is chronic renal failure. Other causes of 2°HPT include vitamin D deficiency, inadequate calcium ingestion, calcium malabsorption, and idiopathic hypercalciuria. 2°HPT is common; population studies suggest a prevalence rate as high as 6.6% in some cases. Reversibility is an implicit feature of this disorder, and correction of the underlying abnormality should result in disease resolution. Cases in which this does not occur either represent misdiagnosis (e.g., primary hyperparathyroidism) or indicate development of tertiary hyperparathyroidism (3°HPT). 3°HPT occurs when chronically stimulated parathyroid tissue in a patient with 2°HPT becomes autonomous, producing elevated and unsuppressed levels of PTH even after correction of abnormal calcium metabolism. The development of 3°HPT therefore represents an additional pathologic event, superimposed on a background of 2°HPT, that produces autonomous parathyroid gland function. The most common clinical scenario in which this develops is in a patient with 2°HPT and chronic renal failure who undergoes renal transplantation. Despite a functional kidney in such cases, and therefore normalization of calcium metabolism, the parathyroid glands continue to overproduce PTH, which results in a condition similar to primary hyperparathyroidism.

Chronic renal failure (CRF) is the most important cause of 2°HPT, and 2°HPT develops in the majority of patients with CRF. Most 2°HPT cases are successfully managed medically; surgical treatment for 2°HPT (parathyroidectomy) is almost always reserved for those cases in which medical management fails. Medical treatment in these cases is complex, however, and unlike most other causes of 2°HPT, parathyroidectomy can play a therapeutic role. In this chapter, we review the pathophysiology and current treatment strategies for CRF-associated 2°HPT and 3°HPT, including medical and surgical approaches.

PATHOPHYSIOLOGY

The pathologic mechanisms resulting from renal failure that lead to hyperparathyroidism are complex and incompletely understood. The primary known stimulus for PTH secretion is low serum ionized calcium, and persistently low serum calcium measurements may well be expected in patients with 2°HPT. Interestingly, patients with CRF and 2°HPT often have serum calcium levels in the normal (or low normal) range, which indicates that more complex biochemical interactions are at play. At least four interdependent factors that affect calcium homeostasis contribute to the development and progression of 2°HPT: hypocalcemia, impaired vitamin D activation, hyperphosphatemia, and parathyroid resistance to fibroblast growth factor 23 (FGF23; Box 1). In the absence of renal disease, absorption of urinary calcium is extremely efficient, reaching 98% in individuals with eucalcemia. As renal failure progresses, however, absorption of urinary calcium is correspondingly impaired and hypocalcemia develops. Renal failure progression also results in impaired vitamin D activation. In normal circumstances, the kidneys convert 25-hydroxyvitamin D to its most active form, 1,25-dihydroxyvitamin D. This compound then acts directly on the small intestine, stimulating calcium absorption, and on the parathyroid glands, where it inhibits PTH gene expression. As loss of functional renal parenchyma progresses in CRF, vitamin D activation capacity is proportionally compromised, which results in both hypocalcemia and direct activation of PTH synthesis.

Hyperphosphatemia, which is common in patients with renal failure, also contributes to hypocalcemia by titrating ionized calcium from the serum as calcium phosphate and by directly inhibiting renal activation (hydroxylation) of 25-hydroxyvitamin D.

BOX 1: Factors that contribute to secondary hyperparathyroidism

1. Hyperphosphatemia
2. Hypocalcemia
3. Impaired vitamin D activation
4. Parathyroid resistance to fibroblast growth factor 23

A recent discovery was the elucidation of FGF23 function in phosphate metabolism. FGF23 acts on the kidney, stimulating phosphate excretion, and on the parathyroid gland, inhibiting PTH synthesis and secretion. As progressive hyperphosphatemia develops during chronic renal failure, serum FGF23 levels correspondingly increase. Despite this increase, however, FGF23 receptor concentrations in the parathyroid gland decline as renal failure progresses. Thus, the abnormal parathyroid tissue characteristic of 2°HPT becomes progressively resistant to FGF23, and hyperparathyroidism results.

3°HPT is diagnosed when the inciting cause for 2°HPT is corrected, and, nonetheless, the parathyroid glands continue to overproduce PTH. This typically manifests biochemically as elevated serum calcium and PTH levels. The inability of the parathyroid glands to revert to their normal inhibitory feedback response, as mediated by elevated serum calcium levels, may relate to the hyperplasia that originally developed during the preceding 2°HPT and CRF.

CLINICAL MANIFESTATIONS OF SECONDARY AND TERTIARY HYPERPARATHYROIDISM

The clinical sequelae of 2°HPT and 3°HPT can be both debilitating and life threatening. All cause and, in particular, cardiovascular-related mortality rates are increased in 2°HPT. Periarticular calcium deposition can produce arthritis, joint space effusion, and impaired joint function. 2°HPT-associated bone disease in the context of CRF, termed renal osteodystrophy, is an additional source of significant morbidity in this patient population. The development of nephrocalcinosis can exacerbate kidney failure and produce a vicious cycle that accelerates the progression of both renal dysfunction and 2°HPT. Finally, calcification of cutaneous arterioles, with associated subcutaneous tissue inflammation, is the hallmark of calciphylaxis, a rare but highly morbid condition associated with CRF-mediated 2°HPT. This condition is characterized by progressive cutaneous ischemia that presents as painful erythematous skin lesions, usually on the distal extremities or trunk, which progress to frank gangrene and subsequent sepsis. Mortality rates in affected patients can reach 80%.

MEDICAL MANAGEMENT

Curative management in patients with CRF-related 2°HPT requires renal transplantation, which, when successful, results in normalization or near normalization of serum calcium, phosphorous, and PTH levels in up to 95% of patients. Demand for donor renal grafts, however, far exceeds supply, and the vast majority of patients with 2°HPT are therefore managed medically. Curative medical therapy remains to be developed, so current medical treatment strategies thus focus on control of serum PTH, calcium, and phosphorous levels.

Consensus treatment guidelines for the management of CRF, including associated 2°HPT, have been published by the National Kidney Foundation (Kidney Disease Outcomes Quality Initiative [KDOQI]) and by the Kidney Disease: Improving Global Outcomes (KDIGO) foundation. These treatment algorithms are designed to minimize cardiovascular (KDOQI) and bone/extraskeletal calcification (KDIGO)–related mortality in CRF-associated 2°HPT. Most experts use one or both algorithms in the management of these patients.

Management of Hyperphosphatemia

Treatment of hyperphosphatemia should be initiated when serum phosphate levels exceed 5.5 mg/dL in stage 3, stage 4, or stage 5 CRF (glomerular filtration rate [GFR], 30-59, 15-29, and <15 mL/min/1.73 mol/L^2, respectively). The treatment goal in these cases is stabilization of serum phosphate levels between 3.5 and 5.5 mg/dL. Management should begin with restriction of daily dietary phosphate intake to less than 900 mg and, when end-stage renal disease is present, dialysis. Phosphate-binding medications should be added when dietary restriction and, if applicable, dialysis fail to consistently produce serum phosphate levels below 5.5 mg/dL.

Management of Serum Parathyroid Hormone Levels and Hypocalcemia

Optimal overall outcomes among patients with CRF requiring dialysis have been associated with serum PTH maintenance between 150 and 300 pg/mL. Treatment in these patients therefore focuses on stabilization of serum PTH levels within this range. Activated vitamin D analogs can lower serum PTH levels, and use of these agents is indicated when serum PTH levels rise above 300 pg/mL in end-stage renal disease or exceed the upper limit of normal in nondialysis CRF cases. Because vitamin D may exacerbate hyperphosphatemia, however, and may produce hypercalcemia, activated vitamin D treatment is contraindicated when serum phosphate levels exceed 5.5 mg/dL or the corrected serum calcium concentration is greater than 9.5 mg/dL. In addition, vitamin D therapy should be discontinued if corrected serum calcium levels exceed 10.2 mg/dL or if serum phosphate levels rise above 5.5 mg/dL. Finally, vitamin D supplementation should be stopped if serum PTH levels fall below 150 pg/mL in patients with dialysis-dependent 2°HPT.

The calcimimetics are a relatively new medication class and function to increase the sensitivity of the calcium-sensing receptor (CaSR) protein to calcium, thus acting to inhibit secretion of parathyroid hormone. Use of cinacalcet, the prototype agent, in the management of patients on dialysis with 2°HPT is associated with improved serum phosphate, calcium, and PTH control. Moreover, cinacalcet appears to attenuate fracture risk, rates of parathyroidectomy, and hospitalization rates in these patients. Cinacalcet therapy should be considered for patients on dialysis in whom phosphate binders provide inadequate serum PTH suppression. Hypocalcemia contraindicates calcimimetic therapy, and treatment should be discontinued if corrected serum calcium levels fall below 8.4 mg/dL. In addition, cinacalcet has not been approved for use in patients with CRF before dialysis; and although cinacalcet is associated with improvements in serum PTH in such patients, its efficacy and safety in this population remain to be established.

The medical management of 2°HPT in patients with CRF is challenging, and the combination and dosage of phosphate binders, vitamin D analogs, calcium supplements, and calcimimetics chosen is patient specific. Treatment assessment and medication dosage titration therefore require careful monitoring of serum calcium, phosphate, and PTH levels. Serum total calcium, phosphate, and PTH should be measured weekly until stable levels are achieved with a given medication regimen, and then every 1 to 3 months. Serum 25-hydroxyvitamin D levels tend to change slowly and should be evaluated every 3 to 6 months in this patient group.

SURGICAL MANAGEMENT

Surgical resection of hyperplastic parathyroid tissue can provide durable resolution of 2°HPT in patients with CRF, with consequent symptomatic improvement, reversal of bone demineralization, and decreases in long-term mortality rates. Because 2°HPT develops when otherwise healthy parathyroid tissue responds inappropriately to pathologic external stimuli, all parathyroid tissue is affected and four-gland hyperplasia results. Thus, the aim of parathyroid surgery in 2°HPT is to remove enough hyperplastic parathyroid tissue to improve calcium homeostasis and treat otherwise unremitting symptoms, without producing hypoparathyroidism.

Indications

Parathyroid surgery for CRF-associated 2°HPT is indicated when: (1) medical therapy fails to control serum PTH levels, hypercalcemia, or hyperphosphatemia; (2) 2°HPT-related symptoms become refractory to medical therapy; (3) intractable rapid turnover bone disease develops; or (4) calciphylaxis is present (Box 2). Patients in whom serum PTH levels exceed 800 pg/mL and in whom serum calcium levels are greater than 10 mg/dL or in whom serum phosphate levels are above 5.5 mg/dL, despite maximal medical therapy, should be offered surgery. Similarly, intractable symptoms in a background of medically refractory 2°HPT merit surgical intervention. These include refractory pruritus, bone pain, muscle pain, anemia, abdominal pain, and weakness. Rapid turnover bone disease that does not respond to medical management should also prompt surgical intervention, especially when associated with pathologic fracture. Finally, biopsy-confirmed calciphylaxis is an absolute indication for emergent parathyroidectomy, which may arrest disease progression and improve wound healing.

Tertiary Hyperparathyroidism

Instances in which PTH levels remain elevated after renal transplantation represent 3°HPT; posttransplantation parathyroid surgery remains the primary management strategy in these cases. Recent studies, however, question this approach. Multiple contemporary series show a significant risk of transplant dysfunction and rejection when parathyroid surgery is performed after renal transplantation. The underlying mechanisms to explain these findings remain unknown, and graft dysfunction does not occur in all postparathyroidectomy transplant cases. Nonetheless, some experts now advocate parathyroid surgery before renal transplantation to potentially avoid postparathyroidectomy renal graft dysfunction. This strategy remains controversial because those patients with CRF in whom 3°HPT does not develop and who therefore do not need parathyroidectomy cannot be identified before transplantation and thus are subjected to unnecessary parathyroid surgery. In addition, renal graft function among patients undergoing pretransplant parathyroid surgery, relative patients receiving parathyroid surgery after renal transplantation, remains to be objectively defined.

BOX 2: Indications for parathyroidectomy in patients with chronic renal failure

1. Persistent hyperphosphatemia, hypercalcemia, or elevated parathyroid hormone, despite maximal medical therapy
2. Refractory hypercalcemic symptoms
3. Intractable renal osteodystrophy
4. Calciphylaxis

Medical therapy for 3°HPT continues to improve. Cinacalcet, for example, has shown efficacy in lowering both serum calcium and PTH levels in 3°HPT cases. Nonetheless, small studies that compare medical therapy with parathyroid surgery for 3°HPT suggest that parathyroidectomy affords superior serum PTH, calcium, and phosphate control. Until long-term outcome data comparing these interventions become available, parathyroid surgery remains the preferred intervention for 3°HPT. Medial therapy should be reserved for patients who are not surgical candidates or for stabilization in anticipation of parathyroidectomy.

Preoperative Assessment

In addition to verification of both the diagnosis of 2°HPT and the presence of associated surgical indications before surgery, the operative candidacy of all patients with CRF-associated 2°HPT should be formally assessed with preoperative risk stratification. Patients in whom severe preexisting comorbidities contraindicate surgery should be managed medically. In addition, imminent renal transplantation is a relative contraindication to parathyroidectomy, at least among those experts who do not ascribe to routine pretransplantation parathyroidectomy (see Tertiary Hyperparathyroidism).

Formal preoperative imaging for purposes of localizing abnormal parathyroid glands is unnecessary in both 2°HPT and 3°HPT, as pathologic involvement of all four glands is expected and four-gland exploration is therefore indicated. Localization imaging should be limited to rare cases in which supernumerary or ectopic parathyroid glands are suspected. All patients with 2°HPT and 3°HPT should, however, receive a formal preoperative thyroid ultrasound scan, both for identification of any potentially malignant coincident thyroid nodules that may be present and for assessment of parathyroid anatomy. Discovery of suspicious thyroid nodules should prompt an appropriate preoperative malignancy workup, and failure to identify all four parathyroid glands is a reasonable indication for additional localization imaging. Preoperative sestamibi or four-dimensional computed tomographic (CT) scanning can be used to localize ectopic parathyroid glands that are not visualized with ultrasound scan.

Operative Technique

Adequate surgical management of 2°HPT and 3°HPT requires either subtotal parathyroidectomy, in which 3.5 parathyroid glands are resected, or total parathyroidectomy with autotransplantation. Despite ongoing debate, the balance of reported data does not demonstrate relative superiority for either procedure, and surgeon preference thus dictates technique selection.

The procedure begins with semi-Fowler patient positioning. The cervical spine is placed in extension, and after application of sterilizing skin preparation, a 4-cm to 6-cm symmetric Kocher's incision is made approximately 2 fingerbreadths above the sternal notch. The relatively prominent anatomic location of this incision should always prompt careful consideration of cosmesis, and whenever possible, postoperative scarring should be minimized by placing the incision within a preexisting skin crease. Dissection is carried through the platysma muscle and subplatysmal flaps are elevated, exposing the underlying strap musculature. The median raphe defining the plane of symmetry between the strap musculature on either side of the neck is then incised, and the sternohyoid muscle is dissected free from the underlying thyroid gland. The thyroid is then carefully mobilized to avoid injury to associated branches of the inferior thyroid artery, which supply both the thyroid and the parathyroid glands. Systematic examination of all four parathyroid glands is then performed. If subtotal parathyroidectomy is planned, all four parathyroid glands should be visualized before resection. This allows selection of the least abnormal-appearing parathyroid tissue for remnant creation. An approximately 40-mg parathyroid remnant,

marked with a nonabsorbable suture or a titanium clip, is left attached to its associated vascular pedicle. The identity of this tissue should be verified with frozen section analysis of its resected component, and the remnant should be carefully observed for signs of inviability. Cases in which the remnant appears inviable should prompt either autotransplantation of remaining parathyroid tissue or creation of a new remnant from a separate parathyroid gland.

The most fragile structure associated with the ipsilateral parathyroid glands, and thus at risk for iatrogenic injury during parathyroid exploration, is the recurrent laryngeal nerve (RLN). Identification and preservation of both RLNs, which supply motor function to the vocal cords, is thus a critical component parathyroid surgery. Although parathyroid gland anatomy can be highly variable, the inferior parathyroid gland is generally situated just anterior to the course of the ipsilateral RLN, and the superior parathyroid gland tends to localize posteriorly relative to this nerve. Cases in which total parathyroidectomy is performed should generally prompt intraoperative parathyroid reimplantation. Although omission of autotransplantation decreases the probability of disease recurrence, most experts prefer to accept an increased recurrence risk in exchange for minimization of permanent postoperative hypocalcemia risk. For autotransplantation, the most normal-appearing parathyroid gland is selected; this tissue is sharply minced into 1-mm fragments. The identity of this tissue should be verified with frozen section analysis before autotransplantation. Appropriate autotransplant acceptor sites include the sternocleidomastoid muscle, the brachioradialis muscle of the nondominant forearm, and the subcutaneous soft tissue of the chest wall. Site selection depends on surgeon preference, although autotransplantation distant from the neck allows either biochemical or imaging-based differentiation between cervical and implant-associated disease in cases of recurrence. Three or 4 pockets adequately sized to accept 5 to 10 parathyroid tissue fragments are then created with blunt dissection at the donor site, and approximately 10 mg of minced parathyroid tissue is placed into each pocket. The aperture of each implantation site is closed with nonabsorbable suture or with titanium clips. Cases in which recurrent disease develops from progressive hyperplasia of autotransplanted tissue may be managed with resection of one or more of the implantation pockets with local anesthesia.

Special Considerations and Intraoperative Adjuncts

Gland ectopy is a relatively common finding in parathyroid surgery. Ectopic inferior glands are most frequently found within the ipsilateral thymus, and ectopic superior parathyroids are often paraesophageal. Other ectopic localization sites include the carotid sheath, the anterior mediastinum, adjacent to the cervical vertebral bodies, and within the ipsilateral thyroid lobe parenchyma. Failure to localize any of the four parathyroid glands in their typical anatomic positions should prompt careful exploration of potential ectopic sites. Cases in which an ectopic parathyroid gland localizes to the anterior mediastinum may require partial sternotomy.

A number of adjunctive intraoperative strategies have been proposed for improving the success of parathyroid surgery. These include ultrasound scan and gamma probe-assisted intraoperative gland localization and titration of parathyroid tissue resection on the basis of serial intact PTH measurements. Although data that support the value of these techniques have been reported, the adoption of these data remains controversial, and the use of intraoperative adjuncts during surgery for 2°HPT remains surgeon specific. The presence of supernumerary glands, although rare, may confound the adequacy of subtotal parathyroidectomy or total thyroidectomy with autotransplantation for 2°HPT and 3°HPT. This potential pitfall may be avoided through intraoperative PTH monitoring, as associated persistent serum PTH elevation prompts further surgical exploration and gland resection. In addition, some experts include routine intraoperative cervical thymectomy in the operative management of 2°HPT and 3°HPT because supernumerary parathyroid gland localization is often thymic.

POSTOPERATIVE MANAGEMENT

2°HPT exists in the context of severe hypocalcemia; thus, rapid decreases in serum PTH levels that occur after successful parathyroid surgery can result in the rapid and profound bony absorption of serum calcium. The sequelae of this process, termed hungry bone syndrome, can produce significant symptoms, including tetany, seizures, and heart failure. Patients after 2°HPT surgery must therefore be carefully monitored for signs and symptoms of hypocalcemia. Although the hypocalcemia may have been corrected in 3°HPT, the bone loss is often present and these patients are also at risk for hungry bone syndrome. Routine postoperative oral supplementation with 4 to 6 g of calcium, divided into 3 or 4 daily doses, should be initiated immediately after surgery, and serum calcium levels should be serially monitored. Patients with persistent hypocalcemia, despite these interventions, need intravenous (IV) calcium gluconate administration. Postoperative hypocalcemia in patients who previously needed dialysis may also be controlled by increasing dialysate bath calcium concentration. Postoperative supplementation with activated vitamin D (e.g., calcitriol) should be started if preoperative vitamin D deficiency is present, if hypocalcemia persists despite aggressive oral calcium supplementation, or if intravenous calcium infusion is necessary. Finally, hypomagnesia can accompany hypocalcemia and interfere with normalization of low serum calcium concentrations. Serum magnesium levels should thus be monitored after surgery, and hypomagnesia should be corrected with oral or intravenous magnesium sulfate. The hypocalcemic nadir after parathyroidectomy for 2°HPT generally occurs 2 to 4 days after surgery, with most patients showing improving serum calcium levels thereafter. A small number of these patients have persistent hypocalcemia, however, presumably as a result of parathyroid remnant or autotransplant failure. These patients need ongoing calcium and vitamin D supplementation. Finally, all patients after 2°HPT and 3°HPT surgery must be followed for the development of recurrent or persistent disease. Serum calcium and PTH concentrations should be measured 1 week after surgery, 6 months later, and then annually. Rising serum calcium and PTH concentrations are suggestive of recurrent or persistent disease and should prompt evaluation for additional medical or surgical therapy.

Metabolic Changes Following Bariatric Surgery

Ali Tavakkoli, MD, and Robert N. Cooney, MD

METABOLIC CONSEQUENCES OF OBESITY

Obesity is an excess accumulation of body fat, and is commonly defined as a body mass index (BMI) of more than 30. Although BMI is easy to calculate, assessing obesity based on BMI has several limitations. For example, athletic individuals may have an elevated BMI because of increased muscle mass instead of excess fat. Although one can calculate body fat and define obesity as percentage body fat more than 32% in women and more than 25% in men, these calculations are difficult. More importantly, neither BMI nor percentage of body fat definitions of obesity provides any information on the regional distribution of excess body fat. This is important because the metabolic consequences of obesity are influenced by both the amount and the distribution of body fat. Abdominal or visceral obesity leads to a chronic inflammatory state caused in part by the release of free fatty acids and cytokines from adipose tissue. Visceral obesity is associated with increased risk of insulin resistance, hyperlipidemia, hypertension, cardiovascular disease (CVD), and stroke. This pattern is also referred to as android obesity and is more commonly seen in men. The gynecoid pattern of obesity is characterized by an excess accumulation of subcutaneous fat in the gluteal and buttock areas, more commonly seen in women, and is less frequently associated with adverse metabolic effects. The importance of central obesity is highlighted in populations who, despite relatively low BMI, have high levels of visceral obesity (e.g., Asians) and are prone to adverse effects of obesity at a lower BMI.

Although the obesity epidemic in the United States is well documented, affecting 36% of the adult population and nearly 20% of children, the problem is an international one, with many Western countries reporting similar rates. The highest rate of obesity is observed in Samoa, where it affects 75% of adults. The global epidemic of obesity is multifactorial and has genetic, environmental, and epigenetic roots. The recent exposure of humans to an environment with excess cheap food is thought to have led to an imbalance between caloric intake and energy expenditure, resulting in pathologic excess fat deposition. The risk of reaching this detrimental state of fat accumulation in our current environment is modulated by genetic risk factors, diet, exercise, and lifestyle.

Although adipose tissue was originally thought to be a relatively quiescent accumulation of stored calories, more recent studies indicate adipose tissue to be metabolically and hormonally active. In severe obesity, excess lipid accumulates in these metabolically active adipocytes, and in hepatocytes and muscle cells. Excess accumulation of nutrients and fat within these cells leads to increased secretion of adipocyte-derived peptides (e.g., leptin, adiponectin, resistin) and cytokines (e.g., tumor necrosing factor–α [TNF-α], interleukin-6 [IL-6]) collectively referred to as adipokines. The paracrine and endocrine actions of these adipokines contribute to a state of chronic low-grade inflammation, which in turn interferes with many physiologic cellular processes (such as insulin signaling) and leads to the metabolic derangements seen in obesity (such as insulin resistance and type 2 diabetes).

The obesity-induced inflammatory state adversely affects most organ systems in the body and contributes to a shortened life expectancy. Each 5-unit increase in BMI is associated with a 30% increase in all cause mortality, with BMIs of more than 40 associated with a reduced life expectancy of 8 years. Obese individuals have a poor quality of life with increased risk of many life-threatening conditions, including: cancers, heart disease, type 2 diabetes, hypertension, stroke, hyperlipidemia, and sleep apnea. The prevalence of these comorbidities often increases with the severity of obesity (Table 1). This is most evident with type 2 diabetes. At age 18 years, women with a BMI of 30 to 35 have a 54.6% lifetime risk of development of diabetes, which is increased to 74.4% for those with BMI of more than 35.

Although modest weight loss (5% to 10% excess weight) can lead to reductions in the risk of these chronic diseases, nonsurgical weight loss is often unsuccessful or short lived in 90% to 95% of patients. As a result, bariatric surgery has become the standard of care in the treatment of medically complicated or morbid obesity. A variety of weight loss operations are in common practice.

METABOLIC IMPROVEMENTS AFTER WEIGHT LOSS SURGERY

Weight Loss

The term excess body weight loss (EBWL), calculated with the actual and ideal body weight, is commonly used to describe weight loss. Not surprisingly, the degree of EBWL varies between procedures. The mean EBWL is 70% to 80% for biliopancreatic diversion (BPD) with or without duodenal switch, 60% to 70% for Roux-en-Y gastric bypass (RYGB), 50% to 60% for sleeve gastrectomy (SG), and 40% to 45% for laparoscopic adjustable gastric banding (LAGB) at 2 years. In general, procedures with higher weight loss are also associated with increased short-term and long-term complications. The balance between the desired weight loss and surgical risk influences the patient when choosing an operation and the surgeon when offering the procedure.

The mechanisms underlying the weight loss are multifactorial and vary by procedure. The proposed mechanisms for postsurgical weight loss are summarized in Table 2. Of critical importance are long-term changes in appetite and hunger after surgery. In contrast, nonsurgical weight loss leads to increased hunger and reduced energy expenditure, which presumably contribute to the ultimate failure of dieting in achieving long-term weight reduction. Weight loss surgery prevents such physiologic responses and maintains hunger control despite limited calorie intake.

Long-term follow-up studies such as the Swedish Obesity Study show significant long-term weight loss in surgical patients compared with control subjects, with up to 20 years of follow-up. The durability of postsurgical weight loss is a concern for patients and clinicians. Definition of successful weight loss for bariatric surgery varies depending on the procedure but for RYGB is described as losing and maintaining 50% or more EBWL. Most patients regain some weight after reaching their nadir weight, with pathologic weight regain (>20% of the maximal weight loss) reported in 15% to 20% of patients. This observation highlights the fact that bariatric surgery is not a replacement for long-term lifestyle changes that are needed to help maintain weight loss. A commitment to changes in diet and exercise are critical for long-term success. The importance of such changes and the need for regular postoperative follow-up examination with the bariatric team should be discussed with patients before surgery.

TABLE 1: Risks of cardiovascular and metabolic disorders with obesity

Life expectancy	30% increase in mortality rate for each 5-unit increase in BMI. In patients with BMI > 40, life expectancy is reduced by 8 years.
Hypertension	5-fold risk of hypertension in obese individuals. 85% of patients with hypertension have a BMI > 25.
Cardiovascular disease	A 9% increase in cardiovascular mortality rate with each unit increase in BMI.
Type 2 diabetes	Men with BMI ≥ 35 have 42-fold increase in risk of diabetes compared with men with BMI < 23. 74% lifetime risk of type 2 diabetes if BMI > 35.

BMI, Body mass index.

TABLE 2: Proposed mechanisms for weight loss after bariatric procedures

Physical restriction of food intake	Although a common belief, especially in case of LAGB, little data support this. Food transit through the stomach is only minimally altered after LAGB, and the supraband compartment is empty of food within 1-2 min after ingestion. BPD has a large gastric reservoir and yet leads to best weight loss results.
Malabsorption	Although a degree of this occurs after BPD, little malabsorption is seen after LAGB, SG, or RYGB as measured with stool calorimetry and nitrogen balance.
Decreased hunger signals and reduced food intake	This is true for all bariatric procedures and the result of hormonal changes along the gut-brain axis after surgery.
Increased energy expenditure and diet induced thermogenesis	Although this has been documented in rodents, little data support this in humans.
Changes in food preference	Changes in food preference have been documented and are related in part to alterations in reward and taste and concerns about physiologic implications of ingestion of certain foods that may lead to dysphagia or dumping syndrome.
Changes in gut microbiota	Animal studies show a role for intestinal microbacteria in obesity and diabetes. Definitive human data are currently lacking, but this is an area of significant scientific interest.

BPD, Biliopancreatic diversion; *LAGB,* laparoscopic adjustable gastric band; *RYGB,* Roux-en-Y gastric bypass; *SG,* sleeve gastrectomy.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is present in more than 70% of individuals with a BMI of more than 35 and represents a spectrum of disease characterized initially by the accumulation of liver fat (steatosis), which if severe, causes inflammation and nonalcoholic steatohepatitis (NASH) and later fibrosis or cirrhosis. Hepatic steatosis and NASH, markers of central adiposity, are thought to be important in the pathogenesis of obesity-related metabolic disorders, often referred to as the metabolic syndrome (visceral adiposity, insulin resistance, hyperinsulinemia, hypertension, hyperlipidemia). NASH is a leading cause of cirrhosis in the United States and one of the main indications for liver transplantation. Therefore, resolution of NASH-related hepatic injury is an important endpoint in bariatric and metabolic surgery. Studies have shown weight loss operations lead to a near universal improvement in the severity of hepatic steatosis, inflammation, and fibrosis. A few cases of worsening fibrosis and inflammation have been reported, although in most cases, this is transient and is thought to be related to the rate of postoperative weight loss. Although all bariatric procedures lead to improvements in the severity of liver injury, a recent study showed patients who underwent RYGB had significantly greater improvement in grade of liver disease compared with those who underwent restrictive-only procedures (SG and LAGB; 95% vs 66%) as a direct result of better weight loss seen after RYGB.

Lipid Profiles

Dyslipidemia is seen in up to 50% of patients who undergo bariatric surgery, with more than 70% experiencing an improvement or resolution of this comorbidity within 2 years of surgery. Surgery leads to reductions in total cholesterol and low-density lipoprotein (LDL) and also increases high-density lipoprotein (HDL) levels. Variation is found in the remission rate of dyslipidemia between the common bariatric procedures, and better results are achieved with the more malabsorptive operations, with BPD leading the way with a 90% remission/improvement rate. In a recent study that compared SG and RYGB, gastric bypass led to a reduction in cholesterol and LDL and an increase in HDL, and the SG only increased HDL without altering LDL levels. Both operations result in a significant reduction in triglyceride levels.

Hypertension

Hypertension is common in obesity and rises in prevalence with increasing weight. The odds ratio for hypertension is 1.7 for individuals who are overweight compared with those of normal weight and is 2.6 for BMI 30 to 34.9, 3.7 for BMI 35 to 39.9, and 4.8 for BMI 40 or more. Elevated blood pressure is seen in up to 50% of patients who undergo bariatric surgery, with 60% to 70% documenting an

improvement or remission after weight loss surgery. Improvements in blood pressure are also linked to weight loss, and the remission rates vary between the bariatric procedures.

A meta-analysis of several studies showed improvement in hypertension in 58% of patients undergoing LAGB. These improvements were less evident when gastric banding was studied in randomized fashion with control arms. In a small Australian study of obese adolescents randomized to LAGB, systolic blood pressure (BP) was reduced by 12.5 mm Hg compared with baseline values; however, this was not significant when compared with the control group. The Swedish Obesity Study, a study cohort that consisted mainly of adjustable or vertical banding, also showed no significant improvement in hypertension at 10 years after surgery compared with control subjects, although a modest improvement was seen at the 2-year time point.

For patients who undergo RYGB, hypertension has been shown to improve or resolve in 60% to 70% of cases compared with baseline, an observation that has been further confirmed in a nonrandomized study. A European study of patients undergoing RYGB or intensive medical therapy showed the rate of hypertension remission was 49% for the surgical group versus 23% for the medical therapy group. BPD has also been shown to resolve hypertension in 60% to 80% of patients.

Cardiovascular Risk and Mortality

CVD remains the leading cause of mortality in the United States. Several risk scores have been developed to calculate an individual's risk of having a cardiovascular event and are widely used to help guide strategies for primary prevention. Of these risk scores, the Framingham risk score (FRS) is most commonly used. This risk score is calculated on the basis of age, gender, and smoking status and cholesterol, HDL, and systolic blood pressure. These parameters are all improved after bariatric surgery; therefore, it is not surprising that weight loss procedures have been shown to reduce FRS and the 10-year risk of a cardiac event by 40%. Serum and laboratory risk predictors, such as creactive protein (CRP), have also been shown to decline after surgery by about 60%.

Two large cohort studies have shown the reductions in risk factors also translate to reductions in mortality rate. In a large cohort study from Utah, at a mean follow-up of 7.1 years, cardiovascular mortality rate was decreased by 56% compared with control groups. Similar improvements in cardiovascular mortality have also been reported in the Swedish Obesity Study.

Type 2 Diabetes

Of all metabolic changes after bariatric surgery, none have been as impressive as the improvements in glucose homeostasis. Type 2 diabetes has reached epidemic proportions in the United States, and despite significant investments in preventive measures, the rate is set to continue to climb. New pharmacologic therapies (glucagon-like peptide-1 [GLP-1] analogues and dipeptidyl peptidase-IV [DDP-IV] inhibitors) have been disappointing, and most patients with diabetes do not reach the therapeutic goals set by the American Diabetic Association and other endocrine societies (glycosylated hemoglobin [HbA_{1c}], <7%). These trends and the remarkably rapid improvement in diabetes seen after bariatric interventions have pushed surgery to the forefront of the diabetes treatment and created the field of *metabolic surgery,* defined as the operative manipulation of a *normal* organ or organ system to achieve a biologic result for a potential health gain.

The observation that alterations in gastrointestinal anatomy can lead to diabetes resolution was noted more than 50 years ago, and improvements in glycemic control after weight loss operations have been well documented for the past 20 years. Several large studies and meta-analyses have confirmed that all bariatric procedures lead to significant improvements in glucose control and diabetes remission, although success rates vary between the different operations with RYGB and BPD offering the best chance of disease remission (Table 3). Although improvements in glycemic control are expected after any form of weight loss (surgical or diet-induced), studies have confirmed weight-independent effects on diabetes after RYGB and BPD.

Three randomized studies have now confirmed that LAGB, RYGB, SG, and BPD lead to better diabetes control than intensive medial therapy. In the study that compared LAGB with medical therapy, surgery led to a diabetes remission rate of 73% versus 13% for the medical arm at 2 years. The improved outcomes in the surgical arm were linked to improved weight loss. Mingrone and colleagues compared medial therapy with RYGB or BPD and showed that at 2 years diabetes remission (defined by fasting glucose <100 mg/dL and HbA_{1c} <6.5% in the absence of pharmacologic therapy) was seen in 0 in the medical arm compared with 75% in RYGB and 95% for BPD. Interestingly, weight loss did not predict glycemic improvement after these procedures. Schauer and associates compared medical therapy with RYGB or SG and showed that after 12 months of follow-up, diabetes remission (defined as HbA_{1c} <6% with or without medications) was 12% in the medical group versus 42% in the RYGB and 37% in the SG arms.

These data have prompted many of the diabetes societies to alter their treatment guidelines for management of type 2 diabetes and recommend surgery in patients with poorly controlled diabetes and BMI of more than 35. The International Diabetes Federation, an umbrella organization that represents many national societies, in their 2011 position statement went one step further, recommending that patients with BMI of more than 30 and diabetes that is poorly controlled with medication should also be considered for surgery.

Although the antidiabetic effects of LAGB are directly linked to weight loss, the studies point to a weight-independent effect for RYGB and BPD. This topic has received significant scientific attention over the last few years with many proposed mechanisms (Table 4). Although many hormones have been investigated to help elucidate the mechanisms of weight-independent effect of RYGB on glucose homeostasis, GLP-1 has emerged as a likely explanation, with several

TABLE 3: Weight changes and metabolic improvements 2 years after bariatric procedures

	Weight loss	Lipid improvement	Hypertension	T2D improvement
BPD	70%-80%	90%	80%	90%
RYGB	60%-70%	60%-70%	60%	80%
SG	50%-60%	50%-60%	60%	70%-80%
LAGB	40%-45%	60%	58%	50%-60%

BPD, Biliopancreatic diversion; *LAGB,* laparoscopic adjustable gastric band; *RYGB,* Roux-en-Y gastric bypass; *SG,* sleeve gastrectomy; T2D, type 2 diabetes.

TABLE 4: Proposed mechanisms for anti-diabetic effects of RYGB and other similar procedures

Restriction and acute decrease in food intake after surgery	Unlikely. Food intake is reduced after many GI surgeries where patients are kept nothing by mouth. Most of these surgeries, however, lead to a state of insulin resistance rather than sensitivity.
Malabsorption	Unlikely. No evidence that RYGB leads to enough nutrient malabsorption to account for the rapid improvement in diabetes.
Changes in postprandial incretin response	Postprandial GLP-1 levels are increased after these surgeries, leading to enhanced insulin release. This is likely from earlier delivery of food to the distal small bowel where GLP-1 is primarily secreted.
Isolation of proximal bowel from nutrient flow	Evidence points to a role for proximal bowel in sensing nutrient availability and quality. Isolation of this region of the intestine from nutrient exposure can lead to alterations in nutrient absorption and glucose homeostasis. This idea is behind some of the metabolic devices currently in development.
Intestinal gluconeogenesis	Rodent studies have suggested that ability of proximal bowel to generate glucose and release it to the portal circulation leads to changes in hepatic insulin sensitivity and glucose homeostasis. Human studies are lacking.
Changes in circulating bile acids	Human and animal studies have shown increased circulating bile acid levels in patients after RYGB and linked this to improved glucose homeostasis.

GI, Gastrointestinal; *GLP,* glucagon-like peptide; *RYGB,* Roux-en-Y gastric bypass.

studies showing increased postprandial levels after RYGB and BPD. GLP-1, an incretin hormone, leads to enhanced insulin secretion and satiety. However, it likely is not the only contributing factor; isolation of the proximal bowel from nutrient exposure also appears to play a critical role by altering nutrient sensing. Alterations in vagal signaling have been identified as a potential mechanism that leads to the metabolic benefit of surgery.

Although more work is needed to help understand the mechanism of diabetes improvement after RYGB and other weight loss operations, we have entered an era of metabolic surgery where surgical outcomes are assessed by improvements in diabetes and cardiovascular risk factors.

METABOLIC SURGERY AND FUTURE DIRECTIONS

The slow progress in finding effective new medical therapy for type 2 diabetes, the increasing prevalence of the disease, and increasing data that confirm effectiveness of bariatric surgery in diabetes remission have been the impetus behind recommendations to lower the BMI threshold for surgical intervention in patients with diabetes to 30, and possibly below. An intense interest also exists in understanding the scientific mechanisms that underlie the antidiabetic effects of these procedures to help develop less invasive alternatives that can replicate the metabolic benefits of these procedures. Alternative surgical procedures have been tested, and significant investment has been seen in developing endoluminal devices for treatment of diabetes, heralding with it the emerging field of "interventional diabetology."

Surgery in Patients With Diabetes and Low Body Mass Index

The 1991 National Institutes of Health (NIH) consensus statement recommends bariatric surgery in patients with BMI of more than 35 and type 2 diabetes. Although most patients with type 2 diabetes are overweight or obese, around 70% have a BMI of less than 35 and fail to qualify for surgical intervention on the basis of BMI. They struggle with their chronic disease, which is often poorly controlled with medications alone. Considering the impressive results of bariatric surgery, the immense interest to lower the BMI threshold for patients with diabetes who are interested in surgical intervention is not surprising. The proposal has been to lower the BMI to 30, with this number lowered to 27 for those of Asian ethnic origin, where adverse metabolic effects are seen at a lower BMI.

Several small studies have confirmed the safety of bariatric procedures in this patient population, although long-term data are lacking. There is also no consensus as to the best surgical procedure for this patient population. In a randomized study from Taiwan that involved patients with diabetes with a BMI of 25 to 34, RYGB was shown to be more effective than SG in achieving diabetes remission (93% vs 47%). The mean postoperative BMI was 22.8 for RYGB and 24.4 for SG, both within normal weight range.

Data, however, have suggested that our current surgical interventions are less effective in achieving glycemic control in patients with diabetes and low BMI. Other studies have documented cases of diabetes recurrence in patients after bariatric procedures, including RYGB. A few cases of pancreatic β-cell hypertrophy (nesidioblastosis) that lead to hypoglycemic episodes and necessitated pancreatic resection have also been documented. These observations have been cited as reasons for caution in declaring surgery the treatment of choice for the low-BMI and diabetes group and highlight the need for more studies to confirm success, safety, and durability of surgical procedures in patients with low BMI.

Alternative Surgical Procedures

Surgical steps in the rearrangements of gastrointestinal anatomy are thought to be critical to the metabolic success of most bariatric surgical procedures. These include (1) isolation of duodenum and proximal bowel from nutrient exposure and (2) earlier exposure of distal bowel and ileum to undigested food (see Table 4). Some surgical groups have worked on developing alternative novel procedures that achieve one or both of the previous goals and could have therapeutic value in patients with diabetes and low BMI. Of these procedures, duodenal-jejunal bypass and ileal interposition with or without sleeve gastrectomy have received the most attention and have been tested in human subjects with good early results. These procedures are, however, complex, and whether they offer any advantages in terms of effectiveness, durability, or safety over the more standard procedures, such as RYGB, is not clear.

TABLE 5: Broad categories of endoluminal devices in development for weight and diabetes

Device category	Mechanism of action	Examples
Restrictive devices	This category includes devices that change gastric volume or shape or modulate transit to induce earlier and prolonged satiety. Most of these devices are placed for a short period of time and lead to modest weight loss.	Intragastric balloons (e.g., BIB, Allergan, Irvine, Calif)
Barrier devices	These devices prevent nutrient contact with the proximal gut, in effect reproducing elements of RYGB. The devices are marketed as metabolic devices. They are designed for temporary placement and, although they have shown promising results, do not have the long-term effect of surgery.	Duodenal-jejunal bypass liner (e.g., EndoBarrier, GI Dynamics, Lexington, Mass)
Neuromodulators	These devices involve a generator that sends signals via laparoscopically placed electrodes to targeted organs, which can be stomach, intestine, or nerves. Signals can be stimulatory or inhibitory. Although device placement involves a surgical procedure, it is less risky than traditional bariatric procedures.	Gastric stimulators (e.g., Tantalus system, Metacure, Raleigh, NC) Vagal blockers (e.g., VBLOC, Enteromedics, St. Paul, Minn)

RYGB, Roux-en-Y gastric bypass.

Endoluminal Devices and the Interventional Diabetologist

With the recognition that gastrointestinal manipulation can lead to improvements in glycemic control, several endoluminal devices are in development to replicate the metabolic success of bariatric surgery without the need for an invasive procedure. Many such devices are in various stages of development, and a few have received regulatory approval in Europe or Australia; none have as of yet received approval in the United States. This is, however, likely to change in the near future. Their induction will herald an era when diabetes management will not be only handled by the endocrinologists but also by surgeons who will help manage obese diabetes with surgery and by advanced interventional endoscopists (interventional diabetologists) who will deploy endoluminal devices to manage patients with poorly controlled diabetes who do not qualify for surgery or wish to avoid it.

The devices in development can be broadly divided in to three groups, as summarized in Table 5. Of these, many achieve modest weight loss and with it an improvement in diabetes; a few however, are marketed as metabolic devices with a primary indication for diabetes management and not weight loss.

Glycemic Control and Cardiovascular Disease Risk Reduction After Bariatric Surgery

Fady Moustarah, MD, MPH, FRCS(C) General Surgery, Stacy A. Brethauer, MD, and Philip R. Schauer, MD

INTRODUCTION

Obesity and cardiovascular disease (CVD) are two chronic conditions that remain leading causes of morbidity and mortality; therefore, there is a need for effective therapeutic strategies to reduce their public health burden on individuals and societies. Bariatric surgery is emerging as an efficient, cost-effective solution to address these two associated chronic diseases. The objective of this chapter is not to present an exhaustive overview of bariatric surgical procedures and their therapeutic effectiveness, as this has been the subject of many comprehensive systematic reviews since 2000. The commonly performed bariatric procedures in North America are reviewed briefly, and the focus is on their effect in reducing CVD risk, especially in terms of improving glucose metabolism and diabetes control. Evidence from controlled trials published in 2012 are highlighted. In addition, results demonstrating reduced CVD incidence and mortality in large population studies, such as the Swedish Obese Subjects (SOS) project, are discussed.

The Obesity Epidemic

Obesity, or excess body fat, is now recognized as a global public health problem. According to the World Health Organization, rates have doubled since 1980; more than 1.4 billion adults, 20 years of age and older, are estimated to have been overweight and obese in 2008. The United States has the highest rates of obesity in the developed world. The World Health Organization and the U.S. National Institutes of Health use body mass index (BMI) to define overweight and obesity along a clinical continuum of increasing severity: overweight is defined as a BMI of 25 kg/m^2 or more and obesity as a BMI of 30 kg/m^2 or more, whereby BMI is a measure of body weight in kilograms divided by the square of body height in meters. On the basis of these definitions, the most recent data on obesity prevalence in the United States, from the National Health and Nutrition Survey, show that more than one third of adults and almost 17% of children and adolescents in the United States were obese in the period 2009 to 2010.

Obesity and Risk for Cardiovascular Disease

These rates not only are alarming but carry additional implications, in view of the adverse clinical effect of excess body fat, especially in relation to CVD risk and death. Many large population studies have now shown that obesity is associated with increased rates of mortality; CVD and cancer are responsible for much of this excess mortality over time. Evidence now implicates obesity as an *independent risk factor* for coronary heart disease (CHD) and show BMI to predict CHD beyond what is expected with measurement of traditional risk factors included in the risk score derived from the Framingham Heart Study (Box 1). Cardiovascular conditions associated with obesity are numerous and include hypertension, early and accelerated coronary atherosclerosis, myocardial infarction, congestive heart failure, and atrial fibrillation (Box 2). The clinical burden of these conditions is more pronounced and difficult to treat in severely obese patients.

Obesity and the Metabolic Syndrome

Beyond being recognized by the American Heart Association as an independent predictor of CVD risk, obesity, particularly the visceral type, is a key component of the metabolic syndrome. This syndrome represents a cluster of metabolic disorders that together increase CVD risk. As defined by the National Cholesterol Education Project Adult Treatment Panel III (ATP III), the concurrence of any three of the five features listed in Box 3 defines the metabolic syndrome. Visceral obesity is often associated with a proinflammatory metabolic state characterized by insulin resistance and hyperinsulinemia, which leads to impaired glucose tolerance, dyslipidemia, atherosclerosis, and progression to type 2 diabetes mellitus (T2DM).

Obesity and Diabetes

Among the modifiable risk factors for CVD (see Box 1), T2DM is a powerful independent predictor of risk. Obesity is strongly associated with T2DM: about 90% of affected patients are overweight or obese, and about 65% die of a cardiovascular event. Although initially part of the Framingham risk score, diabetes was excluded from the updated version in 2002 because it was deemed to be a CHD risk equivalent. In fact, in patients with diabetes mellitus, but no prior cardiovascular events, the risk for future myocardial infarction is equivalent to that in nondiabetic patients with established ischemic heart disease. This fact highlights the importance of effective prevention and treatment strategies in diabetic patients, especially in those who also suffer from clinically severe obesity or have features of the metabolic syndrome, which together increase CVD risk and pose a significant threat to life.

The Therapeutic Role of Weight Loss

Weight loss has been shown to be one of the most effective nonpharmacologic means of reducing risk in obese patients with diabetes. It contributes to lowering blood pressure; raising high-density lipoprotein (HDL) cholesterol levels; decreasing blood glucose, triglyceride, and insulin levels; and preventing the development of T2DM. In fact, the weight loss does not have to be substantial. Even a small (5% to 10%) weight loss, secondary to dietary and behavioral interventions, has been shown to improve blood pressure and decrease the risk of developing diabetes in people in whom glucose tolerance is already subclinically impaired. Evidence regarding the efficacy of lifestyle and behavioral modification in achieving weight loss and improving CVD risk profile is starting to emerge from large-scale randomized controlled prospective studies. The Action for Health in Diabetes ("Look AHEAD") trial is such a study (the largest of its kind, with more than 5000 enrolled patients), which published its interim 4-year results. It showed the promise of intensive lifestyle interventions in keeping overweight and obese patients with T2DM at lower CVD risk and for longer periods of time in comparison with the control group when results were averaged over the 4-year timeline of the study (Table 1). Whether this will translate into lower incidence of CVD and mortality is yet to be established on follow-up. Of

BOX 1: Cardiovascular disease risk factors

Traditional Nonmodifiable
Age (men ≥45 years; women ≥55 years)*
Family history of premature CHD (CHD in male first-degree relative aged <55 years; CHD in female first-degree relative aged <65 years)*
Gender*
Race

Traditional Modifiable
Smoking*
High blood pressure (≥140/90 mm Hg or patient taking antihypertensive medication)*
High cholesterol levels (low HDL cholesterol level: <40 mg/dL)*
Diabetes
Prediabetes condition

Emerging Nontraditional CVD Risk Factors (Associated With Visceral Obesity)
Insulin resistance/hyperinsulinemia
Dyslipidemia with elevated triglyceride levels, low HDL level, and increased apolipoprotein-B serum concentrations
Procoagulation and abnormal fibrinolysis with increased serum fibrinogen concentrations and increased production of plasminogen activator inhibitor
Inflammation with increased serum levels of C-reactive protein, tumor necrosis factor, interleukin-6
Endothelial dysfunction
Premature atherosclerosis
Microalbuminuria

*These risk factors include major independent factors accounted for in the Framingham risk score. The current version of the Framingham risk score was published in 2002. The score is used to estimate the 10-year cardiovascular risk of an individual on the basis of data obtained from the Framingham Heart Study. The score is *gender*-specific. Individuals with *low risk* have <10% risk for CHD at 10 years; those with *intermediate risk* have a 10% to 20% risk for CHD; and those with *high risk* have more than a 20% risk for CHD. In the current version of the FRS, diabetes was removed from the score. If the person has type 2 diabetes, this person is classified as having a CHD risk equivalent.

Sudden cardiac death
Stroke

importance, however, is that the Look AHEAD trial was stopped because no reduction in cardiovascular events were observed over the course of the study.

Despite the importance and effectiveness of weight loss in reducing CVD risk, the problem remaining is that sustaining weight loss over time is more of an elusive goal than the weight loss itself. This has been a consistent result of previous weight loss studies, and the data from the Look AHEAD trial constitutes level 1 evidence to support this finding. The trial showed that the maximum mean weight loss of 8.6% achieved at 1 year with intensive lifestyle intervention was reduced to 4.7% at 4 years. Pharmacotherapy for obesity has also been disappointing, inasmuch as it failed to meet weight loss expectations and has been plagued with multiple medication withdrawals from the market because of undesirable side effects. At present, bariatric surgery is the only established treatment that allows

BOX 3: Diagnostic criteria for the metabolic syndrome*

Three or more of the following five cardiovascular risk factors:
1. Central obesity (waist circumference): ≥102 cm in men; ≥88 cm in women
2. Hypertriglyceridemia: triglyceride levels ≥1.7 mmol/L (≥150 mg/dL)
3. Low levels of high-density lipoprotein (HDL): <1.03 mmol/L (<40 mg/dL) in men; <1,29 mmol/L (<50 mg/dL) in women
4. Systemic hypertension: blood pressure ≥130/85 mm Hg or necessity for medication
5. Elevated fasting plasma glucose level: ≥5.5 mmol/L (≥100 mg/dL)

*As defined by the National Cholesterol Education Program Adult Treatment Panel III (ATP III).

for significant and durable long-term weight loss, along with associated "cures" or sustained long-term improvements in weight-related comorbid conditions. Systematic reviews have previously summarized the weight loss effect of different procedures, and the durability of this weight loss has been reported in multiple-case series and large-scale population studies.

BARIATRIC PROCEDURES

Bariatric surgery has evolved considerably since the 1960s. Commonly performed bariatric procedures today can be classified according to their anatomic and physiologic features. Traditionally, procedures have taken one of two forms, or both: reduction in the size of the stomach, so as to mechanically restrict food ingestion, and bypass of varying lengths of intestine, so as to cause malabsorption of ingested nutrients. Increased recognition of the hormonal contribution to the observed biochemical effects of the practiced procedures has led to the adoption of the term *metabolic gastrointestinal surgery.* Common restrictive procedures include adjustable gastric banding (AGB) and sleeve gastrectomy; combination restrictive/malabsorptive procedures include Roux-en-Y gastric bypass (RYGB) and biliopancreatic diversion (BPD), with or without duodenal switch (BPD±DS) (Table 2 and Figure 1). Procedures vary in terms of their surgical techniques (laparotomy or laparoscopy), magnitude of weight loss and extent of its durability, resolution rate of associated comorbid conditions (Table 3), and risk profile (Table 4). Detailed descriptions of these procedures with technical drawings can be found in the chapter titled "Laparoscopic Surgery for Severe Obesity."

Effect of Bariatric Surgery on Risk Factors for Cardiovascular Disease and Components of the Metabolic Syndrome

Improving glucose and lipid metabolism and alleviating systemic inflammation are among the principal biochemical mechanisms by which bariatric surgery reduces CVD risk. The surgically induced weight loss and associated improvement in blood pressure also contribute independently to decreasing CVD risk. The rest of this chapter highlights the biochemical improvements observed after bariatric surgery, and some of the clinical evidence for such favorably altered metabolism is reviewed.

Glycemic Control

Insulin resistance and T2DM are remarkably improved after bariatric surgery. The American Diabetes Association defines diabetes in

non-pregnant adults based on the following glycemic criteria: (1) symptomatic hyperglycemia with a random plasma glucose ≥11.1 mmol/L (200 mg/dL), (2) a plasma glucose >11.1 mmol/L (>200 mg/dL) 2 hours after a 75-gram oral glucose tolerance test, (3) a fasting plasma glucose ≥7 mmol/L (126 mg/dL), or (4) HbA1c ≥6.5%. Even though improvements in glycemic control after gastrointestinal surgery were reported as long ago as the 1960s, it was in 1995 that in a landmark paper, Pories and colleagues described the durable effect of bariatric surgery in controlling T2DM more than a decade after the operation. Since then, many reports have confirmed the therapeutic effect of the various bariatric procedures in obese prediabetic patients (with impaired fasting glucose) and in patients with frank T2DM.

In fact, bariatric surgery has been shown to improve insulin sensitivity and play a role in prevention by halting the development of diabetes in patients at high risk for T2DM. Today, the mechanisms for such postoperative improvement in glucose metabolism as a function of time remain an active area of research. Clinically, however, glycemic control improves within days after surgery, even when the amount of weight loss is insufficient to explain the observed improvement. In one series, Schauer reported immediate postoperative independence from oral hypoglycemic agents on post-RYGB discharge from the hospital in 30% of patients who were on such medication preoperatively. What is more remarkable than the ability of bariatric surgery to completely reverse established diabetes is the ability to put the condition into remission for prolonged periods of time. In a study published by Pories, 83% of 165 diabetic patients experienced remission of diabetes at a mean follow-up of 9.4 years after RYGB.

The best evidence for the durability of remission over time came from a large-scale controlled observational study, the SOS project. This study showed reversal of diabetes in 72% of the patients who underwent surgery, in comparison with only 21% of the control group, at 2 years of follow-up. The durability of this remission was related to maintenance of weight loss. At 10 years, as weight regain was observed, diabetes remission rates remained impressive but were decreased to 36% in the surgery recipients and 13% in the control subjects. The odds ratios for surgical recovery from diabetes at 2 and 10 years were 8.42 (95% confidence interval [CI]: 5.68 to 12.5) and 3.45 (95% CI: 1.64 to 7.28), both significant at $P < 0.001$ respectively.

Meta-analyses of smaller scale studies also demonstrate the durability of diabetes remission after bariatric surgery. In a meta-analysis, Buchwald and colleagues (2009) reviewed the results of 621 studies and observed an overall 78.1% resolution of clinical manifestations of diabetes after surgery, noting that the proportions of patients with diabetes resolution or improvements were similar before and after 2 years of follow-up. Diabetes resolution was reported to be the most extensive for patients undergoing BPD with or without duodenal switch (95.1%), followed by RYGB (80.3%), and AGB (56.7%). A limitation of this study rests in its use of clinical reports of diabetes remission rather than hard biochemical markers of glucose control.

The superiority of bariatric surgery to conventional medical therapy in achieving improved glycemic control in diabetic patients is still being documented. Evidence is available from three well-designed randomized control trials that addressed this question through the use of hard biochemical markers of glucose metabolism, such as fasting plasma glucose and hemoglobin A_{1C} (HbA_{1C}) levels as endpoints (Table 5). In Dixon and associates' (2008) study, 30 diabetic patients who underwent surgery were compared with a matched control group of 30 patients over a period of 2 years. They found that remission of diabetes occurred in significantly higher numbers of patients who underwent laparoscopic AGB than in those who received standard treatment (73% vs 13%), on the basis of achieving a HbA_{1C} level lower than 6.2%, attaining a fasting plasma glucose level lower than 7 mmol/L, and taking no antidiabetic medications. In 2012, Schauer and associates released the first report from the STAMPEDE (Surgical Therapy And Medications Potentially Eradicate Diabetes Efficiently) randomized clinical trial. This study randomly assigned 150 patients with T2DM (mean age, 49; 68% female; mean preoperative HbA_{1C} level, 9.2%), with equal duration of diabetes before surgery, to receive either intensive medical therapy alone or medical therapy plus RYGB or sleeve gastrectomy; 50 patients were assigned to each of the three groups. After 1 year, weight loss was

greatest in the RYGB recipients, and a HbA_{1C} level lower than 6% (primary endpoint) was achieved in 42% of patients who underwent RYGB, in 37% of patients who underwent sleeve gastrectomy, and in only 12% of those who received only medical therapy.

Also in 2012, Mingrone and colleagues published results of their study on bariatric surgery versus conventional medical therapy for T2DM. Their primary endpoint was diabetes remission at 2 years, as measured by a fasting plasma glucose level lower than 5.6 mmol/L and a HbA_{1C} level lower than 6.5% in the absence of diabetic drug therapy. Patients (mean age, 43.4 years; 47% female; mean preoperative HbA_{1C} level, 8.65%) were randomly assigned to undergo RYGB, BPD, or medical therapy. Better glycemic control was observed in the surgery recipients after 2 years, and although diabetes remission rates were 95% and 75% after BPD and RYGB, respectively, no remission occurred in patients who received only medical therapy. An important post hoc analysis also showed that, in contrast to the previous results with the laparoscopic AGB in Dixon and associates' trial, initial BMI and postoperative weight loss were not predictive of the improvement in hyperglycemia observed after surgery.

For patients with poorly controlled T2DM and BMIs of 35 kg/m^2 or more, bariatric surgery is currently considered as acceptable therapy; however, such treatment remains controversial for patients with class 1 obesity or BMIs between 30 and 35 kg/m^2 (Table 6). In 2011, the International Diabetes Federation (IDF) released its position statement recognizing a role for bariatric surgery as a treatment option alternative for patients with class 1 obesity in whom diabetes cannot be adequately controlled by optimal medical regimens, especially in the presence of other major CVD risk factors. The American Diabetes Association remained conservative on this issue and indicated that surgery for class 1 obesity and diabetes should be restricted to approved research protocols. In 2012, the American Society for Metabolic and Bariatric Surgery (ASMBS) also reviewed the

currently available clinical evidence and released a position statement highlighting the emerging role of bariatric surgery in treating class 1 obesity and T2DM. In summary, the ASMBS stated that AGB, sleeve gastrectomy, and RYGB have all been shown to be safe in randomized trials and are effective in patients with BMIs of 30 to 35 kg/m^2 in the short and medium term. It also stated that patients with class 1 obesity who are unable to achieve substantial and durable weight and comorbidity control with nonsurgical therapeutic methods should be considered eligible for surgery.

Lipid Metabolism

As visceral adiposity diminishes and insulin resistance improves after bariatric surgery, so does the metabolic syndrome with its associated components, including dyslipidemia, thereby decreasing CVD risk. Batsis and colleagues (2008) performed a population-based retrospective study and showed that over a mean follow up period of 3.4 years, the prevalence of metabolic syndrome decreased from 87% to 29% of 180 surgically treated patients, whereas the risk reduction was only 10% in patients who had been treated nonsurgically. Postoperative improvements in serum lipid profiles have been documented in numerous reports and include reductions in total cholesterol, low-density lipoprotein cholesterol, and triglyceride levels and increases in HDL cholesterol. These changes are observed in the majority of patients and are more frequent after procedures with a malabsorptive component. In one study, for example, Nguyen and associates (2006) found that 82% of patients on lipid-lowering therapy were able to discontinue such drugs 1 year after RYBG. A much larger retrospective study performed in 949 patients showed that plasma concentrations of triglycerides, HDL cholesterol, and low-density lipoprotein cholesterol all significantly improved over a similar 1-year time frame after RYGB. At the Cleveland Clinic, a smaller study demonstrated improvement in apolipoprotein B levels as early as 3 months postoperatively. After BPD, long-term 5-year to 10-year improvement in dyslipidemia is particularly impressive; resolution rates of 95% to 100% have been reported.

Inflammatory State

Many investigators have described the favorable modulation of a number of obesity-associated inflammatory markers after bariatric surgery. Adipose tissue is no longer viewed as inert energy storage tissue; it is now appreciated as an endocrine organ that produces a spectrum of adipokines that have important inflammatory and immune functions. Obesity, particularly the central or abdominal type, is seen as a state of chronic systemic inflammation contributing to various aspects of CVD risk, including accelerated atherosclerosis and endothelial dysfunction. Surgically induced weight loss; the resultant improvement in visceral adiposity, insulin resistance, and dyslipidemia; and the reduction in inflammatory molecules all contribute to improving the inflammatory state. High sensitivity C-reactive protein levels, for example, show consistent decreases after bariatric procedures by up to 89%. In one study in which more than 430 patients were monitored for approximately 1 year, C-reactive protein levels were above the 3-mg/dL cutoff level in only 10% of patients after RYGB, in comparison with 35% of patients before RYGB.

Although interleukin-6 levels have been shown to decrease by up to 41% after bariatric surgery, the authors observed no such decreases in interleukin-6 or interleukin-10 levels after RYGB in a prospective study of inflammatory markers in patients evaluated at the Cleveland Clinic; leptin, plasminogen activator inhibitor 1, and C-reactive protein levels decreased significantly, however, at 3 and 6 months of follow-up. Fibrinogen and interleuken-1 receptor antagonist levels also decreased, and adiponectin levels significantly increased at 6 months in the authors' study. Adiponectin is an important adipose tissue–derived cytokine, levels of which are decreased in obesity and increased from 30% to 140% after weight loss surgery, according to some reports. The function of adiponectin is not fully understood at this time, but its presence is correlated positively with improved insulin sensitivity. It can also cause vasodilation by stimulating nitric oxide in endothelial cells and can contribute to decreased atherogenesis and lower CVD risk.

Reduced Cardiovascular Disease and Mortality After Bariatric Surgery

It is now recognized through multiple observational studies that surgically induced weight loss is associated with a reduction in overall mortality. The strength of available evidence varies and is limited by study design, surgical procedure, and patient selection. In 2004, the McGill Bariatric Cohort Study—a retrospective case–control analysis

TABLE 6: American and international guidelines for bariatric surgery eligibility in adults

Guideline	ASMBS (2012)*	American Diabetes Association (2012)	International Diabetes Federation (2011)†
Prioritization for surgery *recommended*	BMI >40 kg/m^2 or BMI >35 kg/m^2 with one serious weight loss–responsive comorbid condition	Surgery *not* prioritized for any group	BMI >40 kg/m^2 or BMI >35 kg/m^2 when diabetes and other comorbid conditions not controlled by optimum medical treatment
Eligibility for surgery can be *considered*	BMI >30 kg/m^2 when substantial and durable weight loss and comorbidity improvement are unachievable with nonsurgical methods	BMI >35 kg/m^2, especially if diabetes or other comorbid condition is not controlled by lifestyle and pharmacologic treatment	BMI >35 kg/m^2, or BMI >30 kg/m^2 when diabetes and other comorbid conditions are not controlled by optimum medical treatment
Comment	AGB, SG, and RYGB have been shown in randomized controlled trials to be safe and effective in patients with BMIs of 30-35 kg/m^2 in short and medium term	Little evidence for patients with BMIs between 30 and 35 kg/m^2; use should be restricted to research protocols	Adjustment of BMI for patients of Asian ethnic origin is advised

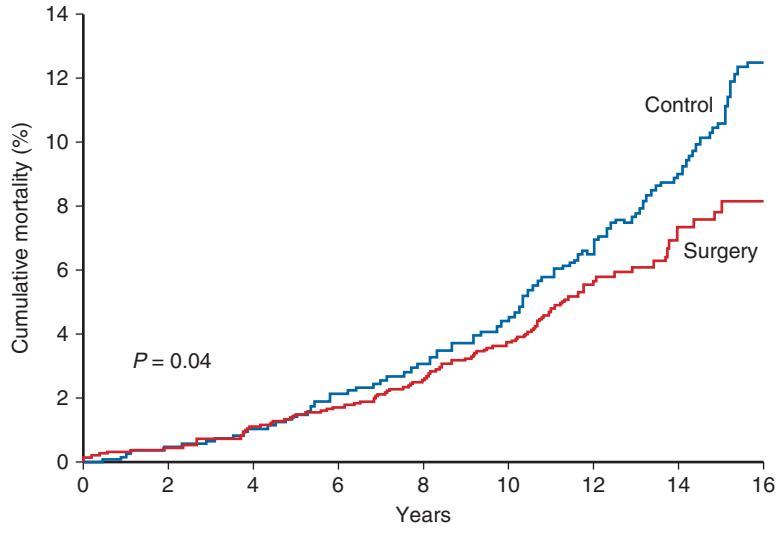
in which more than 1000 surgically treated obese patients were compared with more than 5700 obese control subjects—was the first to report that a 67% excess weight loss at 5 years was associated with an 89% reduction in relative risk for mortality. A retrospective case-control matched study from the University of Utah also showed a survival advantage in their surgical group after RYGB with a mean follow-up of 7.1 years: The adjusted rate of long-term mortality in the surgical cohort of 7925 patients decreased by 40% in comparison with the same-size matched control group (hazard ratio, 0.6; P <0.001). The rate of coronary artery disease–related mortality decreased by 56% among the patients who underwent surgery. Other researchers also demonstrated survival benefits over a 2-year follow-up even in the higher risk Medicare patient population. Specifically, a survival advantage was observed as early as 6 months postoperatively among patients older than 65 years and as early as 11 months in patients aged 65 years or younger. Studies from Europe and Australia have also confirmed survival advantages with AGB.

Despite the evidence for improved CVD risk profile and survival in general after bariatric surgery, what remains to be established is whether this risk reduction translates into decreased incidences of CVD and of related mortality. The best evidence to address this question at present came from the SOS project, an ongoing, nonrandomized, matched, prospective observational study in which more than 4000 patients were enrolled and monitored over time in Sweden. Reports on the primary endpoint (overall mortality rate) of the SOS project were published in 2007 by Sjöström and associates (Figure 2). At 10 years, a 23.7% overall unadjusted (30.7% adjusted) decrease in mortality was observed among patients who had undergone bariatric surgery in comparison with a well-matched control population of patients who did not undergo surgery. This improvement in overall mortality after bariatric surgery, along with the repeated observations of the beneficial effect of such surgery on diabetes, dyslipidemia, and hypertension, suggest that bariatric surgery directly influences CVD.



In fact, in the most recent report from the SOS project, Sjöström and associates (2012) described the effect of obesity surgery on the predefined endpoints of myocardial infarction and stroke, reported as incidence rates of fatal and total (fatal and nonfatal) cardiovascular events (Figure 3). The study groups included 2010 patients who underwent one of three forms of bariatric surgery (BMI ≥ 34 kg/m^2 in men; BMI ≥ 38 kg/m^2 in women): gastric bypass (13.2%), gastric banding (18.7%), or vertical banded gastroplasty (68.1%); and 2037 contemporaneously matched obese control subjects who received usual medical care. Over a median follow-up period of 14.7 years (range: 0 to 20 years), bariatric surgery was associated with a reduction in the number of cardiovascular deaths and first-time cardiovascular events (fatal or nonfatal), after the cardiometabolic risk profile at baseline was controlled. In comparison with control subjects, the adjusted hazard ratio of bariatric surgery for total cardiovascular events was 0.67 (95% CI: 0.54 to 0.83, P <0.001); for fatal cardiovascular events, the adjusted hazard ratio was 0.47 (95% CI: 0.29 to 0.76; P = 0.02). It is noteworthy that weight loss was only about 16% at 15 years in the patients who had undergone surgery, whereas over time the control group showed weight changes around a maximum of 1%. Of interest, secondary subgroup analyses of the SOS data failed to demonstrate an association between initial BMI and postoperative health benefits of bariatric surgery. Even the magnitude of surgery-induced weight loss was not predictive of cardiovascular events in this cohort. This puts into question the current clinical practice of using BMI as a main indication and eligibility criteria for bariatric surgery, when cardiovascular benefits are realized independent of differences and changes in body weight. Further post hoc analysis of the SOS data revealed that, unlike baseline BMI or the magnitude of postoperative weight loss, a high baseline insulin level was in fact a predictor of cardiovascular events in the study. This suggests that weight-independent mechanisms rather than the magnitude of weight loss alone may explain part of the cardiometabolic benefits of surgery.

In an attempt to obtain further insight into the role of bariatric surgery in reducing CVD risk and improving cardiac structure and function, investigators at the Cleveland Clinic performed and published a systematic review of more than 19,500 bariatric surgery patients in 73 clinical studies. Although diagnostic criteria, cardiovascular risk factor reporting, and cardiac imaging parameters varied across published reports evaluated by the review, results were useful. Baseline preoperative prevalence of hypertension, diabetes, and hyperlipidemia were 44%, 24%, and 44%, respectively. On mean

FIGURE 2 The 2007 report of the Swedish Obese Subjects study, describing the effects of bariatric surgery on mortality: **A,** Weight change over time according to bariatric procedure used in the study. **B,** Cumulative mortality rate over course of study. *(From Sjöstrom L, Narbro K, Sjöstrom CD, et al: Effects of bariatric surgery on mortality in Swedish obese subjects,* N Engl J Med *357:741–752, 2007.)*

follow-up of 58 months (range, 3 to 176 months), an average of 54% excess weight loss was reported, and this was associated with a postoperative resolution of or improvement in hypertension, diabetes, and hyperlipidemia in 63%, 73%, and 65% of patients, respectively. What is more remarkable about the review is that echocardiographic data from 713 patients revealed significant improvements in left ventricular function, with regression in hypertrophy after surgery and improved diastolic function. This finding adds to current evidence that bariatric surgery enhances future cardiovascular health and may in fact be doing so by having direct physiologic end-organ effects on the heart.

CONCLUSIONS

Severe clinical obesity and chronic medical illnesses associated with it are no longer the sole preoccupation of patients and their internists. The pandemics of obesity, diabetes, and cardiovascular heart disease have multidimensional effects on individuals and societies, and the surgeon's current role cannot be understated as research into improving therapeutic interventions, understanding mechanisms of bariatric procedures, and developing preventive strategies continue. Beyond achieving weight loss, bariatric surgery is proving to have remarkable metabolic and cardiovascular effects in the short and

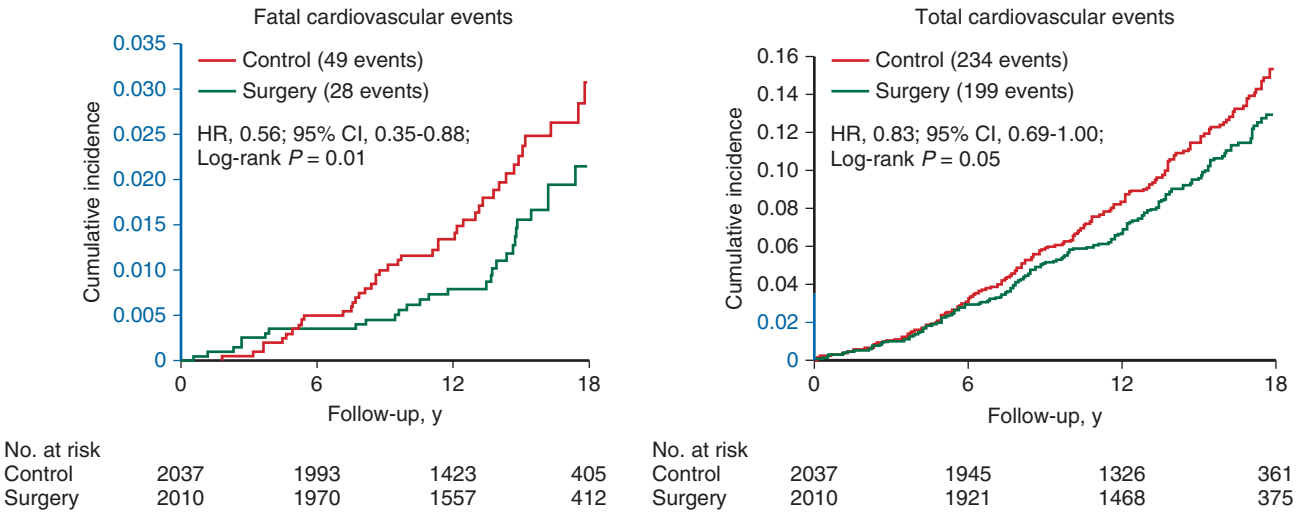

FIGURE 3 Incidence rates of cardiovascular events. The combined endpoint was myocardial infarction and stroke, whichever came first; fatal cardiovascular events and total (fatal and nonfatal) cardiovascular events are shown. The incidence data are based on observations until December 31, 2009. Follow-up time was truncated at 18 years because the number of persons at risk beyond this point was low. All persons are included in the calculation of hazard ratios (HRs). The incidence rates per 1000 person-years for fatal cardiovascular events were 0.9 (95% confidence interval [CI]: 0.6 to 1.3) among patients who underwent surgery and 1.7 (95% CI: 1.3 to 2.2) in the control group; for total cardiovascular events, the rates were 6.9 (95% CI: 6.0 to 8.0) and 8.3 (95% CI: 7.3 to 9.4), respectively. *X*-axis regions shown in *blue* indicate range from 0 to 0.035. *(Data from Sjöström L, Peltonen M, Jacobson P, et al: Bariatric surgery and long-term cardiovascular events,* JAMA *307(1):56–65, 2012.)*

long term, and its safety profile continues to improve. National and international societies have started to advocate a role for bariatric surgery even in patients with class 1 obesity and poorly controlled T2DM, especially in the presence of other CVD risk factors. Results of large-scale systematic reviews and important long-term prospective studies, such as the SOS project, all point to the important role of bariatric surgery in improving cardiovascular risk profile and decreasing the overall incidence of cardiovascular events in severely obese patients over long follow-up periods. Although the majority of patients in the SOS surgical cohort underwent procedures infrequently offered today, similar positive results are expected, and perhaps with greater magnitude, when the more frequently performed malabsorptive procedures, such as RYGB and BPD with duodenal switch, are offered today, while surgeons and scientists continue to find innovative ways to study and serve patients with severe obesity and CVD.

Nonmelanoma Skin Cancers

Paul N. Manson, MD

Common nonmelanoma skin cancers include basal and squamous cell carcinoma. The common forms of skin cancer arise from the upper layers (epidermis) of the skin:

1. Basal cell: the basal layer of the epidermis
2. Squamous cell: the superficial layer of the epidermis
3. Melanoma: the basal pigmented cells of the skin

In the United States, basal cell and squamous cell skin cancers are especially common in individuals of Northern European heritage, and it is estimated that more than 3 million cases of nonmelanoma skin cancers occur in every year. The frequency of these cancers is such that almost everyone in the United States living to age 80 will have one, and their incidence exceeds those of the other common visceral cancers combined. As the life span increases, these malignancies become more common because of the effects of sun exposure and other causative factors. The incidence of basal cell cancers (BBC) is four times higher than that of squamous cell cancers (SCC). Although most of these skin lesions behave rather benignly in comparison with other cancers, certain subtypes need to be identified; these subtypes (more aggressive lesions) must be treated differently, with wider excisions, sentinel lymph node biopsy, and continued periodic observation for regional and metastatic spread. Specifically, with these subtypes, complete negative peripheral and deep margins must be confirmed at the time of resection before reconstruction and recurrence excluded during frequent postoperative observation of the patient. Less commonly, some of these patients need, in addition to surgery, postoperative radiation treatment.

Many patients ignore their initial lesions (Figure 1), which enables development of large tumors. In these cases, and especially on the face, disfigurement may result because they can involve not only soft tissue structures but also muscle, nerves, cartilage, and bone. Statistics indicate that the annual cost of treating basal and squamous cell cutaneous cancer reaches $1 billion.

RISK FACTORS AND PRECURSER LESIONS

Risk factors for basal and squamous cell cancer include a number of carcinogens. The most agreed upon is sunlight. Cumulative exposure to sun, especially tropical sun, without protection, in fair-skinned individuals who "burn" rather than tan, is the risk most generally agreed upon. Although there is a clear relationship between sun exposure and the incidence of nonmelanoma skin cancers, clinicians debate the exact relationship; most agree that sun exposure is linked more closely to the development of squamous cell carcinoma than to that of basal cell carcinoma. Patients who have had sunlamp treatment for psoriasis are especially prone to squamous cell cancers. Some clinicians believe that microtrauma to the skin contributes to the origin of basal cell cancers. Tumors are more common on sun-exposed surfaces such as the face, scalp, and neck. Radiation exposure, such as that delivered commonly at one time for acne, is also known to predispose to the development of skin cancer and thyroid cancer.

Certain lesions are assumed to be precancerous. Actinic keratoses (Figure 2) are red, crusty lesions that weep and sometimes develop cutaneous horn proliferation. At least 15% develop into in situ and/or invasive squamous cell cancer. Therefore, treatment of these lesions with desiccating treatment such as liquid nitrogen, curettage, or excision seems reasonable in appropriate patients. Other authorities believe that topical chemotherapy such as fluorouracil (Efudex) can eliminate superficial lesions.

Because sun exposure has been implicated in the predisposition to these lesions, there has been considerable attention to programs aimed toward preventing excess exposure, especially sunburns. Two guides to this prevention are "Safe Sun Guidelines" and "Skin Protection from Ultra Violet Light Exposure" (avaialble form the Skin Cancer Foundation at www.skincancer.org). The exact effectiveness of this prophylaxis is not known, but it is under study.

Genetics may also contribute to the development of these lesions. Hereditary conditions such as basal cell nevus (Gorlins) syndrome predispose to the development of hundreds of cutaneous basal cell cancers. People of Northern European descent, such as those of Irish and English heritage, also seem more prone to the development of skin cancer. Certain oncogenes (*RIS* and *DOS*) have been implicated, as have the sonic hedgehog signaling pathway for basal cell cancer. The *PTCH* (patched) gene on chromosome 9q has been suggested in the genesis of these lesions as well.

The literature has emphasized that certain infiltrative subtypes of BCC and SCC tend to be incompletely resected, and therefore the lesions carry a high risk of persistence, recurrence, and metastasis. Such lesions are described later in this chapter, so that they may be managed with greater attention to margins.

Immune suppression, such as that utilized for organ transplantation, leads to a greatly increased frequency of cutaneous skin cancer after a period of 10 to 15 years. It is not unusual for individuals who have undergone immunosuppression to eventually suffer hundreds of aggressive skin cancers as a result, which may be lethal. Those who are immunosuppressed also tend to experience more aggressive lesions, which are less differentiated, have a higher recurrence and a lower cure rate.

FIGURE 1 Neglected basal cell cancer originating in the lip, invading the anterior maxilla and the floor of the nose.

FIGURE 2 Actinic keratoses are premalignant in 15% of cases and represent precancerous squamous cell lesions. They are characterized by slight thickening in the skin, redness, and crusting or flaking. They may be capable of cutaneous horn formation.

Ultraviolet light exposure, such as that used in psoriasis treatment, frequently causes sunburns that impair local skin immunity. Certain medications can also predispose to skin cancers.

Although occurrence at a young age has been implicated by some authorities to have an adverse effect on prognosis, there is no general agreement that this is a significant risk factor for a poorer outcome.

CLINICAL EVALUATION OF BASAL CELL AND SQUAMOUS CELL CANCERS

The physical examination and evaluation of basal cell (Figure 3, *A* and *B*) and squamous cell (Figure 4, *A* and *B*) cancers first includes an analysis of tumor location and size. The tumor should be characterized by its appearance as a probable skin cancer type. The borders of the tumor, the entire local and regional area, and local lymph nodes should be evaluated. A generalized skin examination and a complete history and physical examination would indicate whether the lesion is primary, is recurrent, or has less common features. The general health of the patient dictates other treatment considerations. Certain anatomic areas are predisposed to incomplete resection and recurrence, for example, fusion planes (areas where the primitive parts of the face come together) in the head and neck, such as the areas of the nasal labial fold and the groove between the nose and the cheeks. Certain areas such as the ear, mucosal surfaces, genitalia, and lip tend to be affected by squamous cell cancers, which possess a greater capacity for metastasis. The "mask area" of the face is known have deeper skin cancers, which are more likely to be resected incompletely, and therefore they have a higher risk of recurrence or persistence. Lesions that are larger than 2 cm in diameter carry more risk of persistence and recurrence than do smaller lesions. In general, for all lesions that carry higher risk, complete disease-free margins should be determined surgically or postsurgically, as described previously.

Although curettage and desiccation were formally appropriate for small (6-mm to 10-mm or less) low-risk lesions, a higher recurrence rate has been noted, and the practice is becoming distinctly less common in academic medical centers as an acceptable treatment. Tumors that have occurred in areas of prior radiation treatment, those that occur in areas of prior scarring or persistent ulcers, and basal cell or squamous cell cancers that have perineural involvement have a lower cure rate, lower overall survival rates, and higher recurrence rates. Lesions in which large nerve perineural involvement is

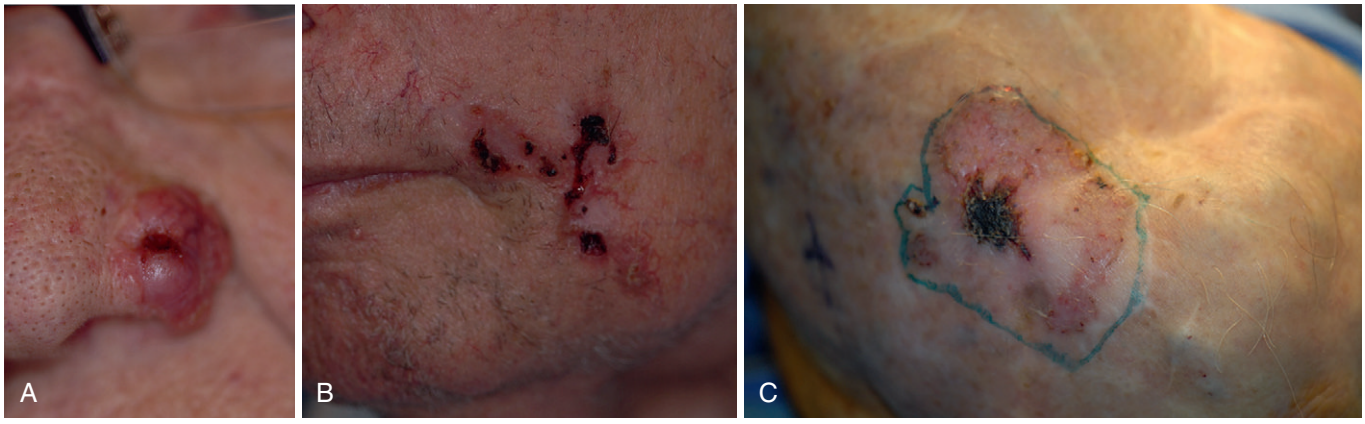

FIGURE 3 Basal cell carcinoma. **A,** Nodular basal cell carcinoma manifests as a nodule of pink, firm, opalescent, generally well-circumscribed tissue in the skin. It may be accompanied by telangiectasia and some redness of surrounding skin. **B,** Micronodular and **C,** Infiltrative and morpheaform basal cell cancer have a flat, red, crusty appearance with poorly defined borders.

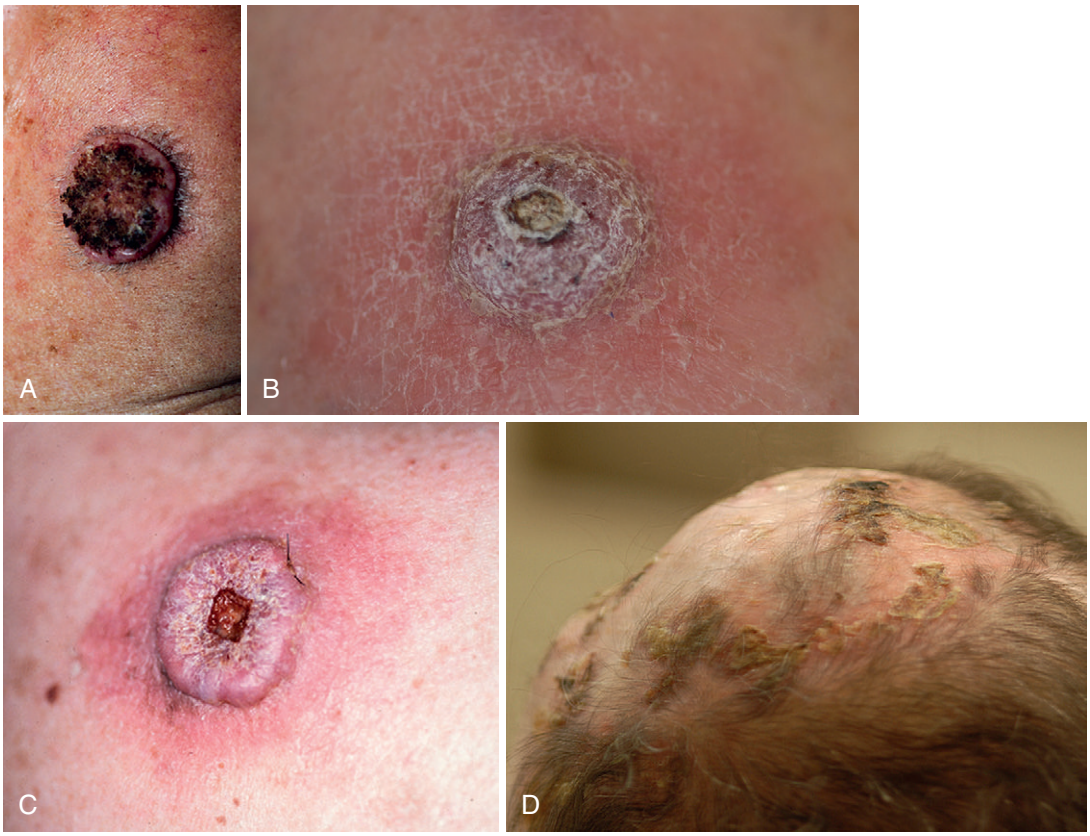

FIGURE 4 Squamous cell cancer. **A** to **C,** Squamous cell cancer, keratoacanthoma variant, has a nodular appearance with scaly superficial margin and some surrounding erythema. It grows rapidly, often from week to week, and is frequently ulcerated in the center. **D,** Squamous cell cancer has a red, scaly appearance with occasional cutaneous horn formation. Frequently, there is bleeding. Some thickening of the skin in the area of tumor is seen.

confirmed should be evaluated with magnetic resonance imaging (MRI) with gadolinium to rule out significant more distant perineural spread. The author has yearly had patients with facial poorly differentiated squamous cell carcinomas who present with sensory symptoms (numbness) and in whom MRI reveals perineural spread along the cranial nerves up to the skull base. In these lesions, and for those with higher risk of infiltrative spread, the peripheral and deep margins may be increased to accommodate these unfavorable histologic characteristics.

With regard to squamous cell cancer, moderate and poorly differentiated lesions have a higher recurrence rate and a greater potential for infiltrative local spread and local or regional lymphatic or systemic (or both) metastasis. Originally, squamous cell cancer was categorized in several grades; however, most pathologists currently believe that two general groups of behavior can be identified for squamous cell cancers:

1. Well differentiated
2. Moderately differentiated, poorly differentiated, and undifferentiated.

Although the prognosis within the latter group is dramatically worse, especially for the poor and undifferentiated lesions, the tendency is to treat these as high-risk lesions with wider and deeper resection margins, perhaps sentinel lymph node biopsy, and histologic confirmation of negative peripheral and deep margins before defect closure or flap reconstruction.

Just as squamous cell carcinoma has higher risk types characterized by less differentiated lesions, basal cell cancer has been characterized into various histologic subtypes, some of which carry a higher risk of more infiltrative spread and, in particular, frequent spread beyond the apparent clinical margins. Basal cell cancers can be divided into two broad groups on the basis of their activity and tendency for subtle infiltrative spread. It is very unusual for basal cell cancers to exhibit lymph node or systemic metastasis, and these lesions are frequently neglected, previously irradiated, multiply recurrent lesions. Nonaggressive subtypes of basal cell cancers include the following:

1. Keratotic
2. Infundibulocystic
3. Nodular
4. Superficial

The primary lesions in this group may generally be managed with 5-mm resection margins.

The subtypes that carry more risk include those with more aggressive growth patterns:

1. Micronodular
2. Infiltrative
3. Sclerosing
4. Morpheaform
5. Desmoplastic
6. Basosquamous carcinoma

Basosquamous tumors have the histologic appearance of both basal cell and squamous cell cancer in some parts of the lesion, and this process probably represents a "collision-type" lesion, which should be treated according to the differentiation of the squamous cell type.

FIGURE 5 Pigmented basal cell cancers resemble melanomas in appearance; the difference is defined only histologically. They frequently demonstrate redness, bleeding, and brown-black pigmentation.

Some basal cells are pigmented (Figure 5) and are easily confused with melanoma by appearance.

Basal cell or squamous cell cancers that develop in an area of chronic ulceration or chronic scarring (Marjolin's ulcers), such as burn scars and pressure sores, have a worse prognosis, perhaps partly because of the difficulty in establishing the diagnosis and therefore late detection and the larger size of these lesions.

The clinician should note the rapidity of growth according to the history provided by the patient because some lesions, such as the keratoacanthoma variant of squamous cell carcinoma, double in size quite rapidly. The more rapidly growing lesions should be removed for diagnosis as soon as feasible because most of these lesions are malignant, and it is impossible to differentiate the benign lesions clinically.

Nerve symptoms are especially concerning; they include numbness, pain, burning sensation, paresthesias, and, in the case of motor nerves, paralysis or muscular symptoms, such as weakness or double vision. These symptoms immediately connote high risk in the treatment of the tumor.

Subtypes of squamous cell cancers, such as adenoid or adenosquamous carcinoma, and those producing squamous cell variants are tumors whose characteristics increase the risk of incomplete resection, recurrence, and metastasis. Desmoplastic cutaneous squamous cell carcinoma similarly is often incompletely resected and thus has a higher risk of recurrence because of deeper extensions along fascial planes with failure to achieve clear margins. Some authorities have suggested that invasion of a tumor into the fat, or invasion deep enough to penetrate lymphatic vessels, constitutes (as is known with melanoma) more potential for recurrence and metastasis through invasion of blood and lymph vessels; confirmation of this opinion is as yet incomplete. These characteristics certainly should be noted by the treating physician, and more extensive treatment and evaluation locally, regionally, and systemically should be contemplated.

Squamous cell carcinoma in situ represents full-thickness atypia of the upper skin layer (epidermis), but the lesions are still noninvasive and may be treated by simple complete excision. Because dermal invasion is not characteristic of this lesion, metastasis is not possible, and so complete excision is all that is necessary. Some authorities believe that topical chemotherapy agents such as fluorouracil (Efudex) can be utilized for squamous carcinoma in situ; however, complete excision is always the treatment of choice and especially for those demonstrating any evidence of recurrence, persistence, or failure of treatment.

Clinical Appearance and Patient Examination

The clinical appearances of lesions such as squamous cell and basal cell are characteristic. Their features include color change, nodularity, and ulceration (see Figures 3, 4, and 5). Scaling and telangiectasis are frequent. In general, the skin is reddened and thickened. Flaking or keratoses may be present, and both types of lesions frequently demonstrate surrounding premalignant lesions, such as keratosis. Frequently, squamous cells arise in area of actinic keratoses, which are known to be precursor lesions.

Once the diagnosis is suspected, a complete regional examination of the skin and lymph nodes should be completed. A complete, careful skin examination is always recommended because of the frequency of additional lesions. Attention should be directed particularly to sun-exposed skin sites. Patients with basal and squamous cell carcinoma are at increased risk for developing melanoma, as well as additional nonmelanoma skin cancers.

In order to determine the best treatment for a particular skin cancer, a full-thickness skin biopsy is often necessary or desirable. This information can usually help establish lesion type, differentiation, and histologic features. Although shave biopsy is commonly employed, it may not reveal the full extent of penetration of the tumor and may miss areas that enable accurate classification of the tumor. Biopsy samples that include the deep reticular dermis help more accurately identify deeper processes and characterize the lesion. Infiltrative histologic features or deeper penetration will be missed by more superficial biopsy, and, in particular, higher risk lesions may be incompletely diagnosed on shave biopsy. For instance, the specimen from a shave biopsy of a squamous cell cancer is frequently interpreted as squamous cell carcinoma in situ, and the invasive component of the lesion is not confirmed. Squamous cell carcinomas with poorly differentiated or undifferentiated histologic characteristics and those larger than 2 cm carry more risk for infiltrative spread and lymph node involvement. Some practitioners, on the basis of histologic confirmation of aggressive characteristics, perform a sentinel lymph node examination for these lesions. Clinically enlarged nodes can be subjected to needle aspiration biopsy; however, a negative result does not preclude the need for excisional biopsy of an enlarged lymph node.

Research since 1990 has resulted in improved treatment of both basal and squamous cell cancers. This improvement is related to accurate pathologic characterization of the tumor. Although either surgery or radiation can be utilized for early lesions, surgery is generally preferred because diagnosis can be confirmed, the completeness of disease-free margin can be evaluated, and it is (usually) a one-step definitive, efficient treatment. In some cases, age, cosmetic, or functional considerations of the part affected may cause the patient to choose radiation. In general, treatment by surgery should include a complete excision of the lesion with an additional margin, whereby margin size is related to the differentiation or subtype and thus the behavior of the tumor. The margins and accuracy of pathologic confirmation of complete resection are much more important in more serious lesions.

In the past, curettage or desiccation was used for many skin cancers, whereas today this treatment is becoming less common because of the desire to achieve a complete histologic examination. Most skin lesions should be excised with confirmation of the diagnosis and the excision margins, especially for more aggressive cancers. For cancers carrying higher risk, complete excision must be confirmed with standard pathologic peripheral- and deep-margin evaluation (either Mohs' microsurgery or standard pathologic study in which frozen section and permanent sections confirm negative deep and peripheral margins).

With curettage or electrodesiccation, if the lesion extends to subcutaneous (fat) tissue, surgical excision should be performed. The effectiveness of treatment of superficial lesions by curettage depends on the clinicians' perception of reaching appropriate normal dermis tissue. Fat, being less dense than dermis, cannot be utilized to determine the characteristics of normal skin tissue. In addition, if some of the curetted tumor is sent for biopsy, the identification of a higher risk lesion should prompt a secondary surgical excision. Curettage

does not provide pathologic confirmation of negative margins or a complete evaluation of the lesion.

Complete Excision and Peripheral Margin Evaluation

For low-risk basal cell carcinomas (less than 2 cm in diameter) with well-differentiated and nonaggressive characteristics, the general cure rate is greater than 90% to 95% with 4-mm to 5-mm clinical margins. The perception of a negative margin depends on identification of the edge of clinically normal skin without erythema, telangiectasis, or any characteristics of the tumor. A nodular lesion with a surrounding rim of erythema must be treated beyond the erythema, which could represent invasion of skin by cancer. With regard to squamous cell carcinoma, margins of 5 to 7 mm are considered more appropriate. Recurrent lesions generally necessitate more margin, such as 1 cm. Careful tracing of the exact margin of the tumor with marking ink under good illumination is required. The proper peripheral margin for cure is then added to the exact lesion border of the tumor, with a second line of marking ink indicating the resection margin. Excision of larger lesions or of those originating in fusion planes may necessitate 10-mm margins, with confirmation of clear deep and peripheral margins.

Reconstruction of the Defect

In most cases, elliptical excision, with the long axis oriented in the relaxed lines of skin tension, and layered primary closure, with careful side-to-side approximation, are appropriate. In some areas, healing can be by secondary intention. The scar from such healing may be more depressed, shiny, and obvious than that occurring from primary layered wound closure. Skin grafting, either partial or full thickness, is a simple method of closing larger defects for which side-to-side approximation cannot be obtained. In the face, considerations of appearance may lead to closure of defects with local flaps, and for more extensive lesions, distant flap reconstruction is required, with secondary procedures for cosmetic improvement. In all cases, the author believes that absolute confirmation of negative surgical margins is always necessary before any complex closure, such as a flap, is accomplished.

Confirmation of Negative Margins

Techniques for rapid or intraoperative evaluation of margins include intraoperative frozen-section assessment and Mohs' surgery. In Mohs' technique, the full length of each margin is determined immediately. In either of these techniques, the immediate margin evaluation may be supplemented by a further determination of permanent margins when more confirmation is desired. Finally, with higher risk lesions, especially those for which a more complex reconstruction is required, margins can be confirmed by immediate permanent analysis techniques before reconstruction is undertaken. The wound may be left open or dressed with an allograft while the final pathologic opinion is awaited. Another technique that has been suggested, in which the size of the lesion would produce a large open, difficult-to-manage wound, is to resect a small strip of tissue at each of the four peripheral margins anticipated for the lesion and immediately close the defect edge to the remaining central specimen; the major portion of the lesion is left intact as the four samples are evaluated. The margins can then be altered appropriately and the remainder of the lesion removed at the definitive resection and reconstruction.

In a complete assessment of the deep and all peripheral margins, the surgeon must be careful to label these clearly so that they can be analyzed by the pathologist in proper sequence and in proper orientation. For all high-risk lesions, all peripheral and deep margins must be confirmed, and this should be completed before any reconstruction is accomplished. If the margins are equivocal in such lesions, a repeat assessment is performed, and the results are awaited before any reconstruction is initiated. An allograft can be placed into the defect until the permanent complete margin evaluation is available. The author prefers sentinel node evaluation for poorly differentiated high-risk squamous cell cancers, although the benefit of this technique routinely and certainly in less differentiated squamous cell cancers has yet to be proven.

Enlarged Regional Nodes

Positive results of needle or excisional biopsy of an enlarged regional lymph node or of sentinel node biopsy confirm the need to remove regional lymph nodes. The sentinel node biopsy technique, in high-risk lesions, has minimized the use of elective regional node dissection, thereby limiting morbidity to cases of proven lymph node metastasis.

Radiation Therapy as Primary or Adjunctive Treatment

Radiation therapy is not generally utilized alone for lymph node treatment or for treatment of high-risk lesions that frequently recur in the absence of initial surgical clearance, but it may be added as adjunctive treatment (for instance, in the management of poorly differentiated squamous cell lesions with the possibility of in transit spread). Sometimes, radiation therapy with or without concurrent chemotherapy is used after lymph node dissection in high-risk cases. Radiation therapy has also been utilized as adjunctive treatment in cases in which the margins are histologically but not clinically positive, for perineural involvement, and when the risk of intralymphatic spread into adjacent skin is high. Patients who have extranodal penetration of tumor—for instance, in extracapsular spread of tumor beyond lymph nodes—are also candidates for postoperative radiation therapy.

Radiation therapy in many cases of primary straightforward, nonmelanoma skin cancer can produce good cure rates and excellent cosmetic results. Many treatments are required, and there is no confirmation of negative margins, nor is there complete assessment of the entire tumor for its histologic characteristics. Of course, as in surgery, proper treatment techniques must be applied. Radiation therapy is often reserved for older patients or for cosmetically sensitive areas that are difficult to reconstruct. Some physicians prefer it for thin, wider intraepithelial lesions, such as Bowen's disease, and for patients who have multiple extensive lesions or who refuse surgery.

Patients with disease remaining after radiation therapy and chemotherapy may be candidates for vismodegib, a hedgehog pathway inhibitor, when further surgery and radiation therapy are contraindicated.

Long-Term Follow-up of Basal and Squamous Cell Cancers

All patients with basal and squamous cell carcinoma, especially those with high-risk lesions, should have a complete skin examination periodically with special attention to the area where recurrence, either locally or regionally, is likely. Although most recurrences of lesions develop within a 2-year period, a tumor can recur, in rare cases, after 5 to 10 years. Of patients who have a basal or squamous cell cancer, one third to half develop another lesion within the next 5 to 10 years. Follow-up schedules should be tailored to the particular severity and extent of disease in the patient, to the risk of recurrence, and to the severity of the original lesion.

With lesions that are capable of in-transit metastases, such as poorly differentiated and undifferentiated squamous cell cancer, an additional margin of tissue, perhaps 1 cm, must be excised to account

for the possibility of in-transit and invasive spread beyond clinically obvious boundaries. These lesions behave like melanoma in that they are capable of intralymphatic spread, which can appear adjacent to the lesion or in regional lymphatic vessels or lymph node drainage areas.

Superficial therapies for actinic keratosis, very superficial basal cells, or in situ squamous cell carcinoma include 5-fluorouracil or imiquimod. It is difficult to predict the cure rate of these treatments because they are not predicated on complete excision, follow-up is generally incomplete, and biopsy proof of eradication is lacking.

DERMATFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans is an uncommon fibrotic skin lesion. The most frequent age range of affected individuals is between 20 and 50 years. Most lesions are located on the trunk or proximal extremities; the head and neck area are affected less commonly (Figure 6). Some patients provide a causal history of trauma; however, the relationship to trauma has not been proved. The lesion grows slowly as a rule and does not metastasize; however it has a strong tendency for local fascial extension along tissue planes in small, thin finger-like projections that evade clinical perception. After conservative surgical excisions, the recurrence rate is up to 60%; therefore, it is recommended that 3-cm to 4-cm clinical margins or Mohs' surgery be utilized.

Dermatofibrosarcoma protuberans manifests clinically as a painless, firm, red to brown or purple plaque (see Figure 6). It can have soft areas or protrusions. This indolent manifestation is often enough to prevent early diagnosis because of its benign nature. The diagnosis can prove difficult, and differentiating it from other fibrotic skin processes can require special stains. Negative results of biopsy in one area should not be reassuring but should prompt more biopsy or complete excision of a suspect lesion. Immunostaining with CD34 factor, factor XIIIA (anti-metallothionein), tenascin, and stromelysin-3 is helpful in making the diagnosis. The lesion is frequently misdiagnosed both clinically and pathologically, and resection is frequently incomplete.

Treatment

Treatment of dermatofibrosarcoma protuberans is surgical excision with wide margins. Up to 4 cm has been recommended. Currently, Mohs' micrographic surgery is the surgical method of choice, which has reduced recurrence rates to about 2%. Regional lymph node biopsy is not indicated because the incidence of metastatic spread is so low (probably 1%). Although adjuvant radiation has been recommended after standard surgical treatment, achieving widely negative margins surgically is highly recommended. The value of radiation therapy in patients who have widely negative surgical margins has yet to be established.

CUTANEOUS T-CELL LYMPHOMA

Lymphomas may manifest as cutaneous lesions and include mycosis fungoides and Sézary disease, which are cancers originating from T4 helper cells. These rare tumors appear as reddish patches, plaques, or reddish lumps. They are sometimes oozing or have a psoriatic appearance. Itching is a prominent clinical symptom. Diagnosis is commonly delayed because its appearance overlaps with those of many other benign cutaneous lesions. In some patients, the lesions progress to frank systemic lymphoma over time, and 5-year survival rates thereafter vary from 50% to 100%.

Therapy includes excision; chemotherapy agents; topical irradiation, such as skin electron beam therapy; and combined chemotherapy and radiation treatment. In some cases, surgery provides control of local symptoms and apparent cure for limited lesions.

BASAL CELL NEVUS SYNDROME

Basal cell nevus syndrome (also known as *Gorlin's syndrome* or *nevoid basal cell carcinoma*) is an inherited autosomal dominant disorder that manifests with multiple cutaneous basal cells, jaw cysts, musculoskeletal and neurologic abnormalities, odontogenic keratocysts, calcification of the falx cerebri, and palmar and plantar pits. The lesions behave as basal cell cancers and are usually managed with surgical excision. It is not infrequent that palmar and plantar pits contain basal cell cancer. The pits are usually small, being 3 mm or less in depth. Usually, affected patients have hundreds of basal cell cancers over the course of their lives. Topical chemotherapy agents such as fluorouracil (Efudex) have been used in an attempt to eradicate early superficial nonfacial basal cells, but surgical excisions are the treatment of choice.

BOWEN'S DISEASE

Bowen's disease is an erythematous, plaquelike lesion that represents a low-grade, slow-growing intraepithelial variant of squamous cell

FIGURE 6 **A–C,** Dermatofibrosarcoma protuberans looks like lumps of fibrous scar tissue. Its indolent appearance belies its invasive character, and the diagnosis must be confirmed by biopsy. Wide margins are necessary because of the tumor's tendency for local invasion.

carcinoma. In essence, the growth of this tumor is intraepidermal, and its history and progression are similar to those of other intradermal carcinomas such as erythroplasia of Queyrat. It is a less common malignancy that appears as a circumscribed, red or pink patch that can weep and look scaly. Many such lesions occur on the trunk or lower extremities and genitalia, but they can involve the head and neck area. The progression of these lesions is limited and normally extends over years. Invasive squamous cell carcinoma can arise in these lesions, and if so, metastasis is eventually possible. Excision with an initial 5-mm margin is recommended. Lesions that occur in cosmetically sensitive areas may necessitate flap coverage; lesions that are large may necessitate skin grafting. In the head and neck, cosmetically sensitive flap reconstructive techniques are preferred when primary closure is not possible.

MERKLE CELL CARCINOMA

This rare neuroendocrine skin cancer is characterized by rapid growth and is a firm, intradermal, red nodule that rapidly progresses to ulceration (Figure 7). Lesions can be traced to a polyomavirus infection, and the disease is definitely more frequent among patients who undergo immunosuppression. The disease progresses rapidly by intravascular and lymphatic spread. Therefore, initial positron emission tomographic (PET) imaging should be performed to evaluate the possibility of regional and distant spread. Positive regional nodes, which occur in 50%, are predictive of poor survival rates; the disease tends to be undertreated by limited surgical resections, and thus local failure is common (in up to one third of patients). Local control may be improved by larger resection margins of 3 to 5 cm, which often generate the need for skin grafting. Sentinel node biopsy is routinely recommended.

Periodic follow-up with local, regional, and systemic monitoring is recommended. Although most recurrences are detected in the first 2 to 3 years, survival is best predicted by nodal and distant disease. The behavior of Merkle cell cancer is usually more aggressive than invasive melanomas, and in fact, the mortality rate exceeds that of melanoma. The histologic diagnosis is confirmed with immunohistochemical staining. Because of the frequency of local failure in treatment when surgical margins are compromised, some authorities have recommended postoperative radiation therapy for the primary tumor, draining lymphatic vessels, and regional lymph node basins. The added value of this treatment when surgical margins are generous, sentinel lymph node biopsy is obtained, and PET scans are negative has not been established. Adjuvant chemotherapy for regional disease has also been recommended (for positive regional node disease) in addition to surgery.

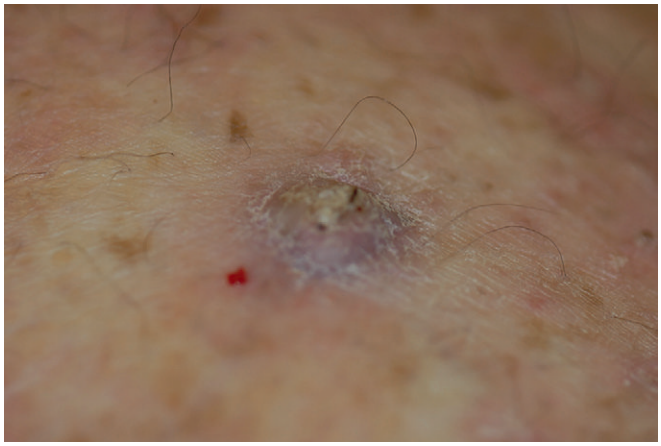

FIGURE 7 Merkle cell skin cancer looks like a tumor lump that frequently grows rapidly. It must be differentiated by biopsy and confirmed by immunohistochemical staining.

ANGIOSARCOMA

This rare vascular tumor of the skin generally occurs as a rapidly enlarging nodule or plaque, sometimes simulating a bruise (Figure 8). In-transit metastasis occurs quickly, and initial manifestation with satellite nodules is common. There is a predilection for occurrence in the head and neck area and in elderly persons. In one series, the mean age was 70 years, and affected patients were predominantly male. Aggressive treatment is indicated with 3-cm to 5-cm margins; flap or skin graft reconstructions are frequently required. Sentinel lymph biopsy is recommended. Local recurrence is frequent because of the tendency for in-transit metastasis, and the prognosis is quite limited with 20% survival being routine. These statistics and the proven aggressive behavior of this tumor have generated the recommendation that radiation and chemotherapy accompany the planned surgery. Despite these additions, the prognosis remains largely unaffected by additions to the surgical treatment proposed.

ADENEXAL TUMORS OF THE SKIN

Adnexal tumors arise from skin appendages such as eccrine, apocrine, and sebaceous glands and hair follicles. Some arise from fibrous or neural tissues. Sebaceous carcinomas usually manifest as slightly reddened nodules whose diagnosis is dependent on biopsy. The prognosis varies with the aggressiveness of the lesion, and wide

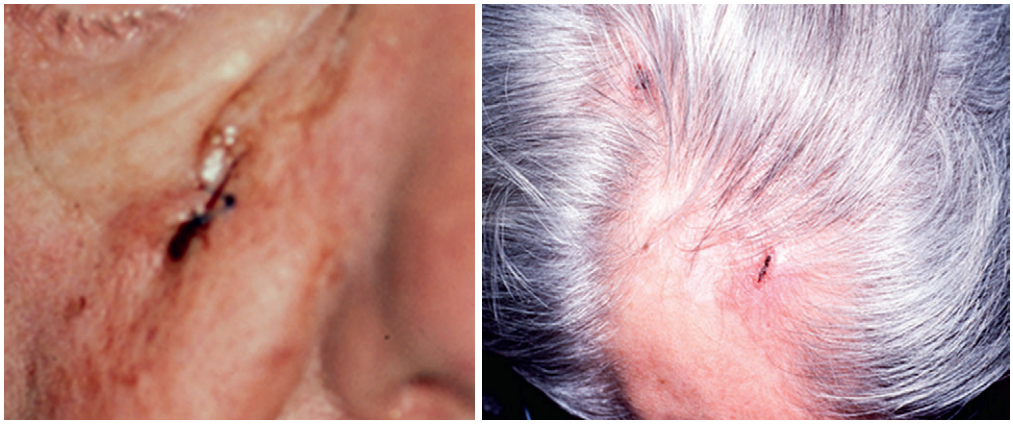

FIGURE 8 Angiosarcoma is a rapidly growing aggressive cancer that often initially appears as a reddish streak or lump, a bruise or hemangioma. It is capable of early intralymphatic and systemic metastasis.

excision with 2-cm margins to fascia is recommended. Some practitioners perform sentinel lymph node evaluations in these more aggressive lesions, but the value of these interventions remains to be proven.

CONCULSION

Nonmelanoma skin cancers vary in severity from the relatively common and benign varieties to very aggressive and frequently lethal lesions. Treatment favors surgical resection predicated on accurate diagnosis and classification, and the aggressiveness of treatment should be based on good pathologic definition of the lesion type.

ACKNOWLEDGMENTS

The author thanks and acknowledges the panels who created the National Comprehensive Cancer Network (NCCN) Guidelines, (www.nccn.org) which form an excellent and carefully considered basis of the recommendations for diagnosis and treatment in these lesions. The author recommends these guidelines in the strongest terms for readers wishing further information and clarification because they serve as a yearly updated summary of current recommendations for evaluation and treatment. The author has extensively relied on NCCN Summaries, Clinical Practice Guidelines, Classifications and Recommendations in preparing this chapter.

The Management of Cutaneous Melanoma

Anna M. Leung, MD, Mark B. Faries, MD, and Donald L. Morton, MD

OVERVIEW

Melanoma is not the most common skin cancer, but it is the deadliest, causing more than 75% of skin cancer deaths. This year melanoma will strike more than 76,000 Americans and kill more than 8790 patients. Despite these bleak statistics, prognosis is excellent with early diagnosis and treatment. Surgery provides the best option for cure of stage I to III melanoma. Surgery is also indicated for certain patients with stage IV disease; in these cases, metastasectomy can prolong survival.

Melanoma risk factors include sun exposure, family history, prior melanoma, blistering sunburn, fair complexion, and dysplastic nevi. Suspicious lesions can be recognized with the ABCD characteristics (*A*symmetry, irregular *B*orders, variegated *C*olor, and large *D*iameter). Rapidly changing lesions or lesions that differ significantly from the patient's other nevi also may be suspicious for melanoma.

BIOPSY TECHNIQUES

Any lesion suspicious for melanoma should be biopsied to provide pathologic information (depth and diagnosis) for management. Excisional biopsies should be done for small lesions, and punch biopsies (4-mm to 6-mm punch) should be performed for larger lesions or lesions in cosmetically sensitive areas. These techniques are preferable to shave biopsies because the base of the lesion should be included for histologic evaluation and final margin determination. If a punch is performed, it should be taken at the thickest, most palpable area of darkest pigmentation. Because reexcision is necessary for a lesion that has been confirmed as melanoma with pathologic evaluation, the original excisional biopsy should be oriented in the direction of any subsequent wide local excision. Longitudinal incisions should be made on the extremities, and incisions on the trunk and back should be oriented to minimize distracting tension on the wound.

TREATMENT OF PRIMARY LESION

Margins

Wide local excision is the treatment of choice for the primary melanoma. Excision should include all affected skin and subcutaneous tissue plus a margin of normal skin around the edge of the previous biopsy site or the widest area of pigmentation. Margin width is based on lesion depth (Table 1). The excision should reach down to the midsubcutaneous region for confirmed in situ lesions and down to the fascia for deeper lesions, with removal of the fascia and underlying muscle if the lesion is more than 4 mm thick or if concern exists for invasion of the muscle.

Elderly patients with chronically sun-exposed skin frequently have abnormal melanocytic proliferation, often clinically unapparent, which makes determination of boundaries of excision difficult. Several punch biopsies should be performed at the proposed margin. If no evidence of abnormality is found, then these punch biopsy sites are used as the margins of resection.

Incision and Reconstruction

The wide local excision is often done through an elliptic incision with a length-to-width ratio of 3:1. If orientation of the excision can be determined initially, then the incision is an ellipse. If orientation cannot be determined, then a circular incision is made preliminarily

and final flaps are oriented subsequently. Most wide local excisions can be closed with straightforward local advancement flaps with a two-layered dermal and subcuticular closure. If the wound cannot be closed primarily with local advancement flaps, then a rotational rhomboid flap, complex V-Y or Z-plasty flap, or skin grafting can be considered (Figure 1).

Although skin grafts provide excellent coverage, healing can take many weeks and the risk of graft loss is always present. Skin grafts can either be full or split thickness. Split-thickness skin grafts (STSGs) can cover larger areas; they have better neovascularization and thus a higher chance of graft acceptance. The most common donor site for STSG is the upper lateral thigh. If the recipient site is also the leg, the donor site should be the contralateral thigh because wide local incision is usually accompanied by a lymphatic procedure. Bolster dressings and negative wound vacuum systems can be used to promote postoperative graft healing. In general, split-thickness skin grafts should not be used in cosmetically sensitive areas such as the face, head, and neck because of mismatch of skin color and type.

Full-thickness skin grafts provide the best cosmetic outcome for the scalp and face. The graft is taken from a matching area of skin, usually the upper chest or postauricular neck. The donor skin must be trimmed of all subcutaneous tissue to the level of the dermis. Reconstruction options should always be discussed thoroughly with the patient. Plastic and reconstructive surgeons may be consulted, but the oncologic portion of the operation should never be compromised for cosmetic reasons.

TABLE 1: Wide excision margins for primary melanoma

Thickness of primary	Excision margin
Melanoma in situ	5 mm
≤1 mm	1 cm
1.01-2 mm	1-2 cm
2.01-4 mm	2 cm
>4 mm	≥2 cm (dependent on location and ease of larger margin)

Special Sites

Nail Bed

Wide local excision for subungual melanoma is based on the same principles as wide local excision for any other cutaneous melanoma. The margins are again based on depth (see Table 1). Removal generally requires a partial amputation at the midproximal phalanx. If the primary lesion is on the foot, preservation of the metatarsophalangeal joint of the great toe is usually sufficient to prevent functional compromise. Subungual melanoma of the distal finger typically requires amputation of one phalanx proximal to the melanoma; melanoma of the proximal finger can be managed with soft tissue excision, skin grafting, and attempted preservation of bone and tendon. If a tendon must be resected, it can be reimplanted by securing the cut ends of the tendon to the distal remaining phalanx with nonabsorbable suture. This helps prevent paradoxical motion of the digit after surgery. Resection for melanoma of the hand must balance the two goals of functional preservation and optimal oncologic outcome.

Sole of Foot

Melanoma of the sole of the foot requires wide local excision down to plantar fascia, with either full-thickness skin grafting or flap coverage. If the melanoma is on an area such as the instep that is not weight bearing then a thinner, split-thickness skin graft can be used. In weight-bearing areas, acral skin may be rotated into the excision site, with skin grafting of the secondary defects.

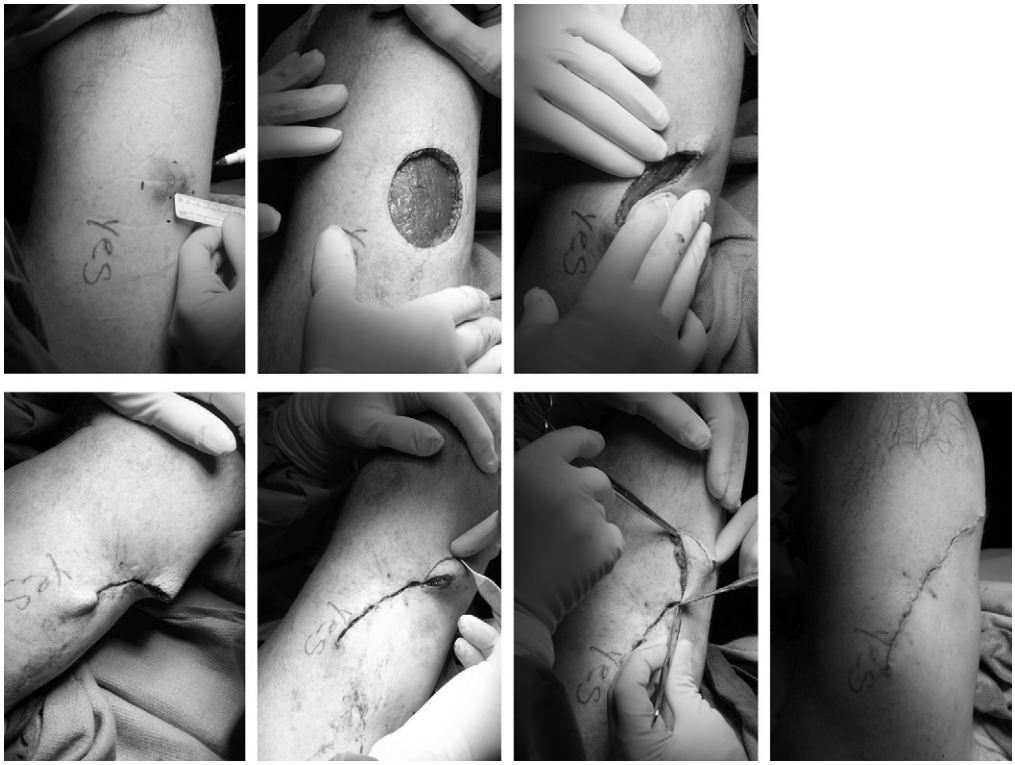

FIGURE 1 Wide local excision of an extremity melanoma. *Top row (left to right):* Measurement of circumferential margin; after excision; assessment of lines of tension. *Bottom row (left to right):* Wound closure after flap mobilization; marking of redundant skin; extension of redundant skin across wound; final closure.

Ear

Wide local excision of ear melanoma is dependent on the location of the lesion. Lesions at the top of the ear can usually be removed with a simple wedge excision. Cartilage is closed with interrupted nonabsorbable sutures, and the skin can easily be reapproximated. By contrast, resection of melanomas on the lower ear usually leaves a defect that requires skin grafting or flaps.

TREATMENT OF REGIONAL NODES

Regional lymph nodes are the most likely first site of melanoma spread. In the past, all patients with intermediate-thickness melanoma and clinically normal nodes underwent elective regional lymph node dissection, but most basins were pathologically clear. Thus, elective nodal dissection subjected patients to a potentially morbid major operation that in many cases had no benefit. In the late 1980s, Donald L. Morton developed the technique of intraoperative lymphatic mapping and sentinel lymph node biopsy (SNB) as a minimally invasive, low-morbidity alternative for identification of patients with occult nodal metastasis. Since then, this technique has been established as a new standard for the management of melanoma.

The Multicenter Sentinel Lymphadenectomy Trial I (MSLT-I) confirmed the accuracy and clinical impact of SNB. Patients with primary melanoma and clinically normal nodes were randomized to treatment with wide local excision (WLE) plus nodal observation, with regional lymphadenectomy for clinical evidence of nodal metastasis during follow-up, or to WLE plus SNB, followed immediately by regional lymphadenectomy for a positive sentinel node. The trial confirmed that the sentinel node's tumor status was the most important prognostic factor for these patients. Among those patients who had nodal disease, disease-free and overall survival rates were significantly improved by early removal, which was made possible with SNB.

Sentinel Node Biopsy

SNB is indicated for patients whose primary lesions are more than 1 mm in depth. Rates of sentinel node positivity are 12% to 20% for 1-mm to 2-mm melanomas, 28% to 33% for 2-mm to 4-mm melanomas, and 28% to 44% for melanomas more than 4 mm. For patients with thin melanomas (<1 mm), other considerations for SNB include young age, male gender, Clark level IV lesion, ulceration, regression, incomplete biopsy (e.g., shave biopsy), or mitotic rate 1 or more.

SNB is conceptually simple but can be technically challenging and requires experience for optimal accuracy. The rate of false-negative lymphatic mapping/SNB in MSLT-I, determined by nodal recurrence in tumor-negative dissected sentinel node basins, was 10.3% for the first 25 cases versus 5.2% in the subsequent 25 cases. The surgeon, nuclear medicine physician, and pathologist must work as a team to ensure a low false-negative rate. Because of the steep learning curve for SNB in melanoma, if facilities are not proficient in all aspects of this procedure, then these cases should be referred to a specialized center. The accuracy and morbidity of SNB are optimized if WLE and SNB are performed at the same operation.

Because the sentinel node is the first lymph node to receive lymphatic drainage from the primary tumor site, if this node is free of disease, then remaining (downstream) lymph nodes also should be free of disease (Figure 2). As a result of the variability of lymphatic drainage from a primary cutaneous melanoma, two tracers are used:

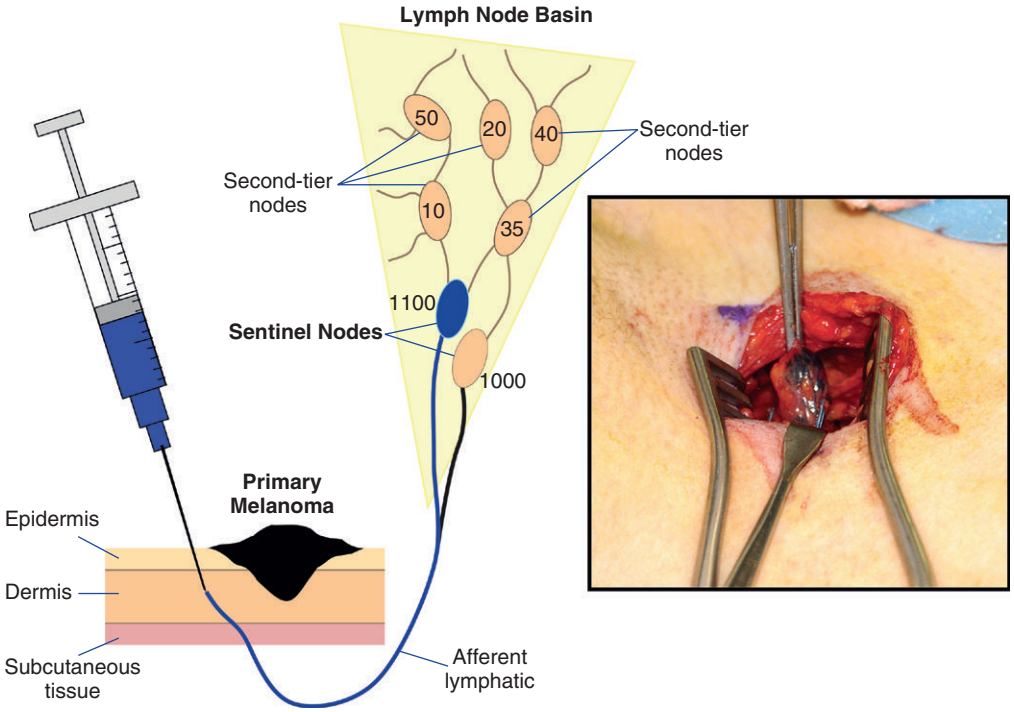

FIGURE 2 At different times, blue dye and radiotracer are injected intradermally at the site of the primary tumor (radiotracer is injected immediately before preoperative lymphoscintigraphy, and blue dye is injected immediately before the surgical procedure). During intraoperative lymphatic mapping, blue-stained afferent lymphatics are visualized and followed to the first blue-stained node (i.e., the sentinel node *[inset]*). A hand-held gamma probe confirms higher radioactive counts within this sentinel node and can identify additional sentinel nodes that are not stained blue. *(Reprinted with permission from Bagaria SP, Faries MB, Morton DL: Sentinel node biopsy in melanoma: technical considerations of the procedure as performed at the John Wayne Cancer Institute,* J Surg Oncol *101(8):669-676, 2010.)*

a radiocolloid and a vital blue dye. Lymphoscintigraphy is performed before surgery on the day of surgery, or the day before surgery, with injection of technetium sulfur colloid intradermally in the skin of the primary site. Because approximately 10% of mapping procedures identify a sentinel node in an ectopic location, imaging of potential drainage basins should include popliteal, epitrochlear, supraclavicular, and internal mammary sites, plus the intramuscular triangle of the upper back. The skin is marked over the sentinel node, and a film identifying this node's location is sent with the patient to the operating room. In some instances, the primary melanoma drains to more than one basin.

In the operating room, before prepping and draping, 1 to 2 mL of isosulfan blue is injected into the intradermal tissue of the operative site. Allergic reactions to isosulfan blue are rare (<1%) but can be as serious as an anaphylactic reaction. Blue dye should not be injected outside the boundaries of the wide local excision because blue-stained skin can remain blue for several months. Injection should always be intradermal rather than subcutaneous because relatively few lymphatic channels are found within the subcutaneous tissue. The density of lymphatic channels within the intradermal tissue allows rapid transit (minutes) of the tracer to lymph nodes; no massage is necessary. A gamma probe confirms the location of the sentinel node, and an incision is made in a location convenient for SNB and compatible with a subsequent completion dissection if that were to prove necessary. Intermittent use of the gamma probe guides the surgeon to the location of the sentinel node, which is identified with color and radioactivity (see Figure 2). The node is removed from the surrounding fatty tissue, with ligation of vessels and lymphatic channels to prevent lymphocele and seroma formation. For radioactive nodes after resection, the point of greatest radioactivity should be marked with a suture to aid the pathologist in the identification of the most likely area of metastasis.

Once the node is removed, the basin should be examined to rule out significant radioactivity, blue-stained nodes, or palpably abnormal nodes. Multiple sentinel nodes can be present, and all nodes that are hot (radioactivity >10% of the hottest node) and blue should be removed. Once the sentinel node dissection is complete, the nodal basin should be irrigated and inspected for hemostasis and the wound should be closed in two layers. Gloves and instruments should be changed before wide local excision of the primary melanoma.

Technically difficult areas include the head and neck, where lymphatic drainage is variable and unpredictable. Also, because the primary lesion is close to the draining basin, there is often a very high background radioactivity. Discussion with the nuclear medicine physician is important to ensure evaluation of all potential nodal locations. During surgery, the gamma probe should be used to confirm identification of all pertinent sites, and nodal basins should also be reexamined with the probe after wide local excision because this removes the high background that the primary lesion produces (Figure 3).

Frozen section examination is not routine because its accuracy for melanoma is low and it uses a large portion of the specimen. Final staining uses hematoxylin-eosin and immunohistochemistry with antibodies to several melanoma marker epitopes (S-100, HMB-45, and MART-1).

SNB is a relatively benign procedure. Complications occur approximately 10% of the time but are generally transient and mild in nature. The most common complications include seroma, hematoma, and infection. Depending on the location of the node, nerves in close proximity can be inadvertently injured. Morbidity can be decreased by avoiding disruption of lymphatic channels and nonsentinel lymph nodes during SNB. The rate of lymphedema associated with SNB is only 1%.

Completion Lymphadenectomy

Because most patients with sentinel node metastasis have no additional positive nodes, the second Multicenter Selective Lymphadenectomy Trial (MSLT-II) is randomizing patients with sentinel node metastasis to either nodal observation (ultrasound scan imaging and clinical examination) or completion dissection. Results will determine whether completion lymphadenectomy is necessary for patients with limited nodal involvement. Until then, completion lymphadenectomy remains the standard of care for all patients with a positive sentinel node or other evidence of regional nodal metastases.

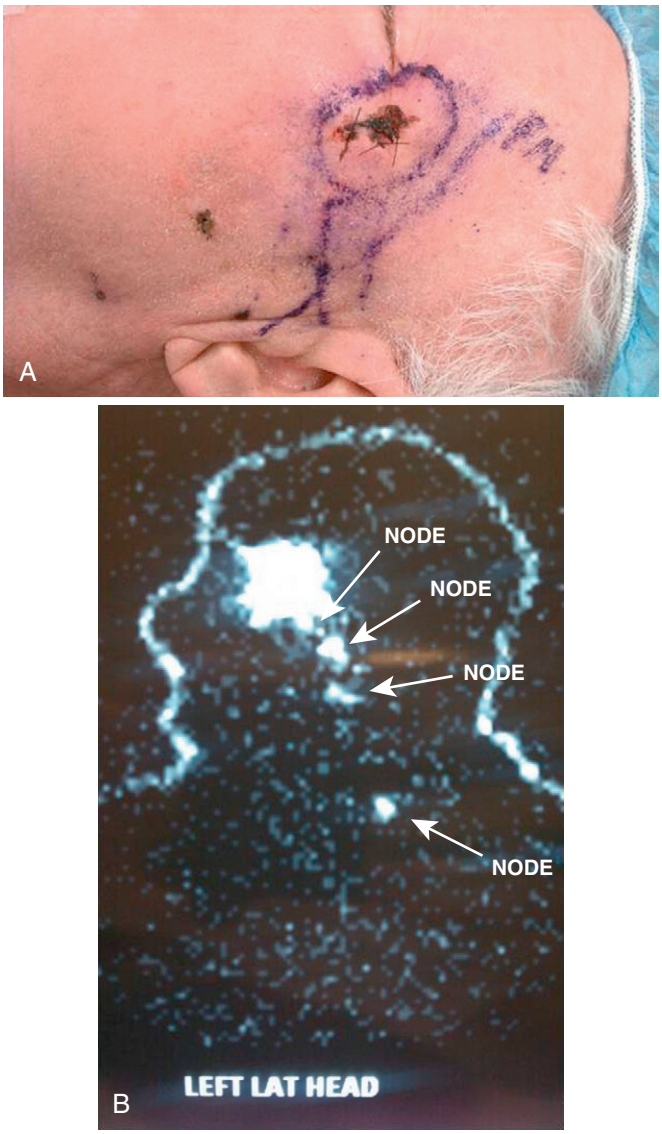

FIGURE 3 **A,** primary lesion *(circled);* and **B,** lymphoscintigraphy of a head and neck melanoma. Note the multiple draining nodes and the high background radioactivity of the primary lesion.

Before completion lymphadenectomy, patients with proven nodal disease should be evaluated for systemic disease. Laboratory values including serum lactate dehydrogenase (LDH), complete blood cell count (CBC), and liver enzymes should be drawn; elevations are suggestive but not diagnostic of systemic involvement. In cases of high concern for systemic involvement (e.g., a patient with clinical evidence of nodal disease), imaging with magnetic resonance imaging (MRI) of the brain; computed tomography (CT) of the chest, abdomen, and pelvis; and full-body positron emission tomography (PET) should be performed to rule out systemic disease. If evidence of systemic disease is found on imaging, then the patient may be a candidate for clinical trials or systemic therapy.

The first step in completion lymphadenectomy is excision of the previous sentinel node scar and the creation of skin flaps. Sharp dissection rather than electrocautery is preferred because it decreases the chances of thermal injury to subdermal vessels that supply the skin flaps. Because melanoma is a cutaneous disease, the skin flaps should be as thin as possible without compromising perfusion. Visible lymphatic channels should be secured with ties or clips to prevent seroma or lymphocele. Lymphadenectomy should be performed as much as possible in an en bloc manner with preservation of motor nerves and muscle. Two closed-suction drains are placed in the basin after dissection through two separate stab incisions. These drains are left in place until the output is below 25 mL/d for 2 consecutive days. Patients can perform gentle range of motion exercises after completion dissection, but strenuous activity should be avoided until after the closed-suction drains are removed and healing is complete. An adequate number of lymph nodes should be evaluated (Table 2).

Neck Dissection

The extent of lymph node dissection in the neck is dependent on location and indications for the procedure. Clinically gross disease requires more aggressive resection, which occasionally may include removal of the internal jugular vein, spinal accessory nerve, and sternocleidomastoid if affected by extracapsular invasion. If nodal involvement is microscopic or limited to the sentinel node, usually all functionally important structures can be preserved. Removal of parotid lymph nodes with superficial parotidectomy should be performed in patients with primary lesions of the face or scalp anterior to the coronal suture or if lymphoscintigraphy reveals drainage to a preauricular node. Bipolar electrocautery should be considered in neck dissection because it allows for better control of current and heat transmission, thus preventing nerve injury.

Axillary Dissection

Axillary dissection is more extensive for melanoma than for breast carcinoma. Dissection should include all three levels of the axilla and skeletonization of the axillary vein. The superior border of dissection is the axillary vein from the thoracic inlet (Halsted's ligament) to the latissimus dorsi tendon. Medially the dissection extends to the serratus anterior and intercostal muscles and should include interpectoral (Rotter's) nodes if the primary lesion is on the anterior chest. The lateral border of dissection is the edge of the latissimus dorsi muscle, and the inferior border is the fourth intercostal space. The subscapularis forms the posterior border of the dissection. The pectoralis minor muscle may be transected or removed if necessary to ensure complete dissection of level III. The lateral thoracic and thoracodorsal neurovascular bundle should be preserved unless directly involved with tumor. Often branches of the intercostobrachial sensory nerves need to be sacrificed, resulting in sensory loss of the posterior upper arm.

TABLE 2: Recommended number of evaluated nodes by basin

Basin	Number of nodes
Axillary	15
Inguinal, superficial	8
Inguinal, deep	6
Cervical, anterior	15
Cervical, posterior	15
Supraclavicular	6
Suprahyoid	4
Parotid	3
Popliteal	2-3

Inguinal Dissection

Superficial inguinal dissection involves the inguinofemoral basin. Superficial inguinal dissection extends 5 to 6 cm superior to the inguinal ligament and clears the tissue superficial to the abdominal fascia. The medial border is the adductor magnus, and the lateral border is the sartorius. All lymphatic tissue overlying or surrounding the femoral vessels is removed. Motor branches of the femoral nerve should be spared, but some sensory branches may be included. Sacrifice of the sensory branches may result in numbness on the anterior thigh. Cloquet's node, which is the highest superficial lymph node and lowest node in the iliac chain, is taken from the femoral canal and identified as such. If Cloquet's node contains tumor, then dissection of the deep inguinal basin is indicated.

Closure of the superficial inguinal dissection includes closure of the femoral canal with interrupted nonabsorbable sutures to prevent a femoral hernia. In addition, transposition of the sartorius muscle over the femoral vessels is indicated if the femoral vessels are exposed and at risk for injury. The sartorius is mobilized and transected at its insertion from the anterior iliac spine, and the muscle is then secured to the inguinal ligament. The wound is then closed in several layers, and closed suction drains are placed.

Deep inguinal dissection involves the iliac and obturator inguinal basins. Indications for deep dissection include positive Cloquet's node, palpable nodes, positive nodes on imaging, extracapsular extension of tumor, and more than four positive nodes on superficial dissection. Deep dissection can be performed by extending the incision for superficial dissection in a superolateral direction onto the lower abdomen, with transection of the inguinal ligament. An alternative method is to use a separate muscle-splitting incision obliquely on the lower abdomen, 5 cm above the inguinal ligament. The musculature of the abdomen is split, and the retroperitoneal space is entered anteriorly. The peritoneum and ureter are preserved and swept superiorly. All lymphatic tissue along the iliac, hypogastric, and obturator vessels is removed. Complications from inguinal dissection include wound infection in 10% to 15% of cases and lower extremity lymphedema in 20% of cases. Techniques to prevent postsurgical edema include leg elevation and graduated compression stockings.

Popliteal Dissection

The popliteal basin is bordered laterally and superiorly by the biceps femoris, medially and superiorly by the semimembranosus and semitendinosus muscles, and inferiorly by the medial and lateral heads of the gastrocnemius. The popliteus muscle creates the deep floor. This basin is considered part of the inguinal basin, and positive lymph nodes in the popliteal basin mandate superficial inguinal lymphadenectomy.

Ectopic Sentinel Nodes

Not uncommonly, lymphatic mapping identifies sentinel nodes in the epitrochlea, flank, or intramuscular triangle of the back or outside the axilla. If these nodes contain tumor, the surgeon should perform complete lymphadenectomy (CLND) of the ectopic basin and CLND of adjacent basins.

Adjuvant Radiotherapy and Adjuvant Interferon-alpha After Completion Dissection

Although melanoma is classically considered radioresistant, radiotherapy may be helpful for patients who have a high risk of regional nodal relapse because of large palpable metastases (>3 cm), extracapsular extension, or more than five involved lymph nodes. Complications from radiotherapy vary by basin. Systemic recurrence is common after lymphadenectomy if the patient has a large number of positive nodes. Interferon alpha slightly improves disease-free survival but not overall survival. Clinical trials are evaluating systemic adjuvant treatment after lymphadenectomy.

IN-TRANSIT DISEASE

In-transit melanoma metastases are unique lesions that represent foci of tumor cells that have spread via the dermal and subdermal route. The risk for in-transit disease is based on the characteristics of the primary melanoma rather than margin of the wide local excision or nodal management. Unfortunately, in-transit disease can be quite extensive, which makes management challenging (Figure 4). In-transit metastasis requires staging to rule out distant disease. Treatment decisions are based on the extent of the lesions (size and number), anatomic location, quality of surrounding skin, depth of in-transit (dermal or subcutaneous) disease, and presence of additional disease. Methods of treatment include local, regional, and systemic therapies.

Local Therapies

Local therapies include topical therapies, intralesional injection, electrochemotherapy (ECT), radiotherapy, and surgery. Topical therapy, intralesional injection, and ECT should be considered in the setting of extensive lesions, lymphedema, or induration of surrounding skin. Topical therapy is noninvasive but tends to be effective only in patients with very superficial in-transit disease. The most common topical agent is imiquimod.

Intralesional injection has been used since the 1960s. At the authors' institution, bacille Calmette-Guérin (BCG) has been injected intralesionally to induce regression of in-transit metastases. Other investigators have reported significant side effects such as systemic toxicity and death; however, the authors' experience indicates that when BCG regimens are based on skin responsiveness to purified protein derivative, side effects are usually mild and limited to local inflammation, erythema, edema, and ulceration. Other intralesional injection agents include cytokines (interferon-alpha 2b and interleukin-2), and rose bengal disodium.

ECT involves electroporation with high-intensity electric pulses to facilitate intracellular delivery of cytotoxic drugs (bleomycin and cisplatin). ECT is not an option in patients with kidney failure, and bleomycin is contraindicated in patients with pulmonary fibrosis.

Simple excision with negative margins should be performed if just a few small in-transits are surrounded by normal skin. A combination of resection and laser ablation can be considered for wider areas. Radiation is generally not effective for gross disease but can be used after resection for prevention of recurrence.

FIGURE 4 In-transit melanoma of the leg. The extensive nature of these lesions makes this patient ineligible for surgical resection for cure. However, this is an ideal candidate for regional hyperthermic perfusion chemotherapy.

Regional Therapies

Regional therapies can be considered if extensive lesions are isolated to a limb. Methods include isolated limb perfusion (ILP) and isolated limb infusions (ILI), which both use the chemotherapeutic agent melphalan. Both perfusion and infusion can deliver a concentration of chemotherapy that is 25 times higher than that delivered with systemic administration, with limited systemic toxicity. ILP requires open cannulation of the vessels and use of an oxygenated extracorporeal circuit. ILP can result in fairly high locoregional toxicity such as erythema, edema, lymphedema, and even extensive damage to the deep tissues resulting in functional loss or need for amputation. ILI is a percutaneous method that does not require open cannulation. In addition to locoregional toxicity being much lower, ILI also uses a hypoxic and acidotic environment that may contribute to the effectiveness of melphalan.

Systemic Therapies

Systemic chemotherapy including dacarbazine has also been used in the treatment of patients with in-transit melanoma. Unfortunately, response rates with the use of chemotherapy have been low and are often coupled with systemic toxicity.

METASTATIC DISEASE

Resection in the setting of metastatic disease is generally contraindicated, but metastasectomy can improve outcomes of carefully selected patients with melanoma. Optimal candidates have slow-growing tumors (tumor doubling times, >40 days), one to three metastases, and good performance status. Although conventional systemic therapy for melanoma yields dismal results, resection with adjuvant vaccine therapy has produced 5-year survival rates of 40%; many patients have survived longer than 10 years. In 2011, the U.S. Food and Drug Administration (FDA) approved two new therapies for stage IV disease: ipilimumab, which blocks CTLA4, and vemurafenib, which is a B-raf inhibitor. In addition, PD-1 inhibitors (programmed death 1 ligand blockade) have shown promise in early-phase studies.

FOLLOW-UP

Recurrence after surgical resection for melanoma is common, especially in patients with thick melanomas or nodal disease. Thus, follow-up with clinical examination and routine laboratory work (LDH, CBC, and liver enzymes) is important. All patients should have routine lifelong dermatologic screening because patients with one melanoma have a 5% to 10% risk of development of a second primary melanoma and an increased risk of basal cell and squamous cell carcinoma. After removal of a thin primary with no nodal involvement, follow-up with the surgeon should be scheduled every 6 months for the first 3 years and then yearly for the following 2 years. For patients with intermediate or thick melanoma and positive or negative regional nodes, the follow-up should be every 3 months for the first 3 years then every 6 months for the next 2 years. After a disease-free interval of 5 years, follow-up can be conducted yearly.

Recurrence usually occurs near the wide local excision site or the regional nodal basin, so these areas should be examined with special care. Distant recurrence can also occur. Because melanoma has an unpredictable metastatic pattern that can target any area of the body, symptoms or abnormality on routine laboratory workup should warrant further imaging.

MANAGEMENT OF RECURRENT DISEASE

Local recurrence is based on either: (1) radial extension of abnormal melanocytes, which results in recurrence at the area of original excision; or (2) local dissemination (metastasis) of tumor cells through lymphatic channels, resulting in satellite or in-transit metastasis. These two types of local recurrence are prognostically distinct. The risk of local recurrence depends not only on the width of surgical excision but also on the pathologic characteristics of the primary lesion. Factors such as depth, ulceration, and neurotropism are associated with higher local recurrence rates. Although local recurrence is dependent on resection margins in radial extension, pathologic characteristics of the primary lesion (thickness, >4 mm), ulceration, and desmoplastic melanoma with neurotropism and spread along nerves are the reasons for satellite or in-transit metastasis.

CONCLUSION

Surgery is curative for early-stage melanoma, but the approach to advanced melanoma is less straightforward. Recent breakthroughs in immunotherapy and improved surgical techniques have introduced the possibility of multimodal regimens tailored to the patient's melanoma and timed to produce synergistic effects. In addition to vemurafenib and ipilimumab, PD-1 and MEK inhibitors have shown promise in early trials and are being tested in combination with existing regimens to provide maximal therapeutic benefit. Ipilimumab, which is approved for stage IV disease, is being considered as a postoperative adjuvant to improve disease-free and overall survival in patients with resected high-risk melanoma (IIIb, IIIc, M1a, M1b). For decades, little progress has been made in the treatment of melanoma, but now aggressive and innovative clinical trials have been designed to create new strategies of treatment and we have the potential for significant improvements in outcome.

The Management of Soft Tissue Sarcoma

Chandrajit P. Raut, MD, MSc, and Alessandro Gronchi, MD

OVERVIEW

Soft tissue sarcomas (STS) are malignant tumors that arise from mesoderm-derived tissue, including fat, smooth and skeletal muscle, blood vessel, and connective tissue. Additional tumors classified as STS include malignant tumors of nerve sheath origin, derived from ectoderm. Approximately 11,000 new cases of STS, representing 1% of all malignancies, with a slight male predominance, lead to approximately 3900 deaths per year in the United States. Although considered rare at all ages, STS is the third most common solid malignancy in children and accounts for 15% of all pediatric cancers.

STS are a heterogeneous group of neoplasms that may be subclassified into more than 70 specific histologies and may be distributed throughout the body. Approximately one half arise in the extremities, and one third arise in the abdomen, pelvis, and retroperitoneum. The most common histologic subtype in adults is now recognized to be gastrointestinal stromal tumor (discussed elsewhere), followed by liposarcoma and leiomyosarcoma. In contrast, these subtypes are relatively less common in children, in whom pediatric (embryonal/alveolar) rhabdomyosarcoma accounts for nearly half of all STS diagnoses.

Tumor-related factors predictive of recurrence or survival include size, grade (low, intermediate, or high), and depth (superficial or deep according to the involvement of the investing fascia), although the impact of these and other risk factors may vary depending on histology and site of origin. The most important treatment-related factor predictive of recurrence is quality of surgical margins (negative/positive). This factor has shown to be the strongest prognosticator of local failure, but it also plays a role in distant failure and final outcome. Pattern of failure depends on tumor grade and histology and site of origin because it influences the possibility of achieving clear surgical margins. In general, low-grade tumors tend to recur locally or locoregionally, with only a low risk of distant spread; high-grade tumors may also recur locally but have a much higher propensity for distant failure. Extremity STS most commonly spread to the lung when they metastasize, whereas retroperitoneal sarcomas generally recur in a locoregional pattern. Some histologic subtypes have peculiar natural histories. For example, myxofibrosarcomas tend to recur locally repeatedly before spreading to distant sites, myxoid/round cell liposarcomas may spread to other organs (lungs, abdominal cavity, soft tissue, and bone) early in the course of the disease, and angiosarcomas are generally multifocal and difficult to control surgically and can give rise to lymph node metastases and distant spread very early in the course of the disease.

Traditionally, surgical textbooks and peer-reviewed literature have discussed the surgical management of STS based on site of origin. Although site of origin remains an important consideration, it has become increasingly clear that surgery must also be tailored to specific sarcoma histology to more accurately reflect tumor biology and pattern of recurrence.

This chapter covers the management of nongastrointestinal stromal tumor (non-GIST) STS. Surgical management is discussed both by specific histology and by site of origin. Although the focus of this chapter is surgery, additional treatments, such as radiation therapy or chemotherapy, and imaging are considered as appropriate.

ETIOLOGY

Most sarcomas arise sporadically, without recognizable etiologic factors. Various chemical agents and herbicides have been associated with specific STS. For instance, vinyl chloride and thorium dioxide (Thorotrast) have been linked to hepatic angiosarcomas. Another well-recognized risk factor is chronic lymphedema in the development of angiosarcoma, a phenomenon known as Stewart-Treves syndrome. Therapeutic and environmental exposure to radiation is associated with development of sarcomas within the treatment field at a median interval of approximately 10 years, with the most common histologies being angiosarcoma and unclassified pleomorphic sarcoma (formerly called malignant fibrous histiocytoma [MFH]; see subsequent discussion).

Germline genetic mutations and molecular alterations have been associated with the development of sarcomas. Li-Fraumeni syndrome, the result of mutations of *p53*, is associated with both STS and osteosarcoma. Neurofibromatosis type I (von Recklinghausen's disease), the result of mutations of *NF1*, is associated with an approximately 15% risk of development of malignant peripheral nerve sheath tumors and an increased risk of development of gastrointestinal stromal tumors. Familial adenomatous polyposis, the result of mutations in *APC*, is associated with desmoid tumors.

Chromosomal rearrangements may lead to gene fusions associated with sarcomas, such as the *SSX-SYT* rearrangement seen in synovial sarcoma. Similarly, chromosomal amplification may be associated with specific sarcoma histologies, such as increased levels of MDM2 and CDK4 proteins in association with chromosomal 12 amplification in well-differentiated and dedifferentiated sarcoma.

GRADING

The American Joint Committee on Cancer (AJCC) has developed a staging system for sarcomas. The AJCC staging system not only incorporates the traditional variables of tumor size, nodal disease, and metastatic disease but also tumor grade. Unlike the more common grading based on differentiation (well, moderate, or poor), STS grading is based on histology specific features, including differentiation, necrosis, and mitotic count, and is most commonly classified as low (grade I), intermediate (grade II), or high (grade III). Tumor stage incorporates both size (T1, ≤5 cm; T2, >5 cm) and depth with respect to fascia (superficial, T1a or 2a; deep, T1b or 2b). True nodal spread is rare.

However, considerable variability is found in outcome amongst patients within each stage, in part because a critical factor, histology, is not incorporated into the AJCC staging system. Other prognostic factors, such as site of origin and patient age, are also not weighted. To address this, several institutions have created nomograms based on STS histology or site that consider specific prognostic factors as continuous rather than categoric variables; in the long run, these may be more useful at identifying prognostically similar cohorts for future studies.

TREATMENT

Surgery remains the standard and only potentially curative therapy in the management of STS. In general, wide or radical resections are necessary to achieve negative margins. In other words, the tumor must be resected en bloc, with a cuff of healthy tissue all around, to avoid contamination from tumor surface and removal of tumor microsatellites that may be present in the healthy tissues surrounding the pseudocapsule. The extent of resection and adequacy of margins depends on a variety of factors, including histology and presence of an intact biologic barrier, such as muscular fascia, vascular adventitia, periosteum, or epineurium.

Patients with STS should undergo evaluation at a sarcoma center because the administration of neoadjuvant or adjuvant therapy may be indicated. Generally, this involves multidisciplinary evaluation by a surgical oncologist and, depending on histology, a medical oncologist and a radiation oncologist. Reevaluation of pathology slides by a pathologist specializing in sarcomas is critical to confirm the exact histology and determine the most appropriate treatment. In fact, approximately 25% of all sarcomas are initially designated with the incorrect histology, and approximately 15% are assigned the wrong histology in a clinically significant manner that impacts the treatment plan. Given the complexity of many operations needed, support from other specialists, including plastic and reconstructive surgery, vascular surgery, urology, thoracic surgery, and anesthesia, is commonly required.

IMAGING

Histology-specific and site-specific imaging recommendations are discussed in further detail in the subsequent individual sections. For better definition of the extent of extremity and truncal STS, including depth of invasion and relationship with neurovascular structures, magnetic resonance imaging (MRI) of the affected site is the preferred imaging study. Further staging studies for patients with extremity STS should include chest imaging: chest x-ray for low-grade lesions and chest computed tomographic (CT) scan for intermediate-grade or high-grade lesions. Patients with abdominal visceral, pelvic, and retroperitoneal sarcomas should undergo CT imaging of the abdomen and pelvis and, in most cases, chest. Those with primary STS of the rectum or metastases to the liver may need further evaluation with MRI of those sites. STS involving vascular structures, such as leiomyosarcoma arising in the wall of inferior vena cava, are usually sufficiently characterized with the standard MRI or CT imaging of the site and (CT) angiography is not necessary. Patients with breast STS should undergo MRI to define depth of extension; mammography is not routinely useful. Those with scalp STS may undergo either a CT scan or MRI. Routine head CT scans are not needed as a staging study. Although much has been written about the use of positron emission tomography (PET) in some sarcomas and many other malignancies, it is rarely indicated in routine sarcoma care. PET scans should only be ordered selectively, when attempting to resolve an ambiguous finding on other imaging or gauging treatment responses under specific circumstances.

HISTOLOGY-SPECIFIC TREATMENT

Atypical Lipomatous Tumor/ Well-Differentiated Liposarcoma

Atypical lipomatous tumor (ALT)/well-differentiated liposarcoma is a low-grade tumor that, when arising in the extremity, has a relatively low rate of recurrence, may not recur for quite some time, and has no risk of distant metastatic spread and death, unless

dedifferentiation occurs over its natural history. Dedifferentiation, if it occurs, in fact entails a risk of metastatic spread as high as 20%. In contrast, low-grade locally recurrent ALT may grow slowly for years. Therefore, such tumors that arise in the extremity can be resected with a limited negative or even a positive margin, especially when preservation of limb function is an issue (Figure 1). Radiographically, ALT may be difficult to distinguish from an intramuscular lipoma, a benign entity that can also arise in deep muscle tissue. ALT/well-differentiated liposarcoma is a more threatening neoplasm when located in the retroperitoneum, even in absence of areas of dedifferentiation. In fact, as discussed subsequently, local control is an issue at this site, and patients often die of locoregional failure, without development of distant metastases (Figure 2).

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a superficial tumor that infiltrates soft tissue for centimeters beyond the obvious margins of the lesion and can recur locally after an inadequate resection. However, the more common variety of DFSP does not display metastatic behavior. Therefore, the goal of surgery should be negative margins, often necessitating reconstruction with plastic surgery. When cosmesis is an issue, limited positive margins may be accepted and a wider resection postponed until DFSP locally recurs. Because of the relatively indolent nature of the growth of DFSP, a tissue expander may be placed and resection may be delayed to allow a single-stage resection and reconstruction (Figure 3). DFSP is usually a relatively superficial tumor, so resection of muscle deep to the tumor is not often necessary. Intraoperative frozen-section margin analysis is not generally helpful because the surrounding fat rarely freezes well for analysis. Mohs' micrographic surgery has been reported as a treatment for this neoplasm, but long-term results are lacking. Radiation therapy is not usually recommended. Follow-up should consist of a physical examination, and imaging may be reserved for patients with a suspicious mass in the tumor bed. Approximately 5% to 10% of patients with DFSP have a more aggressive fibrosarcoma variant that may recur locally and potentially spread. Those individuals should be treated as with a "conventional" sarcoma with more aggressive local therapy (including radiation) and followed with systematic imaging.

Malignant Fibrous Histiocytoma

MFH is an archaic term that covered a variety of sarcoma histologies with very different clinical behavior and treatment approaches. The term MFH has been largely replaced by specific sarcoma histologies, including myxofibrosarcoma, fibromyxosarcoma, etc. Those that do not fall into known histologies and would have otherwise been termed MFH are now typically called unclassified pleomorphic sarcoma.

Myxofibrosarcoma

This tumor when located superficially infiltrates through soft tissue (subcutaneous fat and investing fascia) centimeters beyond the ostensible margins of the visible or palpable mass (Figure 4). When located intramuscularly, the extension of the infiltration is usually limited by anatomic barriers, although it has a higher propensity to invade into those anatomic boundaries compared with other histologic subtypes. Myxofibrosarcoma most commonly arises in the extremities of elderly individuals. It has a 30% rate of local recurrence and a 16% rate of distant recurrence. Multiple local recurrences have been associated with eventual amputation. Therefore, aggressive local therapy is critical. Wide surgical margins (2-cm to 4-cm radial margins beyond the clinical boundaries of the palpable mass, especially in more superficial tumors) should be the goal of surgery, which often requires complex wound closure or flap reconstruction by a plastic and reconstructive surgeon and resection and reconstruction of vessels or nerves. Radiation therapy, either before or after surgery (described subsequently), may be considered, although the direct impact on this specific histology remain unknown. Follow-up imaging should include the primary site (usually with an MRI) and the lungs (with chest CT scan).

Low Grade Fibromyxoid Sarcoma

The similar nomenclature of this lesion to those listed previously belies its behavior. Local recurrence is again a problem, but interval to relapse may vary. These malignant neoplasms follow a more indolent course, and the risk of relapse persists well beyond 5 years. Therefore, patients may be followed at longer intervals early in the postoperative course, but follow-up should continue for a decade or more.

Angiosarcoma

Management of primary and radiation-associated (secondary) angiosarcoma of the breast is discussed in the subsequent section on breast sarcomas. Scalp angiosarcoma (Figure 5) is a particularly

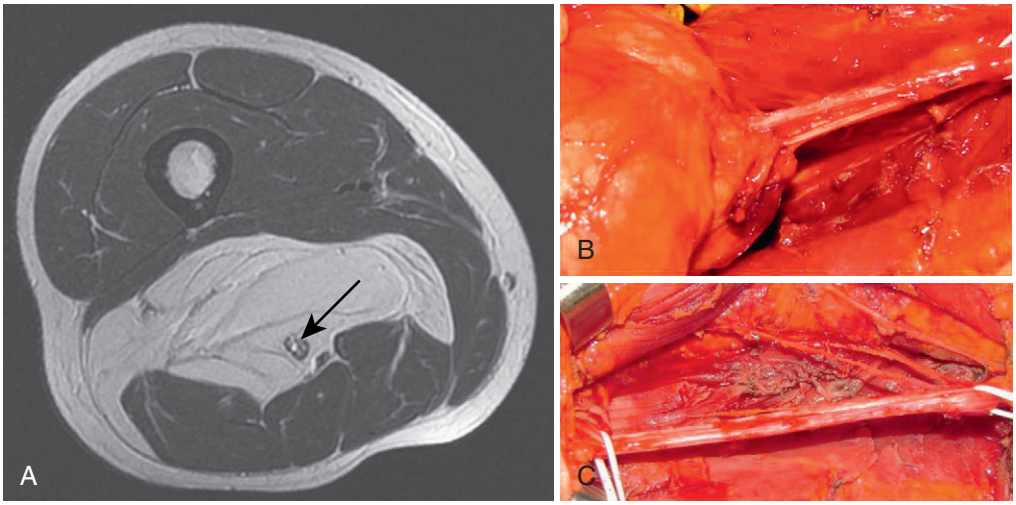

FIGURE 1 **A,** Axial magnetic resonance imaging of the thigh shows a well-differentiated liposarcoma encasing the sciatic nerve *(arrow)*. **B,** Tumor peeled off of sciatic nerve. **C,** Surgical field after resection of the tumor, with skeletonized nerve.

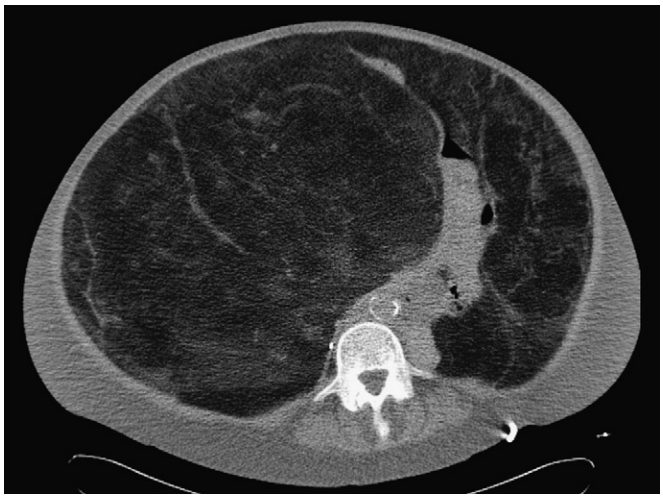

FIGURE 2 Locally advanced well-differentiated liposarcoma.

insidious malignancy. Scalp angiosarcomas are commonly multifocal, with both clinical examination and CT scan or MRI. Although radical surgery is possible (requiring complex flap reconstructions), it is not uncommon for patients to have local recurrences develop immediately outside the margins of resection even if the margins of the initial resection were widely negative and with or without radiation therapy. Angiosarcoma is sensitive to systemic chemotherapy and to radiation therapy. Because surgery is rarely curative, it should not be considered first-line therapy for scalp angiosarcoma. Surgery may be reserved for patients who are experiencing problems with local control (bleeding from a fungating tumor) or who only appear to have a solitary site of disease with both clinical examination and imaging while undergoing systemic therapy.

Radiation-Induced Sarcomas

Radiation-induced sarcomas are rare and include a variety of histologic subtypes, the most common of which are unclassified pleomorphic sarcoma, angiosarcoma, malignant peripheral nerve sheath tumors, and leiomyosarcoma. Beside the intrinsic characteristics of each histologic subtype, they are all characterized by a high propensity to locally recur, given the difficulty of obtaining clear margins. This is the result in part of the difficulty in distinguishing tumor infiltration of healthy tissues from radiation-induced soft tissue changes around the tumor site and in part of the discontiguous and multifocal involvement of tissue within the radiation field (Figure 6). The tumor should be excised with as much tissue around it as possible. This often if not always requires reconstruction and coverage by a plastic surgeon and potentially a more liberal policy of neurovascular resection and reconstruction. Systemic chemotherapy and reirradiation are often considered, given the overall dismal prognosis, although the use of the latter must be weighed with caution.

Malignant Peripheral Nerve Sheath Tumors

Malignant peripheral nerve sheath tumors (MPNST) often arise from a major peripheral nerve, which can be identified macroscopically. They can occur sporadically or in the context of neurofibromatosis type 1 (von Recklinghausen's disease). The high-grade variant is marked by an early propensity for distant metastases. When originating from a peripheral nerve, MPNST also may spread along the nerve fibers proximally or distally. Wider margins at this level should

be obtained (if possible, at least 4 cm of macroscopic healthy nerve; Figure 7) to limit locoregional failure, which eventually may reach the spinal cord. Intraoperative frozen-section analysis may help ensure clear margins. Systemic chemotherapy is used on an individualized basis.

EXTREMITY SOFT TISSUE SARCOMA

Clinical and Diagnostic Evaluation

Patients with extremity STS commonly present with a palpable mass. Initial clinical evaluation should include a thorough history and physical examination, with attention directed to size, precise location, and evidence of neurovascular compromise. No tumor markers are known for STS histologies at present. After a thorough examination, an MRI (or CT scan) of the affected site is indicated for most lesions; small superficial lesions may be directly excised at the discretion of the surgeon. MRI generally provides more detailed soft tissue definition but is less readily accessible, may be problematic for patients with claustrophobia, and cannot be performed in patients with embedded shrapnel and certain types of aneurysm clips, cardiac devices, or other implants. Staging evaluation is completed with a chest x-ray (for low-grade malignancies) or a chest CT scan (for intermediate-grade or high-grade malignancies). Routine head CT scan (other than for alveolar soft part sarcoma) and PET scan are not needed.

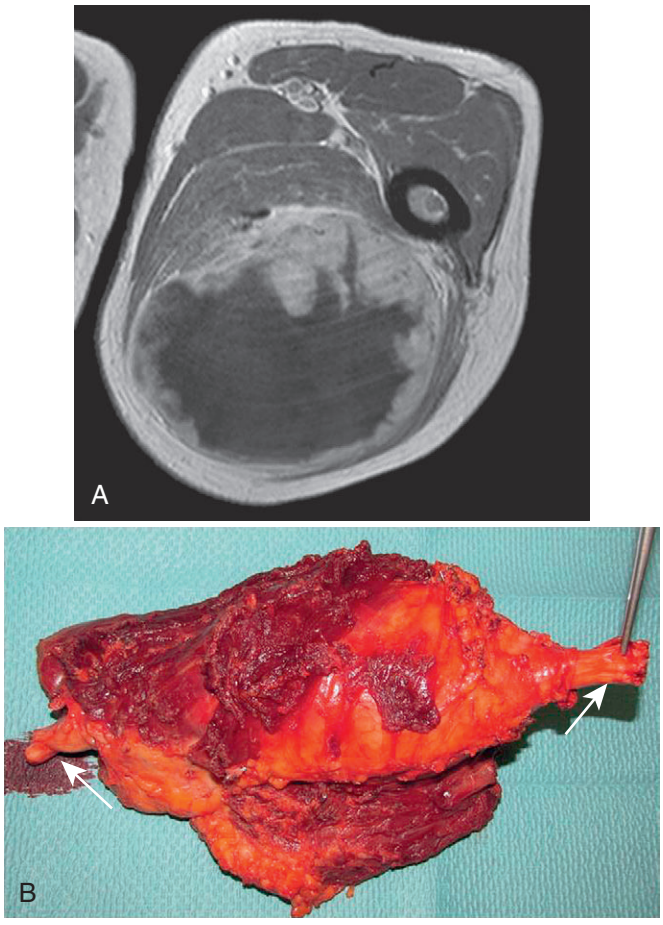

FIGURE 7 **A,** Preoperative magnetic resonance imaging and **B,** surgical specimen showing malignant peripheral nerve sheath tumor arising from the sciatic nerve *(arrows* indicate nerve stumps).

Imaging alone is rarely diagnostic of the specific sarcoma histology, with the exception of well-differentiated liposarcoma (also known as atypical lipomatous tumors). Well-differentiated liposarcomas have a radiographic density similar to normal surrounding fat but tend to be well encapsulated with thick internal septations. Such tumors may be treated with resection (complete excision with a margin of normal surrounding muscle, fat, or fascia to minimize risk of local recurrence) and do not require a biopsy.

Other neoplasms suspicious for sarcoma should be biopsied. The authors prefer to obtain core needle biopsies with radiographic guidance, although they may be performed without imaging depending on location. Although biopsy tract recurrences are exceedingly rare, the site selected for the core needle biopsy should be planned such that it can be included in the incision used during the subsequent definitive resection or at least in the radiation field. Thus, coordination between the surgeon and the interventional radiologist is necessary. It is important to specify core needle biopsy rather than fine-needle aspiration because the latter rarely yields enough tissue and architecture information to distinguish between different sarcoma histologies. A key advantage of core needle biopsy over an open biopsy is that the former can be directed towards a specific portion of the tumor. If a core needle biopsy fails to yield a diagnosis, an open incisional or excisional biopsy should be obtained. Although incisional biopsies have been used for diagnosis commonly, they are often performed improperly in inexperienced hands. Incisional biopsies should be performed through longitudinally oriented incisions placed such that the incision can be included in the final resection when a definitive resection is planned. If a transverse incision is used, then when subsequent reexcision is required, challenges for reconstruction and risk of lymphatic disruption (depending on location) are magnified. Excisional biopsies should be confined to lesions less than 2 cm in size and superficial in location.

Surgical Treatment

Until the early 1980s, the standard of care for patients with extremity sarcomas was amputation. That changed after a seminal randomized controlled trial conducted by Rosenberg and colleagues at the National Cancer Institute. In that trial, patients with high-grade extremity STS were randomized to undergo amputation or limb-sparing surgery with adjuvant radiation therapy. Those undergoing limb-sparing surgery trended towards a higher rate of local recurrence. Importantly, however, no difference was found in overall survival. This altered the standard treatment for extremity STS.

Currently, the goal of surgery is not only limb sparing but also function sparing, with appropriate biologic margins achieved. Surgical resection should be carefully planned based on preoperative imaging. Resections should include not only the entire tumor (without rupture or violation of the surrounding pseudocapsule) but also an adequately wide margin (1 to 2 cm) of normal, nonneoplastic tissue. Resections performed with positive margins do result in higher risk of local recurrences and, to a lesser extent, of distant metastases and death. If the STS is close to the superficial skin, then an adequate skin paddle overlying the tumor should be resected en bloc with the tumor (Figure 8). The surgeon should not compromise the margin by minimizing the skin resection just to avoid a skin graft or flap. Tumors that extend towards but do not involve the fascia should include the fascia as a margin. Superficial tumors that involve the fascia should include the fascia and generally an additional margin of underlying muscle. By definition, when the investing fascia is infiltrated, the tumor is considered deep, even if it is mainly located in the superficial tissues. Similarly, deep tumors that extend superficially to the fascia should include a margin of overlying subcutaneous and cutaneous tissues as a margin. It is uncommon for primary STS to violate a fascial plane, but not recurrent STS. Deep tumors that do not extend in superficial tissues do not need large resection of superficial tissues (Figure 9). The tumor specimen should be oriented with marking sutures. When possible, additional margins may be sent separate from the main specimen, representing the superior, inferior, medial, lateral, superficial, and deep margins of dissection, with the true margins appropriately marked for orientation. Tumors that abut bone may include the periosteum as a margin if the bone is not directly invaded (Figure 10). If necessary, vascular resection and reconstruction should be considered for involved vessels (Figure 11). If a critical nerve is encased, reconstruction with an interposition nerve graft should be considered (Figure 12). Such reconstructions may be compromised if radiation is administered after surgery; therefore, preoperative radiation may be warranted. The specimen should be reviewed with the pathologist for optimal orientation.

Furthermore, it is critical to take into account the specific histology, as described previously. For instance, resection for myxofibrosarcoma requires wider margins than resection for ALT. Thus, the surgeon must understand the different sarcoma histologies, confirm the accuracy of the diagnosis, and review the treatment plan in a multidisciplinary consultation.

Wound closure should be meticulous to minimize risk of wound complications, which can be considerable as described in the next section. Drains may be necessary, particularly after preoperative

radiation therapy or in the setting of recurrent tumors, because ongoing serous drainage may continue for weeks after surgery. Flap reconstruction may be necessary for proper wound closure or if a large, potential dead space is left behind (especially if preoperative radiation therapy had been administered).

Adjuvant/Neoadjuvant Radiation Therapy and Chemotherapy

Limb-sparing surgery generally relies on adjuvant/neoadjuvant radiation therapy to minimize risk of local recurrence, as seen in the National Cancer Institute (NCI) trial. The goal of radiation is to treat the margin to minimize the risk of recurrence, not necessarily to reduce the size of the tumor per se. Radiation therapy reduces the risk of local recurrence from greater than 30% to less than 10% in most series but does not impact distant failure or overall survival.

Radiation therapy may be delivered as external beam radiation therapy (EBRT) or brachytherapy. EBRT may be delivered before or after surgery. One randomized trial, by O'Sullivan and colleagues and sponsored by the Canadian NCI, compared preoperative EBRT with postoperative EBRT. No difference was found in local recurrence rates. Preoperative EBRT was associated with a doubling in the rate of wound complications (35% vs 17%) but importantly with a lower rate of late complications and tissue fibrosis and better functional outcomes. Postoperative EBRT generally covers a larger field (including drain sites) and is higher dose than preoperative EBRT. This is particularly important in young adults of child-bearing age with proximal thigh STS; preoperative EBRT may spare the gonads, whereas postoperative radiation may not.

Brachytherapy may be delivered through afterloading catheters placed across the tumor bed at the end of surgery. The goal of brachytherapy is to deliver additional radiation to a close margin (including neurovascular structures) with minimal treatment to surrounding tissue, particularly when further EBRT is no longer feasible. When the final pathologic margins are confirmed, the appropriate catheters may be loaded with radioactive seeds once or twice a day for a defined treatment period concentrated over the close margins. To minimize wound complications, catheters should not be loaded until at least postoperative day 5. To minimize the risk of dislodging the catheters, any drains placed at the time of surgery should remain in place until the catheters have been removed.

Patients with small (<5 cm), superficial, well-circumscribed STS resected with an appropriately wide margin (>1 cm) of nonneoplastic tissue or biologic barrier (fascia) may not need radiation therapy, provided that they can be reliably followed.

Approximately 25% to 50% of patients with extremity STS have distant metastatic disease develop. Those with large (>10 cm), deep, high-grade STS may be considered for preoperative or postoperative chemotherapy, usually with active agents such as doxorubicin and ifosfamide (response rates of 20% to 40% in patients with metastatic disease). However, no consistently convincing data are found that such an approach improves overall survival for most STS histologies. Some data have suggested limited benefit for specific histologies, such as myxoid liposarcoma and synovial sarcoma, but no consensus exists amongst sarcoma experts about the routine use of chemotherapy in the adjuvant setting for extremity sarcomas.

Hyperthermic isolate limb perfusion (ILP) and infusion (ILI) have been investigated in several institutions as treatment for patients with locally advanced STS in whom limb-sparing, function-sparing surgery may not be possible. These procedures involve placement of vascular access catheters into the main artery and vein of the affected extremity and perfusion with high-dose chemotherapy (usually melphalan) and tumor necrosis factor-alpha under hyperthermic conditions. ILP is generally performed as an open procedure with cut down directly onto the vessels. ILI uses percutaneously placed catheters and is conducted in hypoxic conditions. Although both have proven efficacy in melanoma, the data for STS are more limited. No randomized trials have compared either technique with aggressive limb-sparing resection with EBRT for STS. Arguably, patients under consideration for ILP and ILI usually have locally advanced or multifocal STS and are not necessarily candidates for surgery with EBRT at first evaluation. ILP and ILI should be considered as potential therapies in appropriately selected patients, and eligible patients should be referred to centers where this therapy is available.

RETROPERITONEAL SOFT TISSUE SARCOMA

Clinical and Diagnostic Evaluation

Patients with retroperitoneal STS are often asymptomatic until the mass reaches a large size (often 15 cm or greater). Symptoms include a palpable mass, early satiety, abdominal discomfort, or occasionally a new varicocele in men. Others may be incidental findings during abdominal imaging for other reasons. Initial clinical evaluation should include a thorough history and physical examination, with attention directed to ruling out other diagnoses in the differential, including lymphoma, primary germ cell tumor, and testicular cancer metastatic to retroperitoneal lymph nodes (if male). Although no tumor markers are known for STS histologies at present, screening studies for other diagnoses include lactate dehydrogenase, human chorionic gonadotropin, and alpha fetoprotein. After a thorough examination, a CT scan of the abdomen and pelvis is indicated. Staging evaluation is completed with a chest CT scan. Routine head CT and PET scans are not needed.

Imaging alone is rarely diagnostic of the specific sarcoma histology, with the exception of well-differentiated liposarcoma. As described in the previous extremity STS section, well-differentiated liposarcomas have a radiographic density similar to normal surrounding fat but tend to be well-encapsulated with thick internal septations. Giant lipomas are only identified anecdotally in the retroperitoneum; therefore, any mass consisting of very well-differentiated fatty tissue should be considered as well-differentiated liposarcoma and treated as such (Figure 13). These tumors do not require a biopsy. Other lesions suspicious for retroperitoneal STS should be biopsied. The authors prefer to obtain core needle biopsies with radiographic guidance. Biopsy tract recurrences are exceedingly rare and biopsy tracts do not need to be reexcised during definitive surgery. Furthermore, if preoperative EBRT is planned, the biopsy site is usually included within the radiation field. Again, it is important to specify core needle biopsy rather than fine-needle aspiration because the latter rarely yields enough tissue and architecture information to distinguish between different sarcoma histologies.

Anatomic Features of Retroperitoneal Sarcomas

In patients with extremity STS, distant failure is a common pattern of recurrence. In contrast, retroperitoneal sarcomas (RPS) more commonly recur in a locoregional manner, and mortality in RPS is more often associated with locoregional recurrence. Proper resection of RPS requires appreciation of the anatomic boundaries of the tumor. CT imaging should be reviewed to identify landmarks defining the extent of the mass to determine which structures may be safely resected and which ones cannot. The *anterior* margin of a RPS is generally the ipsilateral colon and mesocolon, pancreas, liver, or stomach. The *posterior* margin is generally the psoas and iliacus muscles inferiorly, the ipsilateral kidney and diaphragm superiorly, and the ipsilateral ureter and gonadal vessels medially. However, this may vary from tumor to tumor, and some or all of these structures could be anterior to the mass, in which case they constitute a portion of the anterior margin. The *medial* margin usually includes the spine and paraspinous muscles, the inferior vena cava (for right-sided tumors), and the aorta (for left-sided tumors). The *lateral* margin is constituted by the lateral or flank musculoskeletal sidewall, although depending on the size and location of the tumor, the kidney or colon could also border the lateral portion of the mass. The *superior* margin is similarly dependent on the size and location of the mass and may include the diaphragm on either side, the right lobe of the liver, the duodenum, and the head/uncinate process of the pancreas for right-sided tumors and pancreatic tail, spleen, and splenic vessels for left-sided tumors. The *inferior* margin may include the iliopsoas muscle; the femoral nerve; the common, internal, and external iliac vessels; and the pelvic sidewall. Clearly, the size and specific location of the mass determine which of the many structures mentioned constitute which specific margin.

In general, the ipsilateral kidney, colon, and mesocolon and at least a portion of the psoas can be safely and relatively easily resected without much difficulty. Resection of the pancreatic tail and spleen

can usually be performed with relatively low short-term morbidity. Resection of other structures, including but not limited to the aorta, inferior vena cava, iliac vessels, femoral nerve, diaphragm, duodenum, pancreatic head or uncinate process, and liver, entail more significant resections, with ensuing greater morbidity.

Technical Aspects of Retroperitoneal Sarcoma Resection

Before surgery, contralateral renal function should be assessed with a nuclear scan if an ipsilateral nephrectomy is planned. Patients should undergo bowel preparation. Patients may be placed in either a supine or modified lateral decubitus position. The abdomen may be entered through a midline, oblique, flank, or thoracoabdominal incision, depending on the precise anatomic location. It is important to adjust the incision to the extent of tumor to provide optimal exposure.

The goal of surgery should be an aggressive multiorgan resection, with removal of involved or attached surrounding organs and retroperitoneal fat en bloc with the tumor in an effort to maximally clear the margins and avoid spilling tumor (Figures 14 and 15). Because of the size of the tumors, exposure and retraction may need to be shifted periodically. Ideally, the operation is conducted with carefully circumferential dissection around the expected specimen, enabling systematic exposure on a broad front. It is important to approach surgery with curative intent. A macroscopically incomplete resection is no more beneficial than nonoperative management.

The resection specimen should be reviewed with the pathologist immediately after removal for orientation and identification of margins of concern.

Radiation Therapy

The role of radiation therapy is controversial, in the absence of phase III randomized controlled trial data. Radiation therapy unequivocally reduces the risk of local recurrence in patients with extremity STS, but this has not been proven in RPS. Furthermore, the proximity of radiosensitive tissues and organs, such as liver and small intestine, together with the large size of the radiation field limits its utility in some patients. Those who use radiation therapy generally favor delivering it before surgery, when the bulk of the tumor itself displaces uninvolved organs out of the radiation field. One ongoing randomized trial is evaluating the utility of preoperative radiation therapy in patients with RPS, based in Europe and open in selected North American centers.

BREAST SARCOMA

The most common sarcoma histologies arising in the breast are angiosarcoma and phyllodes. Angiosarcoma may arise either primarily within the breast parenchyma or secondarily within the breast skin as a consequence of lymphedema or more commonly radiation therapy delivered as a part of breast conservation therapy for breast cancer. Each of these malignancies is considered individually.

Primary Angiosarcoma

Primary angiosarcoma is a disease of the breast parenchyma that arises in young women. Angiosarcoma, irrespective of site, is in general responsive to systemic chemotherapy. However, once chemotherapy is stopped, the disease tends to regrow. Furthermore, despite its sensitivity to chemotherapy, there is no proven survival benefit from systemic therapy. The only potentially curative therapy is surgery. Although breast cancer may be treated with breast conservation limited surgery because of the proven benefit of radiation therapy and hormonal therapy, no such proven beneficial adjuvant therapies are found for primary breast angiosarcoma. Therefore, patients should be offered a simple mastectomy instead of lumpectomy. Partial resection of pectoralis major may be necessary to achieve negative margins. The skin may be closed primarily. Before surgery, the patient should undergo staging with a chest, abdomen, and pelvic CT scan and MRI of the breast. Initial physical examination should include a contralateral breast examination. The contralateral breast may be a site for metastatic disease, but to date, a contralateral prophylactic mastectomy has no proven benefit.

Secondary Breast Angiosarcoma

Secondary breast angiosarcoma is a disease that affects older women. Historically, secondary angiosarcoma arose in the setting of lymphedema. Now, it is more commonly seen as a consequence of radiation therapy. Raditation therapy-associated angiosarcoma is a cutaneous malignancy that may extend into breast parenchyma, whereas primary angiosarcoma is a disease of the breast parenchyma. Thus, the operation for secondary angiosarcoma is different than that for primary angiosarcoma. Patients with secondary radiation therapy-associated angiosarcoma should undergo not only a total mastectomy but, more importantly, resection of the affected organ—all of the breast skin. This disease is often multifocal, and therefore, as much of the irradiated skin should be removed en bloc with the breast as possible. This is critical; a simple mastectomy alone does not remove the organ (skin) involved, and recurrences may be noted within weeks to months. If tumor extends to pectoralis major, then the muscle should be removed as well. All patients need extensive reconstruction, including skin grafting, just to restore a flat, closed chest wall. Preoperative staging should include MRI of the breast and a CT scan of the chest, abdomen, and pelvis. Follow-up imaging should include CT scan of the chest, abdomen, and pelvis. MRI of the chest wall is not usually necessary because local recurrences are often apparent on clinical examination alone.

Phyllodes Tumor

Phyllodes tumors of the breast can grow to be quite large. Surgery alone is the primary therapy. Tumors should be resected with a negative margin; for smaller tumors, a lumpectomy may be possible, but for larger tumors, a simple mastectomy may be necessary. Lymph node biopsy is not necessary. Recurrences may be observed in approximately 15% of patients, including local recurrences in the ipsilateral breast and distant recurrences in locations such as lung and liver. Contralateral breast recurrences are exceedingly rare; thus, contralateral prophylactic mastectomy is not indicated.

DESMOID FIBROMATOSIS

Desmoid fibromatosis is a nonmetastatic neoplasm that displays malignant local behavior. Desmoids may arise in the context of familial adenomatous polyposis (FAP), concurrent with a pregnancy or sporadically. Those that arise in the context of FAP may be quite aggressive, often involving the bowel mesentery and occasionally encasing the mesenteric vessels. In fact, local complications secondary to desmoids are the most common cause of death after colon cancer in individuals with FAP. Those that arise during pregnancy may grow during pregnancy, but often this growth stabilizes postpartum.

Recently, there has been a trend towards less radical surgery and more nonoperative management. The natural history of desmoids may vary, and some tumors may stop growing or even shrink without intervention. Therefore, nonoperative management is justifiable, particularly for tumors situated in difficult locations. Systemic therapy, including cytotoxic intravenous chemotherapy with different agents and schedules, oral tyrosine kinase inhibitors, nonsteroidal antiinflammatory drugs, and hormonal agents such as tamoxifen, has varying degrees of efficacy (Figure 16).

When surgery is undertaken, it is important to avoid compromising function when possible. Mesenteric desmoids may be particularly problematic to resect, especially those associated with FAP, and surgery should be approached with caution. Systemic therapy with cytotoxic intravenous chemotherapy may be effective in shrinking the tumor sufficiently to avoid extensive bowel resection. Wide margins are usually not possible. Extraabdominal desmoids may be more easily resected, but again, achieving wide margins may be challenging, given the infiltrative nature of these tumors. Reconstruction is often necessary.

METASTATIC DISEASE

Unlike adenocarcinomas, STS rarely spread to lymph nodes (<5%). Consequently, sentinel lymph node biopsy (SLNB) and lymphadenectomy are rarely indicated. However, SLNB may be considered in patients with sarcomas known to have a higher propensity for lymph node spread (epithelioid sarcoma, clear cell sarcoma). Importantly, SNLB has no proven therapeutic or long-term survival benefit.

Patients with distant metastatic disease should undergo systemic therapy. Doxorubicin and ifosfamide are two of the most effective agents in STS and may be used in combination. Doxorubicin dosing is limited lifetime by risk of cardiotoxicity. A liposomal formulation of doxorubicin does not seem to have a similar risk. Paclitaxel, gemcitabine, vinorelbine, and dacarbazine, and in Europe, trabectedin (also known as ET743), are additional agents with activity in sarcoma. In general, although response rates are approximately 20% at best, some histologies do have higher response rates to certain agents. For instance, vascular tumors such as angiosarcoma respond to taxanes and gemcitabine, leiomyosarcoma to dacarbazine and trabectedin, and liposarcoma to trabectedin.

Targeted therapies, similar to imatinib mesylate in gastrointestinal stromal tumors, are under investigation. The only established targeted therapy at present is imatinib in DFSP (in this circumstance, it is only rarely needed because DFSP is a surgical disease with a very high cure rate).

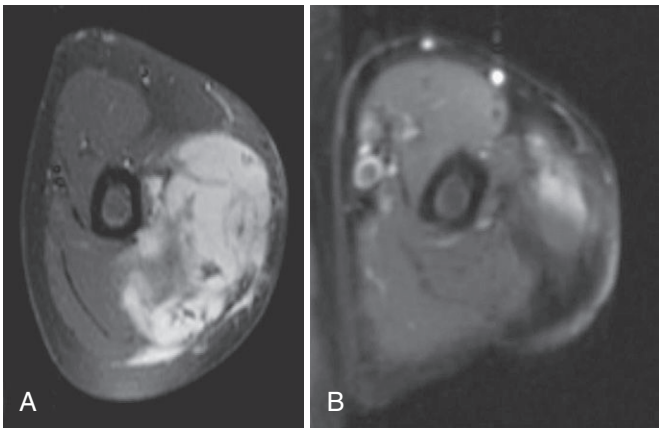

FIGURE 16 Axial magnetic resonance imaging of proximal thigh desmoid-type fibromatosis treated with chemotherapy (specifically, methotraxate plus vinorelbine for 45 cycles over 21 months): **A,** before and **B,** after chemotherapy.

SUMMARY

Soft tissue sarcomas may arise in a variety of body sites and within a variety of tissues. The management of STS requires a thorough understanding of the biology of the different histologies. Limb-sparing and function-sparing approaches should be used when feasible, but extent of surgery should not be compromised for ease of closure. Margins of resection and use of adjuvant radiation therapy and chemotherapy are contingent on accurate histologic diagnosis. However, adjuvant therapy after a marginal resection is not an appropriate substitute for a margin negative operation. Treatment planning should include multidisciplinary consultation to determine optimal therapy, taking into consideration the site and extent of the disease, its natural history and sensitivity to available treatments, surgical challenges, and of course, the wishes of the patient.

Evaluation of the Isolated Neck Mass

Philip W. Smith, MD, and John B. Hanks, MD

OVERVIEW

An isolated neck mass is a common clinical scenario in patients of all ages. Management varies widely with the many etiologies. Success in this scenario requires familiarity with cervical anatomy, an organized approach to differential diagnosis, and a stepwise evaluation as summarized in Figure 1. Tissue acquisition for diagnosis often is required, and surgical treatment is indicated for many etiologies of neck mass. Therefore, the prepared surgeon is well positioned to play a central role in the clinical evaluation, diagnostic workup, and management of neck masses.

Although benign thyroid nodules are common and thyroid malignancy is an important consideration for neck masses, thyroid lesions are addressed elsewhere in this text.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the isolated neck mass is broad and includes congenital, inflammatory, and neoplastic processes (Box 1.) Between 2% and 9% of head and neck cancers present as cervical masses without a known primary. Although malignancy must be considered in all cases of neck mass, the likelihood varies significantly with age. In the pediatric population, less than 10% of neck masses are neoplastic, whereas as many as 80% of neck masses that occur outside of the thyroid are neoplastic in adults over the age of 40 years.

WORKUP

History

The clinical history gives indications as to the likelihood that a given neck mass is benign or malignant. The importance of patient age was highlighted previously. Other history items that raise the probability of malignancy include a known personal history of malignancy, strong family history of malignancy, smoking or other tobacco use, heavy alcohol use, sun exposure, and radiation exposure. Neck-specific history items that are concerning for malignancy include persistent mass, dysphagia, hoarseness or other neurologic deficit, epistaxis, and radiating pain, including otalgia. Constitutional symptoms such as sweats, fevers, fatigue, and weight loss are concerning for lymphoma or other malignancy but also may be present with infectious etiologies. Rapidly developing tender masses are often infectious or inflammatory.

One also should ask about prior treatments, biopsies, and surgical interventions. More often in children, but also in adults, lymphadenopathy may already have been treated with antibiotics. Persistence of lymphadenopathy after antibiotics should be considered concerning for malignancy. Retrieval of relevant prior imaging, operative reports, pathology reports, and pathology specimens is imperative whenever possible.

A history of severe or episodic hypertension rarely may be associated with a head and neck paraganglioma, although only a small minority of head and neck paragangliomas are functional. A history of cough with pressure on the mass has been associated with schwannoma of the vagus nerve. This can be confirmed with palpation on physical examination.

Physical Examination

A thorough physical examination is warranted in all cases of neck mass. On general examination, one should note presence of cachexia and stigmata of alcoholism or tobacco abuse. Examination of skin, lungs, and abdomen may provide clues as to a primary source of metastatic disease to the neck. Axillary and femoral lymph node basins should be examined and may be revealing in a systemic disease process. General examination also helps the surgeon understand a patient's general fitness to tolerate medical and surgical interventions. The clinician also should seek any prior incisions that indicate diagnostic or therapeutic interventions that the patient may have neglected to describe.

Patients and even referring physicians may commonly mistake normal structures for pathology. Such structures may include ptotic salivary glands, the horn of the thyroid cartilage, the hyoid bone, or spinal transverse processes (particularly C2). Therefore, examination of the neck should first confirm the presence of a pathologic finding. If an abnormality is present, a detailed examination ensues. The mass should be measured in at least two dimensions with a tape measure and documentation of the findings. Photographs for the medical record may also be valuable. The location of the mass should be precisely defined. The location should be defined not only in a descriptive fashion relative to normal anatomy (e.g., "at the anterior border of the sternocleidomastoid muscle [SCM] at the level of the cricothyroid") but also by the nodal level based on the system outlined in Figure 2 and Table 1. This system of nodal levels is of value for several reasons: (1) it allows reproducible communication between caregivers and relevant boundaries with physical examination, imaging, and operative anatomy; (2) nodal levels are diagnostically important because malignancies of different origins spread characteristically to different nodal levels (see Table 1); and (3) lymph node levels are important therapeutically because lymph node dissection typically proceeds based on nodal level compartment based dissection.

Other important examination findings include firmness, tenderness, symmetry to the contralateral neck, and fixation to surrounding structures. Neurologic function also should be evaluated, including cranial nerve (CN) function. This evaluation should include facial symmetry (marginal mandibular branch of the facial nerve/CN VII), voice (superior and recurrent laryngeal branches of the vagus nerve/CN X), atrophy and function of the SCM and trapezius (spinal accessory/CN XI), tongue deviation (hypoglossal nerve/CN XII), symmetric air movement (phrenic nerve), and neural and sensory upper extremity function (brachial plexus). Physical examination findings that are concerning for malignancy include firmness, fixation to surrounding tissue, unilateralism, and neurologic deficit.

All other aspects of the neck also should be examined, including the thyroid, salivary glands, and all nodal basins. Visualization of the mucosal surfaces of the upper aerodigestive tract is important, as is evaluation of the skin of the head and neck, including the scalp and auditory canal. Palpation with the gloved hand, including bimanual palpation of the floor of the mouth, may help with identification of abnormalities that exist deep to normal-appearing mucosa. Examination of dentition also is important because dental infection can lead to cervical lymphadenopathy.

With appropriate training, mirror examination or flexible fiberoptic laryngoscopy allows significantly improved visualization and can be performed in the office setting. Evaluation of all mucosal surfaces is possible, from the nasal cavity to the vocal cords. The location of the neck lesion that is concerning for metastatic

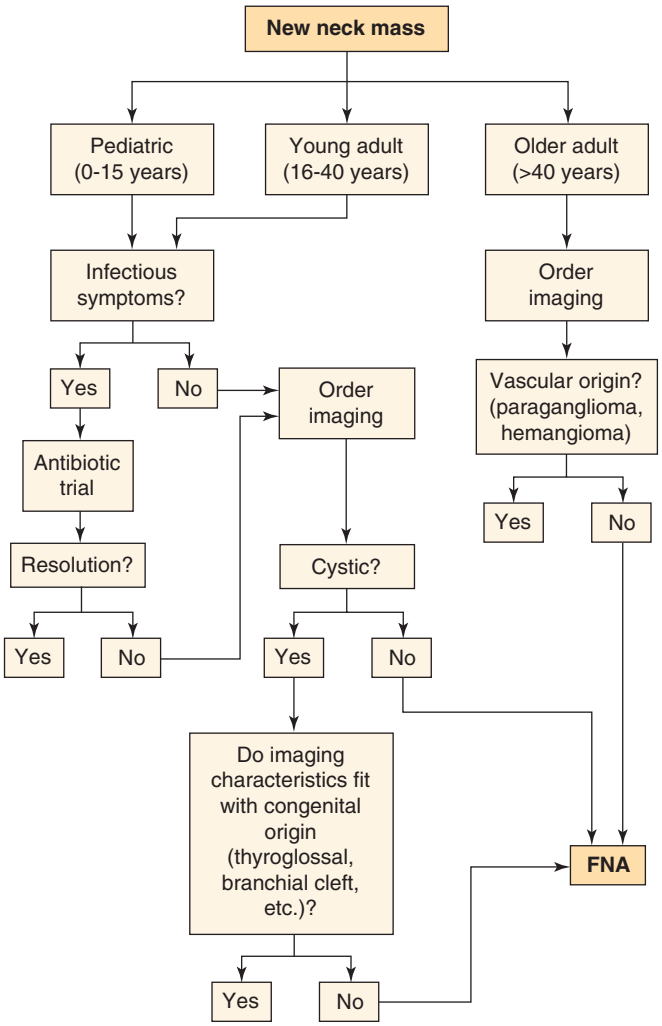

FIGURE 1 Diagnostic algorithm for a new neck mass. The distinction made based on age of 40 years should be taken as a general guideline to be adjusted based on clinical evaluation and not as an absolute rule. *FNA,* Fine-needle aspiration. *(Adapted from Flint PW, Haughey BH, Lund VJ, et al:, editors:* Cummings otolaryngology: head & neck surgery, *ed 5, Philadelphia, 2010, Elsevier,* Fig. 166-2.*)*

BOX 1: Differential diagnosis of neck masses

Developmental
Inclusion cyst
Thyroglossal duct cyst
Congenital vascular malformations
Branchial cleft cyst
Cystic hygroma
Laryngocele
Teratoma
Bronchogenic cyst

Infectious
Bacterial lymphadenitis *(Staphylococcus aureus, Streptococcus pyogenes, Bartonella, Brucella)*
Viral (Ebstein-Barr, HIV, other common viruses)
Protozoal (toxoplasmosis, leishmaniasis)
Fungal (histoplasmosis, blastomycosis, coccidioidomycosis)

Other Miscellaneous
Sialadenitis, sialolithiasis
Sjögren's syndrome
Sarcoidosis
Aneurysm

Benign Neoplasia
Lipoma
Thyroid nodule/diffuse goiter
Parathyroid adenoma (rarely palpable)
Fibroma
Neurofibroma
Sebaceous cyst
Benign salivary tumors (pleomorphic adenoma, Warthin's tumor)

Malignancies
Lymphoma
Carotid body tumor
Thyroid cancer
Malignant salivary tumors (mucoepidermoid, adenoid cystic)
Parathyroid cancer
Plasmacytoma
Carcinoid
Metastasis to cervical lymph nodes (thyroid, squamous cell carcinoma, adenocarcinoma, melanoma)

lymphadenopathy helps to determine the most likely primary sites and so can guide this evaluation. Attention should be paid to all visible surfaces, especially the lymphoid region of the nasopharynx, base of the tongue, and oropharynx (Waldeyer's ring). This evaluation also allows assessment of potential airway difficulties for future surgical interventions.

Two congenital lesions are worth highlighting for their specific physical examination findings. The first is a thyroglossal duct cyst. These cysts occur along the thyroglossal tract between the thyroid and the base of the tongue. They may become infected, which leads to presentation with typical inflammatory symptoms and frequently follows an upper respiratory infection, or they may present as an asymptomatic mass. Most are diagnosed before adulthood, but initial presentation in adults is not uncommon. Thyroglossal duct cysts are found in or near the midline of the neck and typically just below the hyoid bone. Protrusion of the tongue typically results in cephalad movement of the mass. This feature may be more easily appreciable by first applying slight inferior digital pressure on the mass before tongue protrusion. Thyroglossal duct cysts may create a mass effect or develop recurrent infection, and about 1% harbor malignancy. Therefore, when these cysts are found, excision of the cyst, pyramidal lobe if present, and the tract up to the base of the tongue including the central portion of the hyoid bone is indicated (the Sistrunk procedure). Confirmation of the presence of normal thyroid tissue in the thyroid bed with examination or imaging before excision is important.

The other group of congenital lesions is branchial cleft cysts. Similar to thyroglossal duct cysts, these may present in an inflamed fashion after an upper respiratory infection. These cysts are almost always diagnosed before age 20 years and account for 20% of pediatric neck masses. First branchial cleft cysts present inferior to the auricle or just below the angle of the mandible. These may communicate with the auditory canal and may be closely associated with the facial nerve. Second branchial cleft cysts are the most common (95%). They are found inferior to the angle of the mandible on the anterior border of the SCM and communicate with the tonsillar fossae. Third branchial cleft cysts also present on the anterior border of the SCM, lower than a second cleft cyst, and communicate with the pharynx at the thyrohyoid membrane or piriform sinus. Branchial cleft cysts and their tracts are typically excised with care given to the relationship of these tracts to cranial nerves and other deep structures.

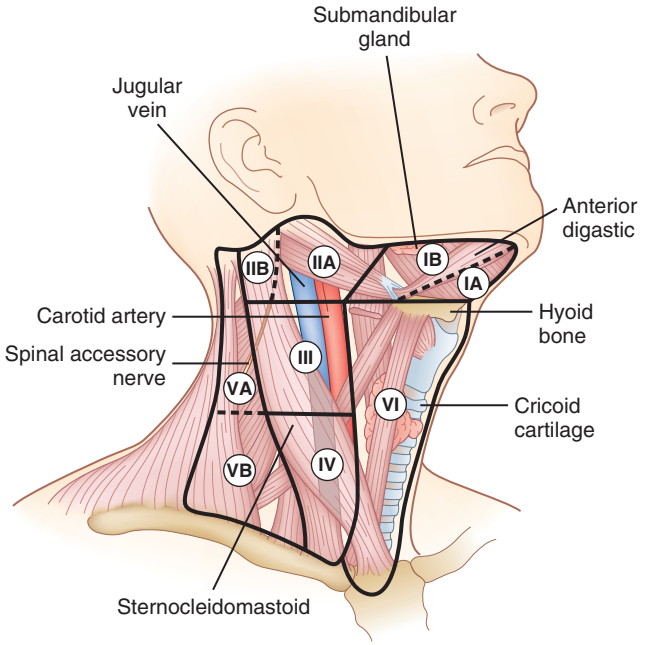

FIGURE 2 Numbered lymph node levels of the neck. Boundaries are given in Box 1. Criteria exist to define these levels clinically, radiographically, and surgically. *(From Townsend CM Jr, Beauchamp RD, Evers BM, et al: Sabiston:* Textbook of surgery, *ed 19, Philadelphia, 2012, Fig. 38-3.)*

Imaging

Imaging may be valuable at several steps in the evaluation and management of a neck mass. It can be valuable in characterizing the primary lesion, in searching for a primary source of a metastasis, and in follow-up after an intervention. Communication with radiologists before a study helps ensure that the optimal study and protocol are performed and maximizes information garnered from each study.

Anteroposterior (A/P) and lateral chest radiographs should be obtained if concern exists that the neck mass is related to an atypical infectious or inflammatory source and in those with history of cough or travel. Chest imaging also is indicated for those masses whose location and biopsy findings are concerning for a thoracic primary malignancy, such as lung cancer, and for patients with a new diagnosis of cancer to evaluate for pulmonary metastasis. Abnormalities identified on chest film often require a computed tomographic (CT) scan of the chest for further delineation.

Ultrasound scan can serve as an extension of the physical examination during the initial office evaluation of the mass. Alternately, formal radiology-performed ultrasound scan may be used. Ultrasound scan allows precise measurements of size and definition of the relationship to normal anatomy, distinguishes cystic from solid lesions, allows assessment of vascularity, and may help distinguish whether the mass is invasive into surrounding structures. Ultrasound scan also allows characterization of lymph nodes based on features other than just size, which can help distinguish benign from pathologic adenopathy; this ability exceeds that possible with CT scan. Ultrasonographic features that suggest malignancy include loss of the normal hyperechoic fatty hilum, hyperechogenicity or hypoechogenicity, cystic degeneration, punctuate calcifications, unclear borders with surrounding structures, and perinodal edema (Figure 3). Ultrasound scan also is ideal for evaluation of thyroid nodules and has the advantage of not exposing the patient to ionizing radiation or intravenous contrast.

CT scan of the neck requires ionizing radiation to the thyroid and is most valuable if performed with intravenous contrast. Contrast may be contraindicated because of renal disease or allergy and may impair delivery of radioactive iodine therapy in the case of thyroid pathologies. Despite this, contrast CT scan is an excellent and widely available imaging modality and is superior to ultrasound scan in providing three-dimensional resolution of the anatomy of the lesion and evidence of invasion or distortion of normal anatomy. Also, if the presenting lesion is thought to be nodal metastasis from a head and neck primary malignancy, high-quality CT scan of the head and neck can identify a primary source in 20% of cases. Therefore, contrast CT scan of the head and neck is valuable and is indicated in many neck masses in which the diagnosis or primary source is not already defined. This scan should encompass at least the region from the skull base to the aortic arch.

Magnetic resonance imaging (MRI) is helpful in some situations and often is better than CT scan in defining the presence or absence of invasion by the mass into surrounding structures, particularly vascular and neural structures. It may also be helpful in patients with significant dental artifact, in pregnant patients, in those with iodinated contrast reactions, and in those in whom iodinated contrast is undesirable because of expected future need for therapeutic radioiodine therapy. MRI is helpful in the diagnosis and evaluation of carotid body tumors, glomus tumors, and schwannomas. Outside of these scenarios, MRI is not routinely indicated for initial evaluation of neck mass.

The role of positron emission tomography (PET) or fusion imaging of PET with CT scan (PET/CT) continues to be elucidated. PET and PET/CT are not appropriate first-line studies for the initial evaluation of a neck mass. However, PET is an appropriate secondary imaging technique for patients who are being evaluated for a metastatic squamous cell carcinoma of unknown primary when CT scan or MRI have been unrevealing. On the basis of specific pathologies, PET and PET/CT also may be appropriate for further workup once a diagnosis has been made or for the monitoring of a patient being followed for malignancy. However, a PET may commonly be obtained for other reasons, and a PET avid lesion may be discovered that is distinct from the primary process. The clinician must then evaluate whether this lesion represents a neoplasm or whether this is a false-positive finding resulting from other hypermetabolic conditions (infection, inflammatory process). This process should proceed similarly to a neck mass discovered on clinical grounds. Remember that PET is not specific for malignancy; inflammation, infection, and muscle activity can lead to false-positive results.

With improvements in the capabilities of CT scan and MRI, diagnostic arteriography is rarely necessary for neck masses. Arteriography may be indicated therapeutically, particularly for embolization of some highly vascular lesions before resection.

Tissue Diagnosis

The presence of an isolated neck mass in an adult over age 40 years should be considered malignant until proven otherwise. These masses frequently are metastatic squamous cell carcinomas from the upper aerodigestive tract. Fine-needle aspiration (FNA) biopsy plays a central role in the diagnostic evaluation of neck masses and should be considered the standard of care in undiagnosed adult neck masses. FNA can be performed with simple equipment, is widely available, is generally safe, and is diagnostic in 90% or more of cases. Samples can be evaluated both for pathology and for microbiology depending on the clinical scenario. Risks associated with this procedure including bleeding and sampling error.

Readily palpable lesions may be amenable to simple manual biopsy, but ultrasound scan is now readily available and real-time ultrasound guidance should most often be used to decrease risk and increase diagnostic yield. In cases of a cystic lymph node, ultrasound scan should be used to ensure that the wall is sampled. Ultrasound guidance also helps to avoid needle biopsy of vascular lesions that are mistaken as a solid mass with examination if imaging is not already completed.

TABLE 1: Boundaries of cervical lymph node levels and considerations for primary site for metastatic disease

	Boundaries and contents	Metastatic primary sites
Level I	Submandibular and submental nodes. Bounded by the mandible superiorly, the midline anteriorly, the hyoid inferiorly, and the stylohyoid muscle posteriorly. Subdivided into IA and IB by the anterior belly of the digastric muscle. IA crosses the midline to the contralateral anterior belly of the digastric.	IA: Floor of mouth, lower lip, anterior tongue, lower gum. IB: Oral cavity, anterior nasal cavity, submandibular gland, midface soft tissues.
Level II	Upper jugular nodes. Bounded by the skull base superiorly, the stylohyoid muscle anteriorly, the inferior border of the hyoid bone inferiorly, and the posterior border of the SCM posteriorly. Subdivided into IIA and IIB by the spinal accessory nerve.	Oral cavity, nasal cavity, nasopharynx, oropharynx, hypopharynx, larynx, parotid gland.
Level III	Middle jugular nodes. Bounded by the inferior border of the hyoid bone superiorly, the sternohyoid muscle anteriorly, the inferior border of the cricoid cartilage inferiorly, and the posterior border of the SCM posteriorly.	Oral cavity, nasopharynx, oropharynx, hypopharynx, larynx, cervical esophagus, thyroid.
Level IV	Lower jugular nodes. Bounded by the inferior border of the cricoid cartilage superiorly, the sternohyoid muscle anteriorly, the clavicle inferiorly, and the posterior border of the SCM posteriorly.	Hypopharynx, thyroid, cervical esophagus, larynx, Virchow's node (lung or abdominal malignancy).
